TRANSACTIONS

OF THE

AMERICAN INSTITUTE

OF

ELECTRICAL ENGINEERS

JANUARY TO DECEMBER 1922.

VOL. XLI

PUBLISHED BY THE
AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS
33 WEST THIRTY-NINTH STREET
NEW YORK, N. Y., U. S. A.
1922

Press of McIlroy & Emmet, 22 Thames Street, New York

Preface

This volume, which constitutes the forty-first in the series of annual TRANSACTIONS of the American Institute of Electrical Engineers, is the first to be published in the present sized pages, corresponding to the size of the Institute monthly JOURNAL. The change in size has been adopted chiefly for economic reasons; otherwise, the makeup of this volume does not differ materially from that of the preceding volumes. It is composed of papers, discussions, reports, etc., presented at the meetings of the Institute held during the year 1922. The TRANSACTIONS contains, therefore, no material which has not previously appeared in the JOURNAL. It is designed to be used principally as a book of reference for electrical engineers and its contents have therefore been selected by the Publication Committee to include only such material as will prove of permanent usefulness and interest to engineers. The arrangement of the contents is chronological, and each paper or group of papers is followed directly by the discussion thereon. The contents are conveniently indexed by title and author's name, affording ample facilities for ready reference. The material appearing in the monthly JOURNALS which is not included in this volume consists mainly of news of Institute activities and various contributed articles. The most important of these articles, however, are made available for reference by means of a supplementary index referring to the issues of the JOURNAL in which they are published. The synoptical and topical indexes have been omitted from this volume, and it is believed that they are less necessary than heretofore, because most of the principal articles are prefaced with a "Review of the Subject," giving a very complete synopsis of the article. A small table of contents is also included at the head of many articles, giving the title of each subdivision of the article, as well as the number of words under each subdivision. The A. I. E. E. Standards have usually been published in previous volumes of Transactions, but have been omitted from this volume as the frequent additions to the Standards have made them so voluminous that they now comprise a volume of considerable size by themselves. It is also considered that the publication of the Standards in the TRANSACTIONS was merely for a historical record and not for current reference. As the periodic revision of the Standards generally follows the publication of the TRANSACTIONS closely, the standards contained therein are obsolete nearly as soon as published and are of little value for reference purposes. This volume also contains the annual report of the Board of Directors for the fiscal year ending April 30, 1922 and lists of the officers and committeemen for the current year.

Key West–Havana Submarine Telephone Cable System

BY W. H. MARTIN

The system discussed in this paper includes three single-core continuously loaded submarine cables, each of which provides, in addition to a telephone channel, direct-current and carrier-current duplex telegraph channels. A description is given of the design and construction of the cables, of the method of superposing the various channels on each cable and of the terminal apparatus used for their operation.

ON April 11, 1921, commercial telephone service was inaugurated between the United States and Cuba over three submarine cables laid across the Florida Straits between Key West, Florida and Havana, Cuba. These submarine cables are the longest and most deeply submerged which are in use for telephonic communication. They are from 100.2 to 104.9 nautical miles (186 to 195 km.) in length and are laid in water which for a part of the route is about 1000 fathoms (1830 m.) in depth.

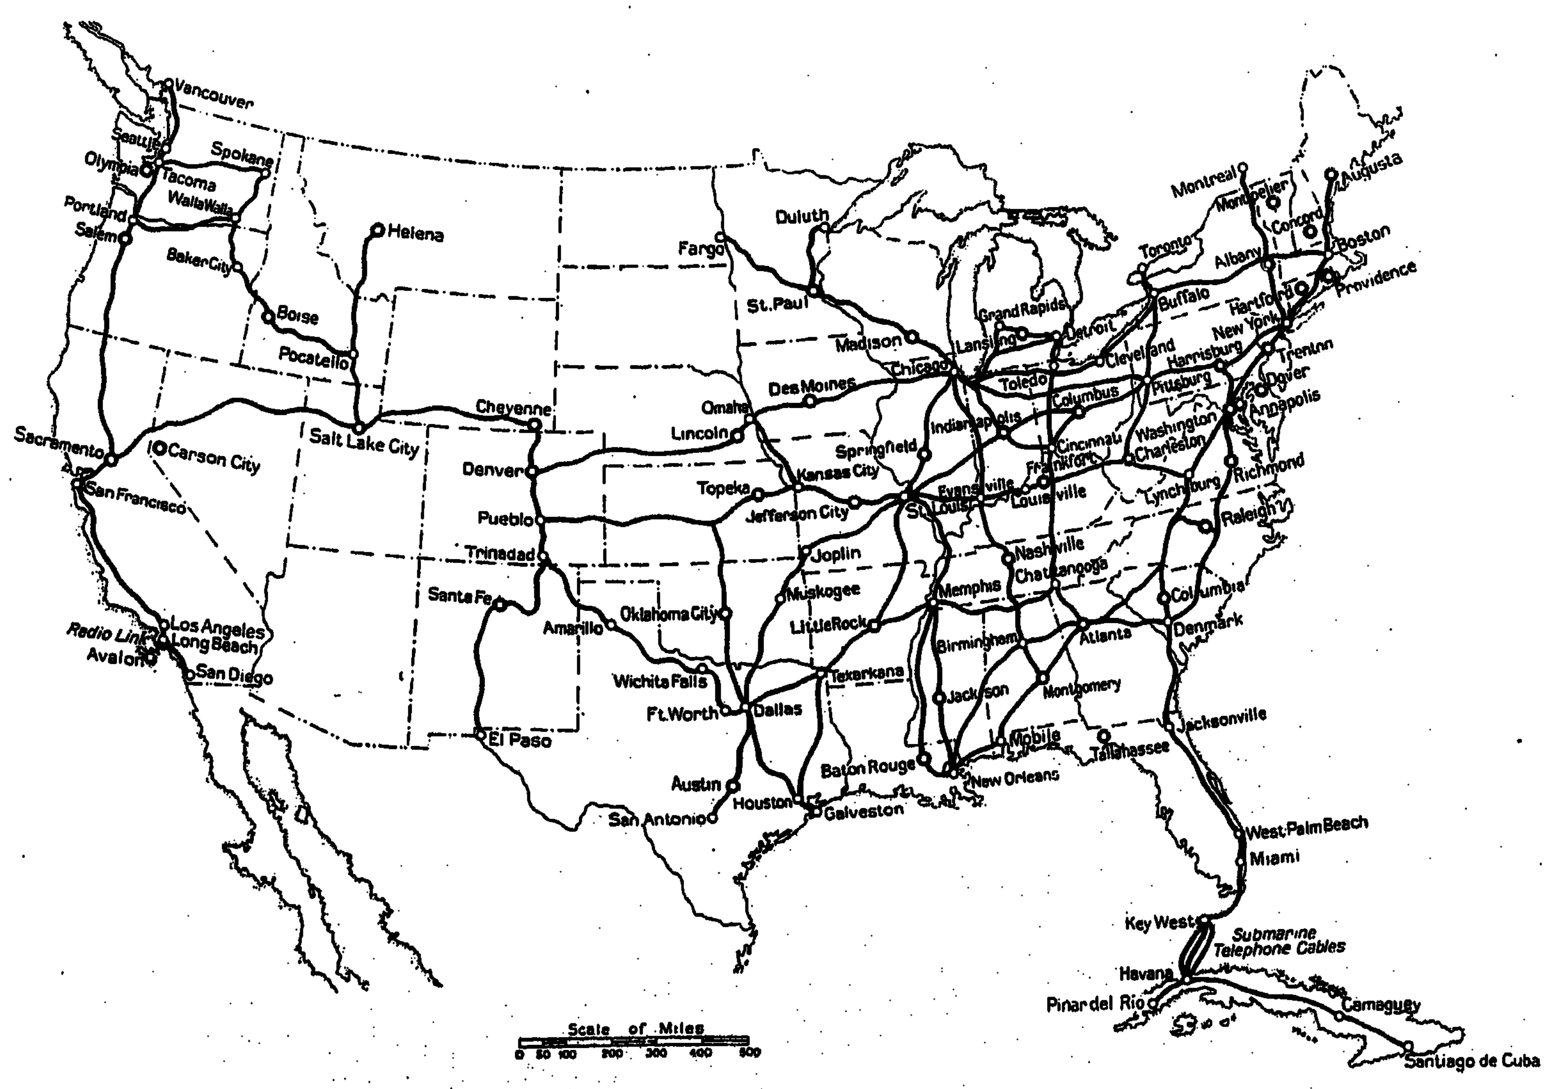

FIG. 1—MAP SHOWING THE SUBMARINE CABLES AND SOME OF THE IMPORTANT TOLL ROUTES IN THE UNITED STATES AND CUBA

The location of these cables and some of the important toll lines in the United States and Cuba are shown in Fig. 1. The cables were installed by the Cuban-American Telephone and Telegraph Company, an organization formed in 1919 by the American Telephone and Telegraph Company and the Cuban Telephone Company, for the purpose of providing telephone facilities between the United States and Cuba which would be suitable for connecting the telephone toll lines in the two countries.

The design of the submarine cables and the associated terminal equipment differs from previous systems because of the service which is furnished, the depth of water in which the cables are laid, and the length of the cables. The general features of this system will be indicated by the following summary of the requirements and the means which have been employed to meet them.

To give the service desired over these cables, it was necessary that the telephone channels be suitable for use in circuits connecting points in the United States, such as New York and Chicago, 1557 and 2453 miles (2510 and 3940 km.) distant from Key West, with Havana and other points in Cuba, which is about

---

Presented at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

700 miles (1126 km.) in length. It was required also that the cables furnish, simultaneously with the telephone, a number of telegraph channels. These are provided partly by direct-current channels and partly by carrier-current channels[1] using frequencies above the telephone range.

Because of the depth of water and other conditions, the cables are of the single-core type, generally used for deep sea submarine telegraphy in which the return path of the circuit is through the sea. An important modification of this type has been made for these cables in order to make the circuits more suitable for telephone and carrier use. This consists in surrounding the insulation of the central conductor with a wrapping of copper tapes forming an uninsulated return conductor.

In order to obtain the necessary efficiency for the telephone channels over cables of this length, the cables are "loaded," that is, the inductance of the circuit is increased by the use of iron, and vacuum-tube repeaters[2] are used at the terminals for all connections over the cables.

To provide the desired services, required, in addition to laying the submarine cables, the extension in the United States of suitable toll lines to Key West and the installation of vacuum-tube repeaters in the Cuban toll lines.

General Design of System

The construction of an open-wire land line along the causeway of the Florida East Coast Railroad which connects the string of small islands off the southern end of Florida, made it possible to land the cables at Key West and thus materially reduce their length. The landing points of the cables are on the western side of the entrance to the harbor of Havana and the southern side of the Island of Key West. This point in Havana is about a mile (1.6 km.) from the telephone toll office and that in Key West an equal distance from the existing telephone office. The distances from the cable landing points to the telephone terminal offices were kept as short as practicable in order to reduce the possibilities of interference from power circuits.

The water in the Florida Straits, starting from Key West, increases gradually in depth. Five miles (9.3 km.) from shore it is about 40 feet (12.2 m.) deep, at 15 miles (27.8 km.) about 700 feet (214 m.), and at 35 miles (65 km.) about 3000 feet. (915 m.) From that point on to within about three miles (5.6 km.) of Havana it is from 3000 feet (915 m.) to 6000 feet (1830 m.) in depth, being about a mile (1.86 km.) deep within five miles (9.3 km.) of Havana. These depths of water eliminated from consideration the use of a paper-insulated cable such as is commonly employed for telephone purposes on land or in shallow water. The most suitable construction for great depths submarine telegraph type of cable with an insu of gutta-percha or similar material

Previous gutta-percha or rubber-insulated subı telephone cables have, in general, contained fouı arranged to provide three and sometimes fou: phone circuits. Two of these circuits, the "phys have been obtained directly from the two pairs of one superposed circuit, the "phantom," has obtained from the two wires of each pair in paral in some cases a second superposed circuit ha: formed by the four wires in parallel with a sea : There was considerable question, however, i case, whether a cable of this type could be suffi well balanced to keep the cross-talk between t superposed circuits and the physical circuits low ‹ to permit of their simultaneous operation wi required amplifications.

In comparing the four-core cable with a syste sisting of three single-core cables, the following were important: First, the cross-talk factor; the lack of any experience with laying and re four-core cables in water of these depths; th relative cost of the two systems; and four superiority of the single-core cables from the im standpoint of insuring continuity of service, for an initial installation of cables. A consider all these factors led to the adoption of single-coı for this case.

The inductance of a circuit may be increase‹ periodic insertion of loading coils, or by "cont loading, which is the wrapping of iron wire around the conductor. Because of the depths involved, the use of loading coils was impra The placing of such coils in a cable causes, at tl of insertion, changes in the size and constructi‹ cable which are sources of weakness, both in co with the stresses imposed on the cable in la; repairing and also because of the necessity o: the cable resist the penetration of water, whi‹ deepest point reaches a pressure of over a square inch (140 kg. per sq. cm.). The use of ous loading for these conditions is advantag only mechanically in that it gives a uniform but also from the standpoint of keeping the impedance of the cable uniform over the frequencies to be used. In repairing a c‹ cable in deep water it is practically impossible tain the regular spacing of the coils which is for this uniformity of impedance. This uni: important in obtaining the close balance be impedance of the cable and that of a network ance elements which is required for the two-w tion of amplifiers on the circuit.

These cables were planned to provide N Havana connections for which a transmission of under fifteen miles of standard cable (ca resistance of 88 ohms and capacity of 0.054 ı

per loop mile) was desired. Since the operating equivalent of the New York-Key West portion of the circuit is about ten miles, the sum of the amplifications applied at the terminals of the cable must be within five miles of its equivalent. It was estimated that practicable cables could be obtained which would have transmission equivalents of about 25 miles of standard cable. This required that the amplifications at the terminals should average about ten miles. As the interference produced on such a cable by power systems, by other communication systems, and by natural disturbances and the cross-talk between the cables themselves are amplified also, the requirements for these factors were correspondingly more exacting.

To reduce the interference at the terminals of the cables from local power circuits, two-wire metallic circuits are used from the telephone offices to the landing points and the submarine cables are connected to the land lines through transformers so that these lines are balanced to ground. The operation of direct-current telegraph over the cables requires, however, that connections be arranged for carrying these telegraph channels around the transformers.

Operation of Single-Core Continuously Loaded Cables

The preliminary studies of the results to be expected with a loaded "grounded" cable circuit arranged for simultaneous telephone and telegraph operation indicated that satisfactory operation was dependent upon a number of factors regarding which little information was available. These included the effect of the sea return on the attenuation for alternating currents, the interference from natural electrical disturbances and from power systems at the terminals, the induction between cables and the interaction between currents of different frequencies resulting from their superposed fields in the iron used for loading.[3]

The effect of the sea return for the single-core cables used for submarine telegraphy has not been serious because it is practically negligible for the low frequencies involved. For direct currents, the cross-section of the return path is very large and its resistance low, even though the specific resistance of sea water is relatively high, of the order of ten million times as great as that of copper. For alternating currents, however, the return currents crowd in near the cable and the resistance of the return path is higher. This crowding effect of the return currents increases with frequency and consequently the resistance of the return path becomes greater. For frequencies in and above the telephone range the return currents are forced into the steel armor wires around the cable and into the layer of water just outside of the insulation. The small effective cross-section of the water involved and the losses in the armor wires cause the resistance of the return path to become a large part of the total resistance of the circuit and thus to have a large influence on the attenuation. The results of a few measurements of the sea return resistance for telephone frequencies, which had been made by British and French engineers, were published[4] in 1913 in an article discussing the factors involved in the use of single-core cables for telephony.

In connection with the plans for the Key West-Havana cables, a theoretical investigation[5] was made to determine how the resistance of the sea return is affected by the dimensions and construction of the cables and how it varies with frequency. This work in addition to giving a basis for investigating the effect of the dimensions of the cable and of the number and size of armor wires on the resistance of the sea return, made possible also the determination of the effect of a method proposed for reducing the losses in the sea return by providing a path of low resistance for the return current. It has long been the practise, when necessary to protect the insulation from the teredo, a marine borer, to wrap the gutta-percha insulation of submarine cables with a thin tape of brass or copper. This conducting tape suggested the use of a heavy copper tape, which, being just outside of the insulation, would be in the position which the high-frequency return currents would naturally seek to occupy. With this construction the lower frequency currents divide between the sea water, armor wires and the copper tapes, but as the frequency increases the part which returns through the tapes increases until finally for the upper frequencies in the telephone range practically all the current returns through the copper tapes. The resistance of these tapes becomes, therefore, practically the upper limit to the resistance of the return path. By making this path sufficiently low in resistance, it is possible to increase materially the efficiency of the cable. Furthermore, it is relatively inexpensive to place copper outside of the insulation, the main limitation to the amount being a mechanical one; namely, that as the tapes are made heavier and consequently stiffer, there is danger of damaging the insulation when the cable is bent. It was found that this idea of providing a conductive tape for the return was not new,[6] but investigation failed to show that it had ever been used or that any quantitative information had been published as to its effectiveness. This construction forms practically a concentric cable in which the outside cylinder is in contact with the water. In addition to its beneficial effect on the sea return, it is desirable also in that by reducing the external field of the circuit

it decreases the induction between adjacent cables and also tends to decrease the effect of extraneous electrical disturbances.

In order to get directly experimental information regarding the interference and the effect of the sea return on submarine cables, permission was obtained from the British Columbia Telephone Company to make tests on their cable to the island of Vancouver,[7] from the Western Union Telegraph Company to test their cables landing at Key West from Cuba, and from the United States Government to make measurements on a cable from Key West to Sand Key, a small island about 8 miles (14.8 km.) from Key West on which are located a lighthouse and a weather bureau station.

The Vancouver cable is a four-core continuously loaded gutta-percha cable with a brass protective tape wound around the group of cores. Measurements were made of the sea return for grounded circuits, of the interference on grounded circuits and of the induction from a telegraph cable of the Canadian Pacific Railroad which parallels the telephone cable. In addition, tests were made to get some indication of the cross-talk which might be expected between the physical and superposed circuits in such a cable and of the regularity of the impedance in a continuously loaded cable. Tests were also made of the interaction between currents of telegraph and telephone frequencies. The superposition in the iron wire loading of the fields of these two currents has been found[8] to increase the attenuation of the circuit for telephone currents. This has been called the "flutter" effect.

The Western Union cables are single-core gutta-percha-insulated non-loaded cables with protective metal tapes. Measurements were made of the interference on the cables and also of the cross-talk between the cables.

The Sand Key cable is a four-core non-loaded rubber-insulated telephone cable which has no protective metal tape. On this cable the sea return effect and the interference were measured.

It should be noted that measurements cannot be made directly of the sea return resistance for telephone frequencies. The resistance of the grounded circuits was determined from measurements of the impedance of the circuit, from measurements of the attenuation and from such data regarding the constants of the cables as could be obtained from tests on short pieces. The resistance of the conductor itself was obtained from tests on metallic circuits. For the Vancouver cable, this included the effect of the loading on the resistance of the circuit for alternating currents.

The magnitude of the sea return effect so determined checked closely the theoretical computations. In the case of the Vancouver cable this check involved taking into account the thin protective brass tape which had an appreciable effect. It was found also that th terference both from natural sources and from p systems would not be serious with amplifications larger than those required on the Key West-Ha telephone cables. The tests for cross-talk betwee cables at Vancouver which were about a mile (1.86 apart for their length of about thirty miles (55.6 gave no indication of induction from one cable t other. The test on the Western Union cables wh terminated in the same hut at Key West gave a mum cross-talk of less than 10 units at 1000 cycles (of cross-talk being a ratio of current in the dist circuit to current in the disturbing circuit of 1,000,000). The flutter tests on the Vanc cables showed that if the currents of the several nels were kept within reasonable limits, this should not cause trouble even for longer cables.

The results of these tests removed any questi serious interference and cross-talk with singl cables under the proposed conditions. They v the serious effects of the sea return resistance, b providing a check on the theoretical work, gave ance that this could be applied in estimating the of employing heavy copper tapes to limit the resi of the sea return.

Cable Design

Conductor. To provide flexibility and se against breakage, it is customary to make the conductor of a submarine cable not of a singl wire but of a central wire surrounded either by of copper wires or by a layer of thin copper In the present case the latter construction wa because of the smoother surface it provides for th ing wires. It also tends to give somewhat lo sistance and capacity for a given weight of The actual conductor consists of a round copp 0.115 inch (2.92 mm.) in diameter surrounded copper tapes each 0.077 inch (1.96 mm.) wide and inch (0.32 mm.) thick. This conductor has a of 350 lb. (159 kg.) per nautical mile (1.8 It was specified to have a resistance not to 3.52 ohms per nautical mile at 75 deg. fahr. (cent.)

Loading. The cable is loaded with a sing layer of iron wire 0.008 inch (0.2 mm.) in d applied directly upon the central copper co There are approximately 120 turns of this wire per inch length of the conductor. W equally efficient cable for the transmission of t frequencies could have been produced at a lo by using a smaller conductor with heavier in the form of more layers or thicker iron wire the requirements of the carrier telegraph m lighter loading more desirable, as will be sho

Insulation. The loaded conductor is trea Chatterton's compound and insulated wit percha mixture applied in three layers, thus f

7. La Belle and Crim, "The Gulf of Georgia Submarine Telephone Cable." A. I. E. E. Trans., 1913.

8. Fondiller and Martin, loc. cit.

"core." The amount of this insulating material is 315 lb. (143 kg.) per nautical mile which provides a wall thickness of approximately 0.135 inch (3.4 mm.). Because of the loading and the high frequencies for which the cable is used, low alternating-current conductance was specified for the dielectric, requiring the use of a special gutta-percha mixture.

Return Conductor. As already stated copper tapes were applied to the outside of the core to diminish the losses caused by the sea return. In the actual construction a copper tape 1 inch (2.54 cm.) wide and 0.004 inch (0.1 mm.) thick is applied directly upon the core with short enough lay to provide safe overlap. Upon this tape are laid two heavier copper tapes, each 0.625 inch (1.59 cm.) wide and 0.022 in. (0.56 mm.) thick. These two heavier tapes are applied with a much longer lay, and are laid side by side with the edges not quite touching. The entire system of copper tapes, weighing approximately 850 pounds (390 kg.) per nautical mile, provides a return conductor with a direct-current resistance in the laid cables of approximately 1.65 ohms per nautical mile. The thin tape first applied directly on the core furnishes also the protection against injury of the core by the teredo.

Sea Grounds. The main core with loaded central conductor and uninsulated return conductor, as described above, extends through the entire length of cable. In submarine telegraph cables it is the practise, in cases where it is especially important to reduce as much as possible all disturbances from outside sources, to construct portions of the cable near the ends with two cores so that the return part of the circuit is carried some distance out to sea before being connected to ground. In accordance with this practise, portions of each end of these cables were made with such two-core construction. In these portions the return or sea ground core has the same central conductor as the main core, no loading iron, the same amount of insulating material per unit length, and the thin protective copper tape but no heavy copper tapes. At the outer end of each of these sea ground cores its conductor is connected by electric welding to the conductive copper tape on the main core.

Armoring. The armoring protects the core and gives tensile strength to the cable to permit its being handled for laying and for subsequent lifting in case of repairs. As is usual, the size and number of armor wires are adapted to the location, taking into account such matters as depth, nature of bottom and water currents. The shore end portions, where because of relatively shallow water the cable is most likely to be injured, have the heaviest armor wire, which in this case has a diameter of 0.3 inch (7.6 mm.). The portions of the cable lying in the deepest water are armored with wire having a diameter of 0.104 inch (2.6 mm.). Intermediate portions of the cable have armor wires whose diameter is 0.192 inch (4.9 mm.). The 0.104 inch armor wire for the deep sea cable is a springy steel wire intended to give great tensile strength to the cable, while the heavier armor wire for the shore end and intermediate cable in shallower water consists of soft iron. The armor wire in all types of the cable is galvanized and is coated with preservative compound before being applied to the cable. The wires for the deep sea portions, in addition to being compounded, are individually wrapped with an impregnated fabric tape, which serves the double purpose of protecting the wire and making the cable more flexible by keeping the armor wires separated.

Before the armor wires are applied, the core or cores are served with tanned jute yarn applied in one or more layers to form a bedding for the armor wires. In those portions of the shore end cable which have two cores, these are laid up together with a relatively long lay and with tanned jute in the interstices between the two cores, before applying the jute bedding for the armor wire.

TABLE I

LENGTHS OF THE SEVERAL TYPES IN EACH CABLE

Type of Cable	Armoring or Sheathing	Length—Nautical Miles* Western Cable	Center Cable	Eastern Cable
	Key West End			
Shore end twin with lead-covered cores...	17 No. 1 (0.300 inch) wires	0.2	0.2	0.2
Shore end twin plain cores..............	15 No. 1 (0.300 inch) wires	3.0	3.0	3.0
Shore end single.......	10 No. 1 (0.300 inch) wires	14.0	9.5	10.5

Shore end twin plain cores..............	15 No. 1 (0.300 inch) wires	1.8	1.3	1.3
Shore end twin with lead-covered cores...	17 No. 1 (0.300 inch) wires	0.2	0.2	0.2
	Havana End			
Total................		104.5	100.2	104.9

*A nautical mile is 6087 feet (1855 meters).

The total length of cable laid on each of the three routes as given is somewhat greater than the distance along the route in order to provide slack.

In the extreme shore ends a short length is made with each core covered with a close fitting tube of lead to protect it from light and air, which would tend to cause deterioration of the gutta-percha in those portions which may extend out of the water.

The lengths of the several types differ somewhat in the three cables because of differences in the routes. In a general way the heaviest type of armoring extends from the shore to a point where the depth is approximately 100 fathoms (183 meters) and the intermediate type from this point to one where the depth is approximately 250 or 300 fathoms (457 to 549 meters), with the deep sea type in all the deeper parts. This arrangement carries the heavily armored cable much farther

out from the Key West end than from the Havana end because of the much more gradual increase of depth of water at the Key West end. For the same reason the two-core or twin cable, which provides the return core for the sea ground, is carried out considerably farther at the Key West end. The approximate length of each type actually installed and the sequence of types are given for each cable in Table I.

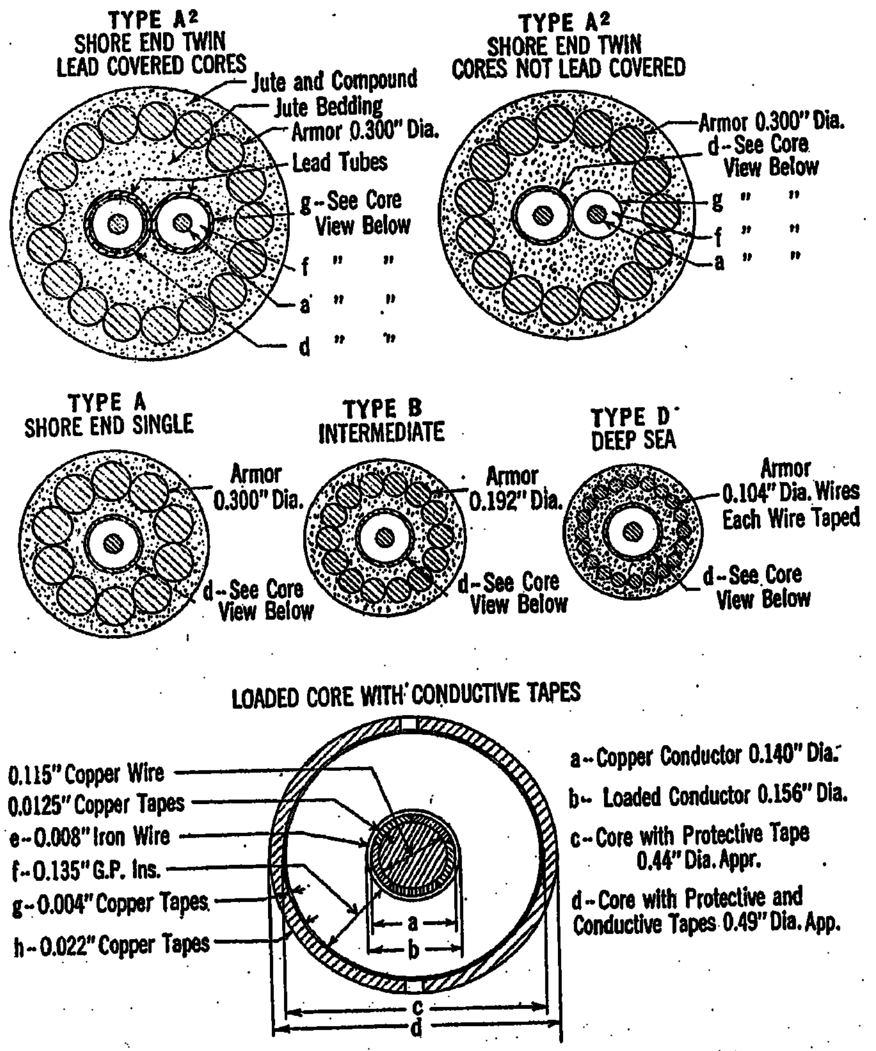

FIG. 2—CROSS-SECTIONS OF THE VARIOUS TYPES OF CABLE USED

Some of the principal details of the design of the several types of cable with their relative dimensions are shown in the diagrams of Fig. 2. A photograph of specimens showing the appearance of the cables and some details of their construction is reproduced in Fig. 3. The over-all diameter of the largest shore end cable is approximately 2.4 inches (6.1 cm.) and that of the deep sea type approximately 1.2 inch (3.0 cm.).

CABLE MANUFACTURE AND TESTING

The cables were manufactured and laid by the Telegraph Construction and Maintenance Company, Limited, of London.

Since the mechanical structure of these cables is in most respects similar to that of gutta-percha-insulated submarine telegraph cables, the manufacture was in the main carried on along the lines followed in making such cables. Briefly, this process is as follows: The central conductor is made by stranding around a copper wire a layer of finer copper wires or a layer of thin copper tapes. This conductor is then covered with the gutta-percha insulating material, generally applied in two or three layers to diminish the chan a defect extending through the insulating enve Before applying the gutta-percha, the conduct treated with a thin coating of Chatterton's compour fill the interstices in the conductor and to increas adhesion between the conductor and the gutta-pe The insulated conductor so formed is known as a " and is manufactured in lengths generally ranging 1½ to 3 nautical miles (2.8 to 5.6 km.), depending the weight of the core. In general it is necessa manufacture heavy core in shorter lengths than core. After the necessary inspection and tests core lengths are served with tanned jute yarn, in more layers to form a bedding for the armor In case the cable is to be protected against the te the core, before being served with the jute beddi covered with a close overlapping layer of metal (generally brass). Either before or after being s with the jute bedding, the individual cores are j together to form longer lengths. They then pa the armoring or closing machine, which applie armor wires. The galvanized armor wires, being used, are coated with preservative compoun the armoring machine applies over the outside armor wires wrappings of tarred jute yarn or heavy burlap-like fabric known as "Hessian" Between the armor wires and these outer wrap as well as between and over the several wrap

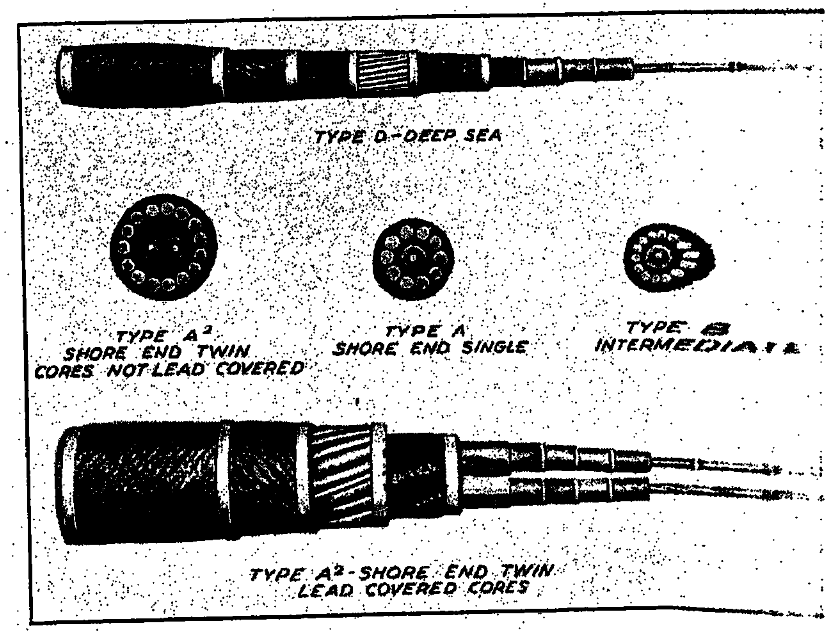

FIG. 3—SPECIMENS OF THE VARIOUS TYPES OF CABI

coatings of preservative compound are applied. the armoring machine the cable is laid directly i factory cable tanks, where it is treated with wh to prevent sticking, and where it is then kept sub in water until it is transferred to similar tanks cable ship, for transport and laying.

In the splicing of two lengths of cable, either factory or on the cable ship, a core joint is first unite the conductor and its insulation in the t tions of cable. Over this the jute bedding reapplied by hand, and finally the armor wire had previously been opened up and laid as

laid back in such a way that the armor wire from one of the two pieces extends for a length of 15 feet (4.6 m.) or more over the armor wire of the other part. After laying the armor wire in place the splice is served with several tight bindings of galvanized iron wire and the whole covered by a continuous close binding of tarred yarn.

In the manufacture of these cables the application of the iron loading wire to the conductor added an operation which, because of its relative slowness, largely determined the length of time required for manufacture. The heavy conductive copper tapes which are applied to the outside of the core could, because of their weight, be handled only in limited lengths of something like 200 feet (61 m.). Successive portions of this tape were joined together by welds. A soldering or brazing operation would have required the insertion of a dissimilar metal, which would increase the tendency to electrolytic corrosion when in contact with sea water.

The cable in process of manufacture was subjected to the usual visual and manual inspections and electrical tests. The core was manufactured in individual lengths of approximately two nautical miles (3.7 km.) each. These individual core lengths, after 14 days' submersion in water, were tested at a temperature of 75 deg. fahr. for d-c. conductor resistance, insulation resistance and capacity. During the process of jute serving and armoring frequent electrical tests were made so that if any injury or fault should develop it could be detected and the defective part removed or repaired. Measurements of d-c. conductor resistance, insulation resistance and capacity were again made on the completed cable at various times during and after the manufacture, the loading upon shipboard and during the transport and laying of the cable.

In addition to these tests, which are customary for all gutta-percha-insulated submarine cables, additional measurements were made on the present cables. The inductance and capacity of each length of core were measured by alternating-current methods. A large number of short lengths of core selected so as to represent all parts of the cable were measured for capacity and conductance at 1000 cycles per second and at 75 deg. fahr. It was found that the capacity as measured by a direct-current galvanometer method agreed within one per cent with the capacity obtained by measurements with alternating current of 50 cycles or 1000 cycles per second. Table II gives the average values per nautical mile of the several electrical constants as measured on the cores at a temperature of 75 deg. fahr. 14 days after manufacture.

TABLE II

Direct-Current resistance	3.32 ohms
" " capacity	0.311 microfarads
" " insulation resistance after one minute electrification	920 megohms
1000-Cycle inductance	4.35 milhenrys
" " conductance	12.8 micromhos

The corresponding values for the completed cable when laid are in some respects materially different. The insulation resistance is higher in the laid cables because it increased both with age and with the lower temperature at the sea bottom. The 1000-cycle conductance decreased with age but increased with the lower temperature—these two effects thus tending to offset one another. The inductance for the completed cable corresponds to that of a central loaded conductor with a concentric cylindrical return circuit, while the inductance measured on the individual cores was that of a gutta-percha-insulated loaded conductor in bifilar form. The conductor resistance is, of course, different because of the lower temperature of the laid cables.

These extensive measurements were made to obtain data regarding the electrical properties of the cable and of the individual lengths of core. The data on the core lengths were used to determine their best sequence, in order to make the impedance at the ends of the cable as uniform as possible over the range of frequencies required for telephone transmission.

Cable Laying

The cable ship arrived at Key West February 7, 1921, and after certain preliminaries such as securing barges and tugs and making the necessary arrangements with the Government authorities proceeded with the laying operations.

Where the water was deep enough the cables were laid directly from the cable ship which brought them from the cable factory to the Florida Straits. In shallower water the cables were laid from a barge or lighter towed by a tug. The actual sequence of laying each cable was as follows: First a length of approximately 6 or 8 miles (11 or 15 km.) was laid from a barge at the Key West end. The barge with its length of cable was brought as near as possible to the Key West cable hut. The extreme Key West end of the cable was pulled from the barge to the shore, laid in a trench on the beach and terminated 'n the hut. To facilitate this landing, the portion between the barge and the hut was supported at intervals by empty casks, to which the cable was tied by ropes, and thus floated in the water. After the landing of the shore end, the main portion of this cable section remaining on the barge, its length having been suitably chosen, was laid outward to a point having a depth sufficient for the cable ship. At this point the end was sealed and dropped to the bottom with an anchor attached to a marking bouy. Later this cable end was picked up by the cable ship and spliced to the next length, which was then laid by the ship from this point to the end of the intermediate type of cable, which as already stated reached to a point where the depth of water was about 250 or 300 fathoms (457 or 549 meters). Again the end was sealed and laid overboard with an anchor and a marking bouy. Next a short length of shore end cable was laid by barge from the Havana cable hut outward and its end lifted to the ship and there spliced to the main length of cable, which

was then laid by the ship from this point near Havana to the point where the bouy marked the location of the end of the intermediate cable previously dropped. After lifting this bouyed end the final splice was then made on the ship connecting the bouyed end to the main cable on the ship and the work of laying completed by dropping the final splice overboard.

After the completion of the laying of the three cables the final acceptance tests were made at the ends of the cables in the Key West cable hut. These tests covered only such measurements as are customary on submarine telegraph cables; *i. e.*, measurements of direct-current conductor resistance, direct-current insulation resistance and direct-current capacity. They were intended merely to determine these direct-current properties and to insure the electrical integrity of the cables after completion of the laying. The results of these tests are shown in Table III which gives values per nautical mile:

TABLE III

	Western Cable	Center Cable	Eastern Cable
Conductor resistance—ohms	3.13	3.11	3.11
Capacity-microfarads......	0.315	0.316	0.314
Insulation resistance after one minute electrification—meghoms.......	8900	7600	8500

These tests were completed the evening of February 25, 1921, and on February 26, 1921, the surplus and spare cable was delivered into the storage tank at Key West and the cables were formally accepted.

Cable Characteristics

In view of the fact that the return circuit of the single-core cable includes the sea water, the operation of the cables could not be determined accurately until they were laid. The lengths of the laid cables are such that determinations at telephone and carrier frequencies of the primary constants, resistance, inductance, capacity, and conductance can not be made directly. The secondary constants, the impedance and attenuation, can be measured and these data together with the results of the tests on short pieces used to estimate the primary constants.

After acceptance, extensive alternating-current measurements were made on the three cables, covering the range from about 100 to 6000 cycles. These tests included determinations of the ratio of the current received at one end of the cable to that sent in at the other and measurements of the impedance at each end of each cable with the far end closed through the characteristic impedance of the cable. From these measurements of the ratio of the "received" current I_2 to the "sent" current I_1, the attenuation constant α per nautical mile of each of the cables was obtained from the relation

$$e^{-L\alpha} = \frac{I_2}{I_1}$$

where L is the length in nautical miles. These values for a range of frequencies are given in Table IV. It is seen that the values for the three cables do not differ materially. The average of the attenuations for the three cables is shown also in Fig. 4.

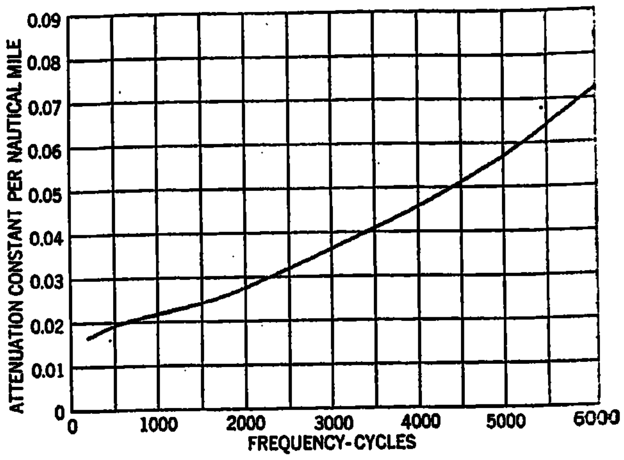

Fig. 4—Average Attenuation Constant of the Cables

The transmission equivalent of the center cable, which is the shortest, is shown in terms of miles of standard cable at 800 cycles (attenuation of one mile of standard cable at 800 cycles is 0.109) in Fig. 5. This figure gives in addition the combined equivalent of the compositing apparatus in the two huts and the land cables at the two ends between the cable huts and the offices, and also the total equivalent of the circuit from the Key West office to the Havana office.

Table V gives the total equivalent of the circuit over the center cable between the two offices and the corresponding current ratios.

The variation of the resistance and reactance components of the impedance of the cable is illustrated in Fig. 6. The deviations of these curves from those that would be obtained if the cable were absolutely uniform throughout its length are under 3 per cent.

From these measurements, from the tests in the factory and from computations, it is possible to estimate fairly closely the constants of the cables. The average of these constants for the three cables is given in Table VI. The conductance is not given for frequencies of 1000 cycles and lower as its effect for this range is so small as to make determination of its value practically impossible under the conditions.

TABLE IV
ATTENUATION CONSTANT PER NAUTICAL MILE

Frequency Cycles per sec.	Cables: Western	Center	Eastern	Average
200	0.0170	0.0165	0.0168	0.0168
500	0.0196	0.0197	0.0190	0.0194
1000	0.0216	0.0216	0.0216	0.0216
2000	0.0278	0.0278	0.0278	0.0278
3000	0.0357	0.0361	0.0371	0.0363
4000	0.0450	0.0460	0.0470	0.0460
5000	0.0558	0.0574	0.0594	0.0575
6000	0.0710	0.0716	0.0748	0.0725

Estimates were also made of the distribution of the resistance in the circuit for a range of frequencies.

TABLE V

TOTAL EQUIVALENT-HAVANA OFFICE TO KEY WEST OFFICE
CENTER CABLE

Frequency Cycles	Equivalent Miles Standard Cable 800 Cycles	Current Ratio
200	19.8	0.116
500	19.4	0.121
1000	20.8	0.104
2000	27.2	0.0516
3000	35.7	0.0204

6000	72.7	0.00036

The curves of Fig. 7 give average values for the three cables of the d-c. conductor resistance, the increase of the conductor resistance with frequency due to skin effect, the resistance of the sea return and the resistance added to the circuit by losses in the loading iron. The large part contributed by the loading at the higher

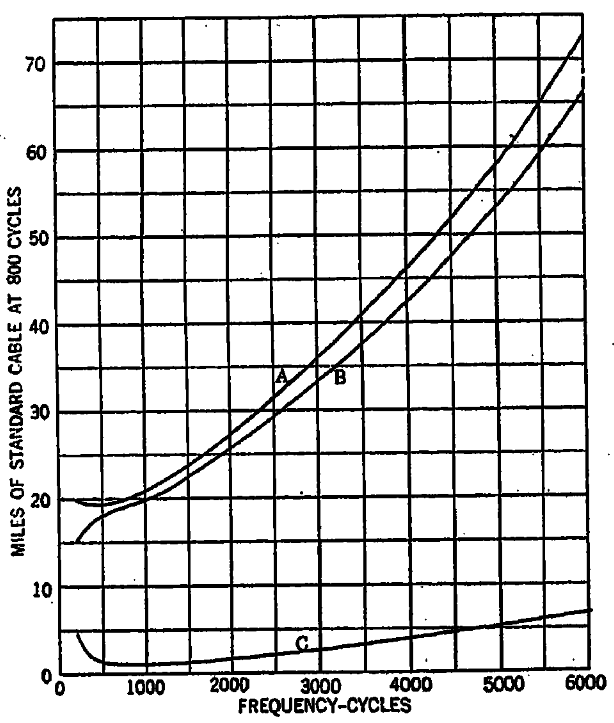

FIG. 5—TRANSMISSION EQUIVALENT OF CIRCUIT OVER CENTER CABLE BETWEEN KEY WEST AND HAVANA TELEPHONE OFFICES

frequencies shows why it is desirable to use the light loading where carrier frequencies are to be transmitted. The use of iron wire 0.012 inch in diameter would have increased the resistance added by the loading by about 55 and 90 per cent at 3000 and 5000 cycles respectively above the values obtained with 0.008-inch wire. These increases in resistance, in spite of the increase in inductance resulting from this change, would have increased the attenuation by 33 and 65 per cent at these frequencies.

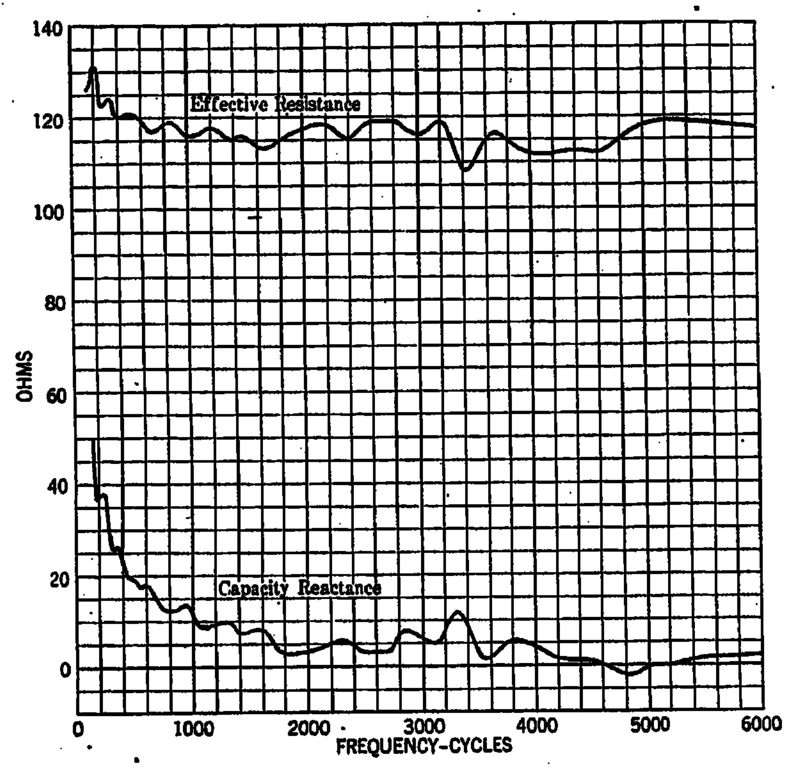

FIG. 6—IMPEDANCE OF EASTERN CABLE AS MEASURED FROM THE KEY WEST TERMINAL

Estimates of the resistance of the sea return which would have been obtained in the deep sea portion of the cable if no copper tapes had been provided give values of 4, 6.5 and 8 ohms per nautical mile at 1000, 3000 and 5000 cycles. The resistance actually obtained with the copper tapes does not exceed 1.7 ohms at 5000 cycles, as shown on the curves of Fig. 7. The greater values would have increased the attenuation

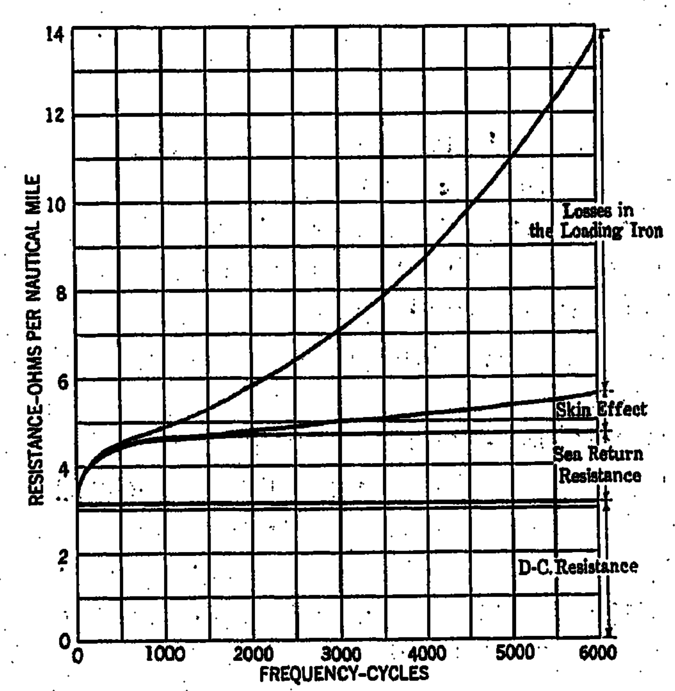

FIG. 7—ANALYSIS OF THE RESISTANCE OF THE CABLE CIRCUIT

by approximately 30 per cent at 1000 cycles and by 50 per cent at the two higher frequencies.

The results of the measurements of the cross-talk obtained at Key West between two adjacent cables are shown in Fig. 8. It will be noted that the cross-

talk between the cables when the connection is made to the copper tapes is less than one per cent of that obtained when the connection is made to the insulated sea ground conductors.

Measurements of the interference on these cables showed this to be practically negligible. As might be expected, the interference of frequencies in the d-c. telegraph range was greater when using the return tape than when using the sea ground. The interference at the telephone and carrier channel frequencies was, however, many times greater when using the sea ground conductors, the interference when using the return tape being so small as to be negligible even with amplifications larger than required for operation. The maximum interference currents obtained with the tape return were less than one microampere and this was largely 180-cycle current, which was probably produced by a harmonic in a power circuit near the terminal.

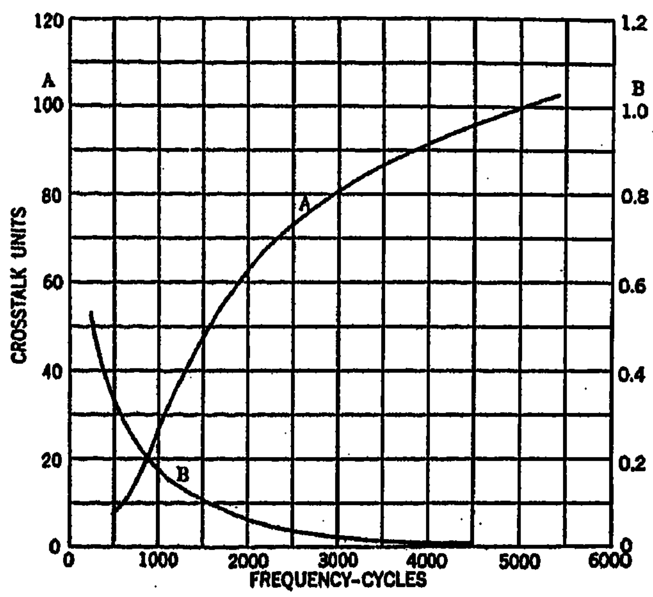

Fig. 8—Cross-talk between Two of the Cables

A. Both cables using sea ground.

B. Both cables using copper tape return.

The results of the cross-talk and interference tests confirm the expected operation of the heavy copper tape return, that is, that practically all the current of frequencies in the important part of the telephone range and above would return through the tape. On the same basis the tape acts as a very effective screen against interference currents of these frequencies.

Measurements of the flutter effect between the d-c. telegraph and the telephone channel showed that the passing of the telegraph currents over the cable simultaneously with currents of frequencies in the telephone range, reduced the magnitude of the received telephone current by only a small fraction of one per cent. The maximum value of the d-c. telegraph pulses was about 14 milliamperes. The maximum effect on the carrier telegraph operation of the d-c. telegraph and the telephone together was a reduction of under 3 per cent in the magnitude of the received carrier currents. This was inappreciable in the operation of the carrier system, as the receiving circuit is designed to be saturated with the normal incoming current, so that slight changes in the sent currents or changes in the circuit efficiency have no effect on its output.

Investigation was also made of "modulation" effects in the loading. Where two currents of different frequencies, A and B, are superposed on the circuit and hence have their fields superposed in the iron wire loading, currents of other frequencies are set up in the cable as a result of the non-linear characteristics of the iron. The frequencies of these modulation currents are the sums and differences of the frequencies A and B and of their various harmonics, such as $A \pm B$, $2A \pm 2B$, $2A \pm B$, $A \pm 2B$, $3A \pm 3B$, $3A \pm 2B$, $3A \pm B$, $A \pm 3B$, and so on. The superposition of additional currents of frequencies different from A and B produces of course additional resultant modulation currents.

The even order modulation currents, that is, those of frequencies for which the sums of the coefficients of A and B are even numbers, such as $A \pm B$ and $2A \pm 2B$, are due largely to magnetic bias of the loading and are therefore materially affected by the amount of direct current flowing in the circuit. The odd order terms, such as $2A \pm B$, $A \pm 2B$ and so on, are produced by the non-linear force-flux characteristic of the iron and are less affected by the direct current.

The principal modulation currents found in the work on the cable were those of frequencies $A \pm B$, $2A - B$, $2B - A$, $3A - 2B$, and $3B - 2A$. Others were present but were either so small in magnitude or so high in frequency as to be negligible compared to the above. The measurements of the small modulation currents necessarily involve highly selective circuits, large amplifiers and special circuit arrangements in order to prevent the currents causing the modulation from entering the circuit measuring the modulation currents and also to eliminate the modulation effects in the measuring apparatus itself. For the present arrangement of channels with the 3000-cycle carrier flowing into the cable at Havana and the 3800-cycle carrier at the Key West end the modulation currents produced by the carrier telegraph currents are very small. The $2A$-B term, which is the largest, is only 0.2 microampere. If the two carrier currents are sent into the cable at the same end, however, the modulation currents while still small are appreciable, as shown in Table VII.

TABLE VII

Magnitude of Carrier Currents Entering Submarine Cable

A—3000 cyles, 13.6 milliamperes

B—3800 " 18.5 "

Modulation Currents from Cable

Frequency	Microamperes
A − B, 800 cycles	0.3
A + B, 6800 "	less than 0.1
2A − B, 2200 "	4.7
2B − A, 4600 "	1.3
3A − 2B, 1400 "	1.3
3B − 2A, 5400 "	0.3

While for these arrangements the modulation effects were found to be so small as to cause no serious interference, they may under some conditions become large enough to require consideration, particularly in connection with increasing the number of carrier telegraph channels over the cables. In that case, these modulation currents affect the number of channels, the current levels and the frequencies which can be used. This effect appears not only as noise in the telephone but also as interference between carrier channels. As an illustration of the magnitudes which may be obtained, Fig. 9 shows the 2 A-B term for a constant A frequency of 2500 cycles with the B frequency varying from 3000 to 5000 cycles. The magnitudes of both A and B are 30 milliamperes into the submarine cable at the same end, the modulation currents being measured also at that end. It is seen that for the lower frequency values of 2 A-B, the magnitudes are comparable with those of components of the telephone currents on the cable.

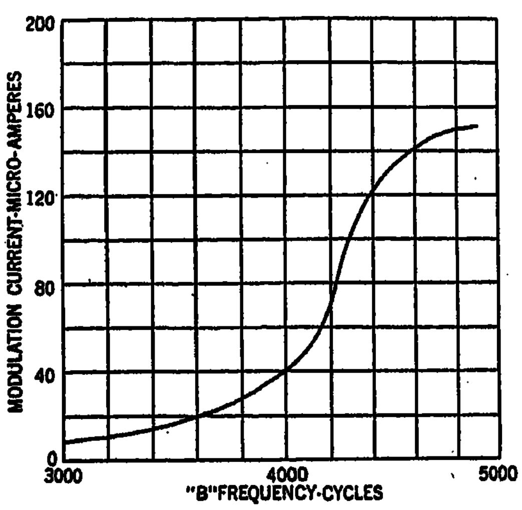

Fig. 9—Modulation Effect in Cables
Current of 2 $A-B$ frequency for A frequency = 2500 cycles. Current of both A and B frequencies = 30 milliamperes into submarine cable.

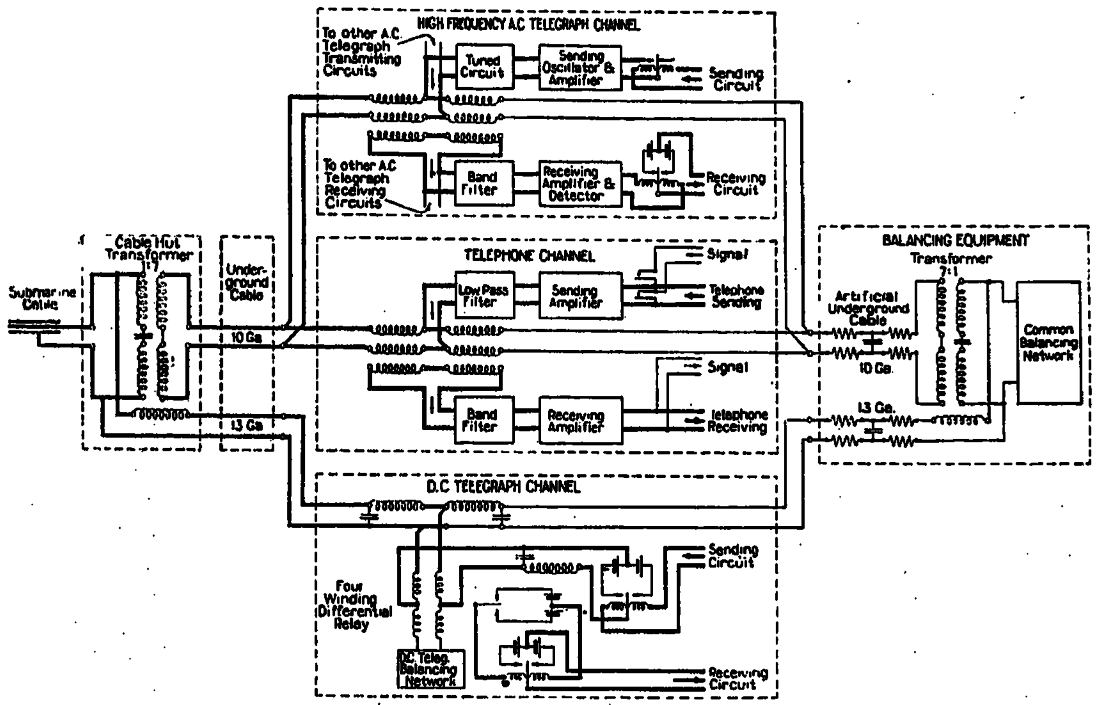

Fig. 10—Compositing Arrangement at Terminals

Compositing Arrangement at Terminals

For the initial operation over the cables, arrangements were made and apparatus provided for two duplex telegraph channels and a telephone channel over each of the three cables. One of the telegraph channels is furnished by the direct-current system and the other by the carrier-current system using frequencies above the voice range. In addition to the above, a signaling channel required for the operation of the telephone channel uses currents of frequencies in the voice range. It is possible to employ this range since it is not required simultaneously for signaling and talking.

The general method of superposing these channels on the cable and connecting them to the terminal apparatus is shown in Fig. 10. As the channels are required to operate in both directions, the usual balance system is provided for each channel to prevent the currents sent out at one terminal from operating the receiving apparatus at that terminal. The balance system consists essentially of a "bridge transformer" and a network of impedance elements designed to simulate the impedance of the line for a range of frequencies. The bridge transformer is a transformer with three windings, from two of which accurately located center taps are brought out. This transformer is thus suitable for providing a Wheatstone bridge circuit in which the two windings having mid-point taps serve as ratio arms. The transmitting amplifier output is connected to the mid-point taps and the receiving amplifier input to the third winding of the transformer. With the balancing network adjusted to have an impedance equal to that of the line, the transmitting amplifier does not send current into the receiving amplifier.

Filters or selective circuits are placed in the sending circuits to insure that the outgoing currents of any channel do not contain frequencies which will interfere with the other channels, and in the receiving circuits to admit only those currents in the proper frequency range.

At the cable hut the submarine cable is connected by a 1 to 7 impedance ratio, specially balanced transformer to a two-wire underground cable circuit of No. 10 A. W. G. (diameter 0.102 inch, 2.6 mm.) conductors. Across the cable side of the transformer is bridged a No. 13 A. W. G. (diameter 0.072 inch. 1.8 mm.) two-wire circuit for the direct-current telegraph channel. The No. 10 circuit carries the telephone and the carrier telegraph channels to the office. The transformer serves to insulate the grounded submarine cable from the land cable and thus renders the latter less susceptible to interference from power systems. It also steps up the impedance of the cable to meet the impedance of the telephone and carrier channel terminal apparatus and aids in keeping the d-c. telegraph currents out of the higher frequency channels. This latter function

is assisted by the condenser at the mid-point of the cable side of the transformer.

The telephone and carrier apparatus is connected in parallel to the No. 10 A. W. G. underground cable circuit. Each set of equipment contains a bridge transformer which separates the sending and receiving circuits. These two bridge transformers are connected in parallel both to the cable and to the common balancing network so that the sending circuit of either channel will not send current into the receiving circuit of the other channel. The sending channels are not so balanced against each other, but since each contains a filter or tuned circuit which presents high impedance to currents from the other sending circuit, little current flows from one sending circuit to the other. The receiving side of the telephone is protected by balance against the sending side of the telephone and by both balance and selectivity against the sending side of the carrier channel.

The d-c. telegraph channel is also in parallel with the telephone channel but is connected to it at points different from the carrier channel. The inductance coils and condensers in the d-c. channel constitute a low-pass filter which transmits frequencies from zero to about eighty cycles. This channel has one branching arrangement which is designed so that the receiving circuits of the higher frequency channels are balanced against both the outgoing telegraph currents and the disturbances produced in the relay windings by the operation of the relay armature under the actuation of the received signals. It has also the second branching arrangement in the windings of the receiving relay, to separate the sending and receiving telegraph circuits. This requires the second balancing network which is connected with this relay.

It will be noted that associated with the main balancing network shown in the right of Fig. 10 is a duplicate of all the apparatus and circuits between the terminal apparatus and the submarine cable. The balancing network itself is adjusted to simulate the impedance of the submarine cable over the range of frequencies required for the operation of the telephone and telegraph channels, particular attention being paid to have it meet this impedance for the range of the telephone channel. Because of the degree of uniformity obtained in the impedance of the cables, it was possible to get a very good simulation with a simple network of three impedance elements. If the cables had been less uniform it might have been necessary to employ a multi-section artificial cable such as is used with long submarine telegraph cables. The balancing transformer and artificial underground cable are adjusted to match the impedances of the corresponding elements in the cable circuit. By this means, it is possible to obtain a balance at the terminals of the bridge transformers which for any frequency in the telephone range is within 3 per cent of being perfect, thus making it possible to use high amplifications with this channel. The degree of balance is on'y slightly poorer in the carrier telegraph range.

Since the attenuation in the range available for carrier telegraph use is greater than that in the telephone range and the amplifications therefore necessarily larger, the land-line carrier telegraph practise was followed in not relying entirely upon the balance to prevent interference between the outgoing and incoming carrier currents but in using different frequencies in the two directions with the selective circuit and filter in the sending and receiving branches tuned respectively to these different frequencies. For operation from Havana to Key West a carrier frequency of 3000 cycles is used and for the opposite direction a carrier frequency of 3800 cycles.

The arrangement of the terminal apparatus in the cable hut is shown in Fig. 11. Each of the submarine cables is terminated in one of the boxes at the left, which

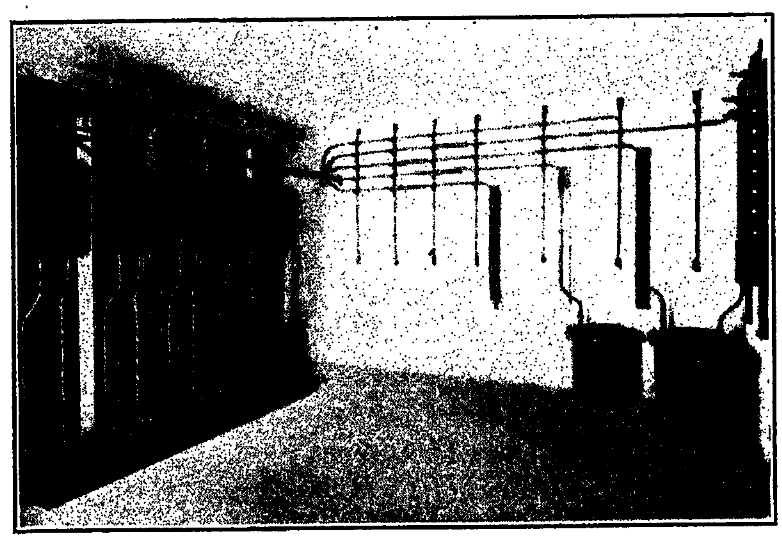

Fig. 11—Apparatus in Cable Hut

are water-proof. The submarine cable enters the box from below, the two cores entering through separate bushings. The underground cable circuits from the office are brought into the boxes from above. Cables also lead from these boxes to the pots at the right which contain the transformers, condensers and inductance coils located at the hut. A tie cable enters all the boxes from below to make possible cross-connection of the circuits and apparatus.

Terminal Equipment

Amplifiers and signaling apparatus for the telephone circuits and terminal apparatus for the telegraph and carrier telegraph channels are provided for each cable at the terminal offices in Havana and Key West. Although these terminal units in general resemble those developed for similar uses on land-line telephone and telegraph circuits, they differ in many respects because of the high attenuation of the submarine cables and the different methods of operation required on these circuits.

The general theory and operation of telephone repeaters[9], carrier telegraph apparatus[10] and vacuum

9. Gherardi and Jewett, loc. cit.

10. Colpitts and Blackwell, loc. cit.

tubes[11] have been described in various publications. Those features in which the cable apparatus is similar to earlier types will not be discussed here in detail.

The terminal apparatus was designed, manufactured and partly installed before the laying of the cables, in order that service might be given as soon as possible after they were laid. The design of the apparatus was based on the estimated characteristics of the cables

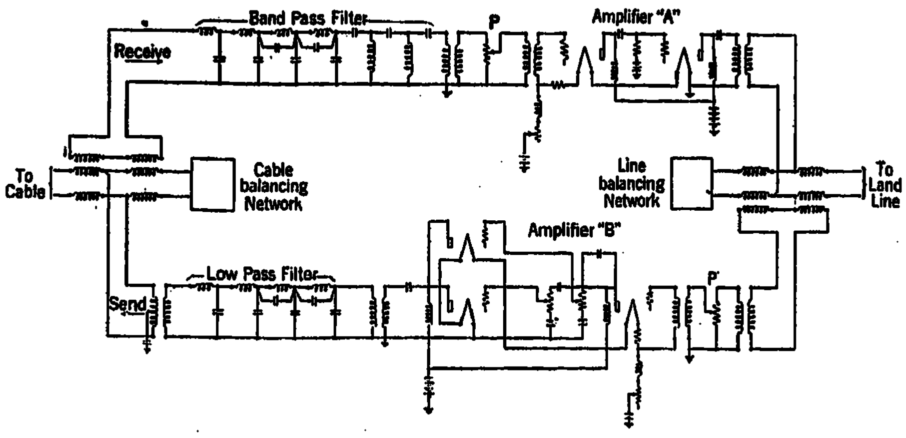

Fig. 12—Circuit of Telephone Repeater

but in order to provide for satisfactory operation, in case the attenuation and interference should exceed the expected values, the terminal apparatus was made adjustable over a wide range of amplifications and current levels.

Telephone Circuit

The telephone channels of the cables are connected to the land lines through bridge transformers and amplifiers as shown in Fig. 12. The third winding of each bridge transformer is connected through an amplifier to the center points of the line windings of the other bridge tranformer, thus forming the two-way, two-amplifier repeater circuit generally called a "22-type" circuit[12]. Since a close and constant balance has been secured between the cable and its network, as pointed out above, the repeater may be worked with large gains[13] even when the balance between the land line and its network is not close. Such is the case in terminating connections where the land end of the repeater is connected through the toll switchboard to subscribers' lines, as in calls to or from subscribers in Havana or Key West, without intervening toll lines of considerable length which could be balanced more closely.

Networks are provided to balance the average subscribers' lines as well as possible. When the repeater is to be connected to land lines of considerable length, networks of the general character described in an earlier paper[14], which provide a better balance for these lines, are used. Such networks are provided for use with the circuits extending north from Key West and also for use with the toll circuits in Cuba.

The repeaters combine the operating characteristics of "through-line" and "cord-circuit" repeaters. A through-line repeater is one which is permanently connected in a toll line, the whole forming a through-line circuit, no part of which is under the control of an operator at the repeater station. In a cord-circuit repeater the two line ends of the repeater circuit appear at the toll switchboard as plugs and this repeater cord circuit may be used to connect toll lines which terminate in jacks in the switchboard. Such a repeater is arranged so that the gain can be adjusted by the toll operator to the value specified for the circuits which it is used to connect. In the Key West and Havana repeaters the cable bridge transformers, the cable balancing networks and the amplifiers are permanently connected to the cables, the repeaters being thus through-line in character on the cable side. The repeaters at Key West on the through circuits are permanently connected to the land lines and their balancing networks, with certain arrangements for patching to be noted below. Such circuits are shown schematically in heavy lines in the upper part of Fig. 13. At Havana, and at Key West on the one circuit terminated there, the land sides of the repeaters terminate in the switchboard, so that these repeaters have some of the features of cord-circuit repeaters. These so-called "terminating connections" are shown in sche-

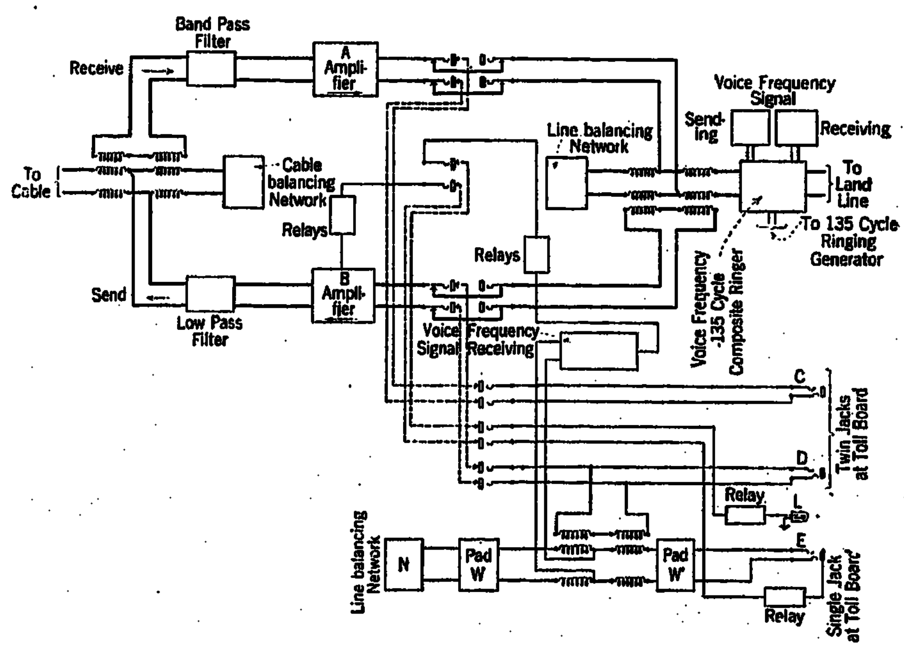

Fig. 13—Circuit of Through Line Telephone Repeater

matic form in Fig. 14. In the terminating as well as in the through-line circuits, the gains of the amplifiers are adjusted by means of the potentiometers P and P' shown in Fig. 12. These are set at the proper values by the repeater attendant. The control at the switchboard of the effective gains of the terminating repeaters is obtained by means of artificial lines or pads on the

11. Van der Bijl, "The Thermionic Vacuum Tube and its Applications." McGraw-Hill Company, New York.

12. Gherardi and Jewett, loc. cit.

13. The term "gain" is extensively used in telephone and carrier practise to indicate amplification and is generally expressed in terms of the number of miles of standard cable, the attenuation of which it will just neutralize.

14. Gherardi and Jewett, loc. cit.

line and network sides of the bridge transformers H and H' as shown in the lower part of Fig. 14.

In the terminating circuits, the land side of the repeater appears at the switchboard in both a single-jack and a twin-jack termination, as shown in Fig. 14. The single-jack termination is used for connections to local subscribers' loops and the twin-jack arrangement for connection to land toll lines. A call coming

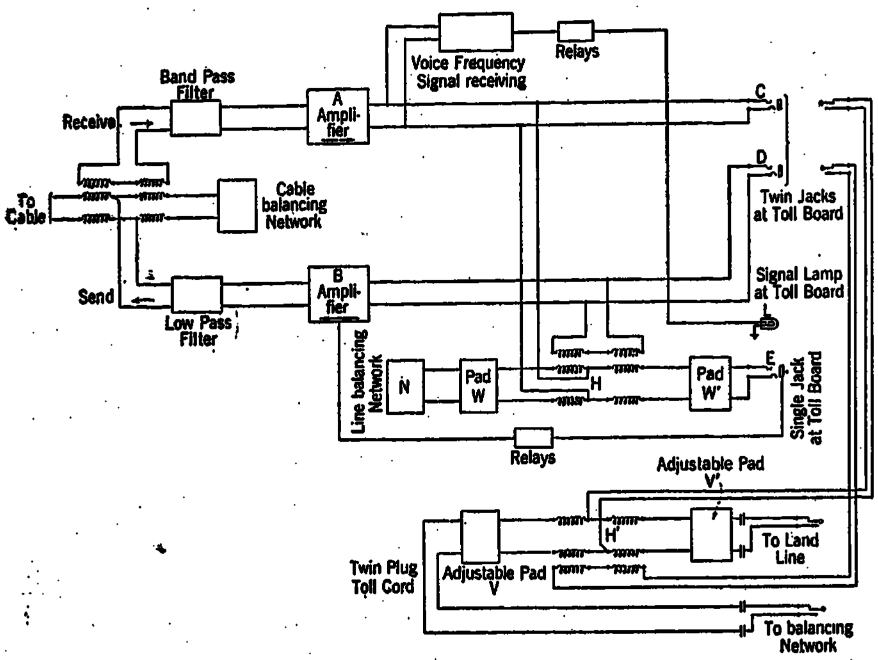

FIG. 14—CIRCUIT OF TERMINATING TELEPHONE REPEATER

over the cable, indicated by the lighting of the signal lamp L, is answered with a single-plug toll cord, the plug being inserted in the jack E. If the call is intended for a local subscriber, the other end of the cord is plugged directly into the local circuit at the switchboard. This circuit is balanced by a network N designed to balance the average local connection. When the circuit is not in use the net work N is disconnected and the two equal pads W and W' preserve the proper impedance balance on the two sides of the bridge transformer H, so that singing in the repeater circuit is prevented. The insertion of the cord-circuit plug in the single jack E operates a relay which connects the network N in place. When connection to the subscriber's instrument has been completed, the current from the central battery through his transmitter operates a train of relays which reduces the transmission loss introduced by the pads. The same change in the pads is produced when the operator, by throwing her talking key, causes current to pass through her transmitter. If the call is routed to a toll line, the connection is made by the insertion of a "twin-plug toll cord" in jacks C and D, which disconnects the single jack circuit automatically. The twin plug at the other end of the cord is inserted in the jacks connected to the desired toll line and its balancing network. The circuit of this twin plug toll cord is shown schematically in the lower part of Fig. 14. In this case the operator may control the effective gain of the repeater by a key which changes the number of sections in the adjustable pads V and V'.

In through-line use of the repeaters both amplifiers are continuously supplied with filament current and are maintained in operating condition. In cord-circuit or terminating use the amplifier which receives from the cable is kept in operating condition in order that signals may be received. When a connection is made through either the single- or double-jack circuits, relays are operated which cause current to be supplied to the filaments of the sending amplifier. No current is supplied to this filament circuit except when a connection is established.

In view of the fact that it may sometimes be desired to terminate temporarily at the Key West switchboard any one of the through-line circuits, the repeater circuits have been arranged to facilitate this. It will be noted in Fig. 13 that the through-line circuits pass through a group of jacks. These are located in the "jack panel," a unit in which are terminated all the principal circuits associated with the cable. When the connections indicated by the dotted lines are made the resulting circuit is the same as that of Fig. 14.

In order to protect the telephone apparatus against interference due to the telegraph channels, a filter system is connected in the telephone circuit between each amplifier and the cable bridge transformer. The filter in the receiving branch (Fig. 12) freely passes the range of frequencies (250 cycles to 2300 cycles) assigned to the telephone channel and greatly attenuates currents of all other frequencies. The filter in the send-

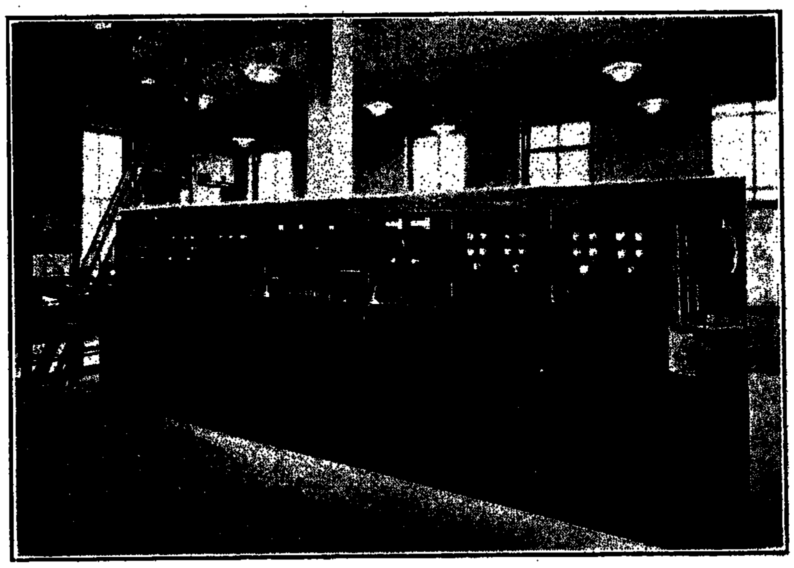

FIG. 15—TELEPHONE REPEATER PANELS, JACK PANEL AND TESTING PANELS

ing branch prevents the passage of currents of frequencies which would interfere with the carrier telegraph channel.

The amplifiers, filters and other equipment of each repeater are mounted in a unit panel. These, together with the panels containing the terminal equipment associated with the other communication channels, are arranged in a double row in each terminal office. One of these rows is shown in Fig. 15. Four of the panels, two at each end, are repeater units, three of these being associated with the three cables. Owing

to the importance of these circuits a spare unit has been provided to insure against interruption of service.

Signaling Systems

The signals for the telephone channels are transmitted over the cables by a "voice-frequency" signaling system, which involves the generation, transmission and reception of an alternating current, the frequency of which changes abruptly from 950 cycles to 1300 cycles and back, this alternation of frequencies taking place

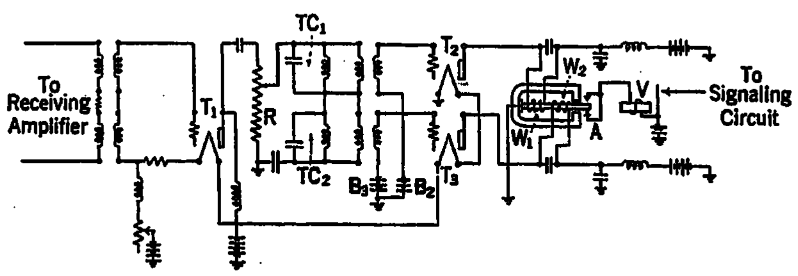

Fig. 16—Receiving Circuit for Voice Frequency Signaling

at the rate of 16 cycles per second. Signals are transmitted over the land lines north from Key West and over the toll lines terminating at Havana by means of the usual 135- and 16-cycle currents.

By means of a ringing key in the toll cord circuit, the operator at one end of the cable causes the voice-frequency current described above to be sent out by the signaling oscillator, a vacuum-tube oscillator of the usual type arranged so that the capacity in the oscillating circuit is changed 32 times a second. This sends out alternately currents of the two different frequencies through the sending amplifier B (Fig. 14) to the cable. At the other end of the cable these currents flow into the receiving side of the repeater and through the amplifier A. If the telephone circuit is terminated at this point, part of the amplified signaling current passes into the receiving circuit for voice-frequency signals as can be seen from Fig. 14.

The details of the voice-frequency signal receiving circuit are shown in Fig. 16. The input impedance of this circuit is high so as to produce no appreciable loss in the telephone transmission circuit across which it is connected. The incoming signaling currents are amplified by the tube T_1, from which they pass into the high resistance R. Connected in series across this resistance are two tuned circuits TC_1 and TC_2, of which one is tuned to 950 cycles and the other to 1300 cycles. Each tuned circuit is connected through a transformer to the input side of a vacuum-tube rectifier. The grids of the tubes T_2 and T_3 are made just sufficiently negative by means of the batteries B_2 and B_3 so that there is normally no current flowing in the plate circuits of the tubes. The tubes thus function as detectors of incoming currents. When 950-cycle current is impressed on the circuit TC_1 a voltage is applied to the grid of tube T_2 causing current to flow through the relay winding W_1. The next instant rectified 1300-cycle current passes through winding W_2. The armature A of the polarized relay then vibrates back and forth at the rate of 32 times a second, thereby interrupting the current through the relay V. The armature of this relay therefore falls back, lighting the signal lamp L (Fig. 14) at the switchboard.

In the through-line circuits at Key West, such as the Havana-New York circuit, as shown in Fig. 13, the voice-frequency signaling current coming from the cable causes 135-cycle signaling current to be sent out automatically on the north-bound land line by a special type of "composite ringer" indicated in the upper right-hand part of this figure. The voice frequencies are received by a circuit similar to that just described and operate a relay which connects a generator of 135-cycle current to the land toll line, thus sending out this type of signaling current to call the distant operator. In through-line calls from the north 135-cycle current is sent over the land toll line to Key West. Here it enters the composite ringer and operates the voice-frequency sending set which puts on the cable the voice-frequency currents described above. These currents are received at the Havana toll office in the circuits shown in Figs. 14 and 16 and cause the operation of the signal lamp L at the toll board.

The receiving circuit for voice-frequency signals which is used in the case of terminating connections is included in the repeater unit. The composite ringers, which in the case of through-line circuits effect the

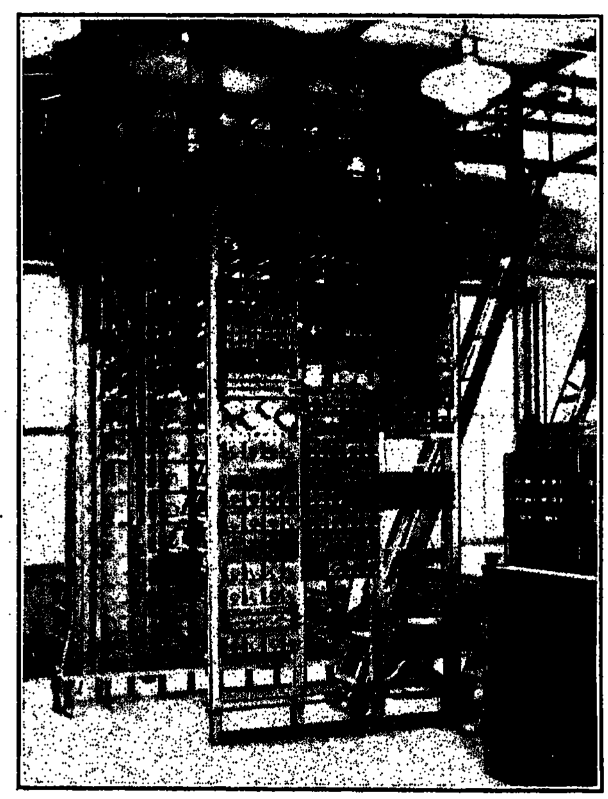

Fig. 17—Relay Rack Containing Signaling Oscillators and Power Control Circuits

change from voice-frequency signaling on the cables to 135-cycle signaling on the land lines, are mounted on the upper right-hand side of the relay rack shown in Fig. 17. Below the composite ringers are two oscillator sets for furnishing the 950- and 1300-cycle currents

for telephone signaling over the cable, one of these being a spare unit.

Carrier Telegraph

A carrier telegraph terminal unit is permanently associated with each cable at both the Key West and Havana Offices. The circuits in the units used at

Fig. 18—Carrier Telegraph and D-C. Telegraph Panels

the two terminals are the same, with the exception of the filters in the receiving branches. The carrier panels and their location with respect to the other apparatus are shown in Fig. 18. The four units containing vacuum tubes at the left of the row are the carrier telegraph units, one being a spare unit.

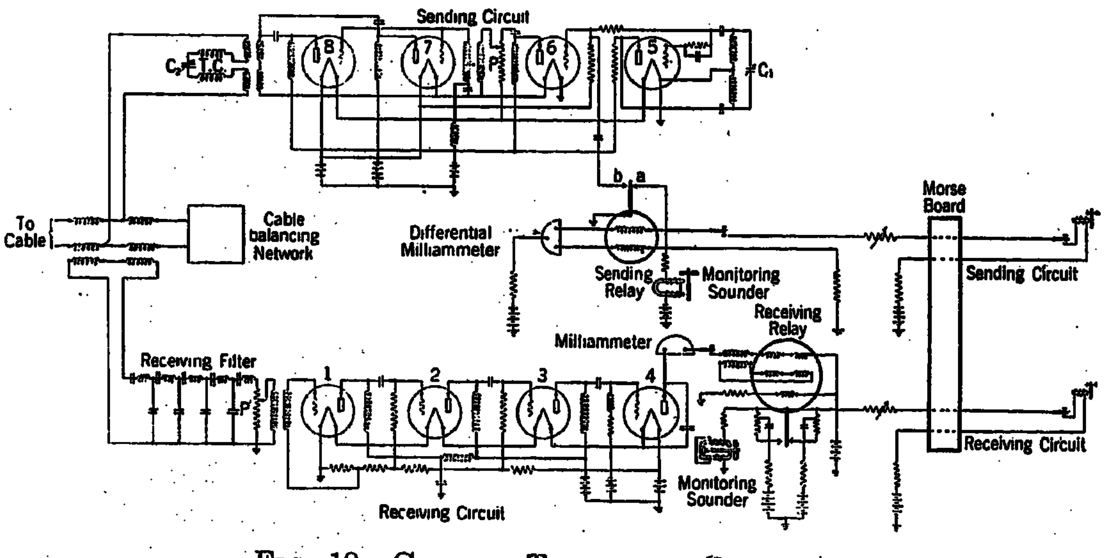

Fig. 19—Carrier Telegraph Circuit

The operation of the carrier telegraph channel may be stated briefly as follows: Direct-current telegraph signals received from a subscriber's loop or other land line, actuate the sending relay in the carrier set, causing the oscillator to send through the cable high-frequency alternating current, interrupted in conformity with the signals. This alternating current enters the carrier receiving circuit at the other cable terminal, is rectified and actuates the receiving relay which sends direct-current telegraph signals into the associated land circuit.

The arrangement of the complete carrier terminal circuit is shown in Fig. 19. The details of carrier telegraph circuits have been described in an earlier paper[15] and only the outstanding features will be mentioned here. The armature of the sending relay[16] is normally held against the contact a. Under this condition the oscillator transmits a steady high-frequency current through the amplifier and tuned circuit to the cable. When a "spacing" signal is transmitted over the subscribers' sending loop, the armature of the sending relay moves to contact b which shunts the sending amplifier, interrupting the flow of high-frequency alternating current to the cable. A "marking" signal causes this armature to move to contact a, thus sending the high-frequency current out upon the cable. The sending relay, therefore, causes the signals transmitted over the land line by direct current to be converted into pulses of alternating current which are sent into the cable.

The outgoing high-frequency current passes through a two-stage amplifier, the last stage of which consists normally of one vacuum tube, either No. 7 or No. 8 in Fig. 19. By means of a switch at the carrier panel, the second tube may be connected in parallel with the first to increase the current. The output of the transmitter is controlled by the interstage potentiometer P. The current from the amplifier passes through a single tuned circuit $T\,C$ in Fig. 19, which can be accurately tuned to the frequency of the outgoing current by means of the adjustable condenser C_2. The frequency of this current is controlled by the adjustable condenser C_1 in the oscillator circuit.

At the other terminal of the cable the high-frequency alternating current passes through the bridge transformer and receiving filter. Since the attenuation of the cable for the carrier currents is high, the received current is passed through a multi-stage amplifier before it reaches the detector which rectifies it and causes it to operate a sensitive receiving relay. As shown in Fig. 19, the receiving relay retransmits the signals by means of direct current over the subscriber's receiving loop. The receiving circuit differs from that used in land carrier telegraph systems in the following features: Instead of the usual double tuned circuit for selecting the proper frequency, a narrow-band, highly selective fixed filter is placed before the amplifier. The gain attainable in the receiving amplifier is much higher than is provided in land-line systems. When

15. Colpitts and Blackwell, loc. cit.

16. For clearness and simplicity in showing the relation of the relays to the telegraph circuits the conventional representation of relays shown in Fig. 19 has been used in this paper. It is to be understood that the windings shown within the circle, act to magnetize the armature which moves back and forth between the poles of a permanent magnet, its position at any time depending upon the polarity of the resultant magnetism in it.

less than the full gain is required tube No. 1 can be cut out by means of a key.

The sending and receiving carrier telegraph circuits work directly into subscribers' loops at Havana. In through-line traffic, which is the only type of telegraph traffic now required at Key West, the carrier circuits are arranged to operate standard land-line duplex telegraph sets. The d-c. telegraph circuits from the carrier apparatus pass through jacks in the morse boards for convenience in connecting them to any desired land lines or subscribers' loops.

The arrangement of Fig. 19 is that used for full-duplex operation, that is, when it is desired to transmit messages simultaneously in both directions over the cable. By means of a switch on the carrier panel the circuit may be adapted to half-duplex operation. In this case, messages can be transmitted over the cable in both directions but not simultaneously.

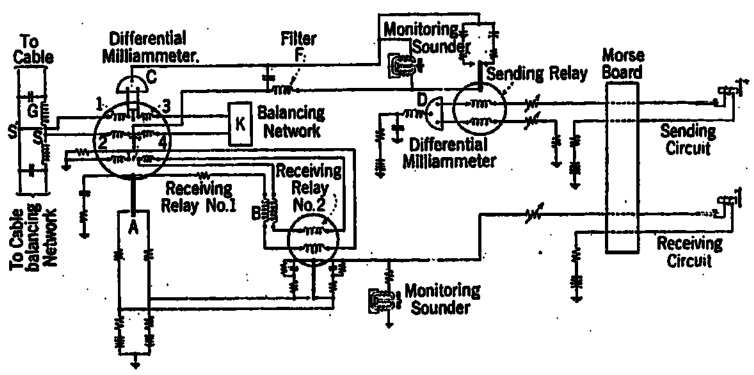

Fig. 20—Direct-Current Telegraph Circuit

Direct-Current Telegraph

A direct-current telegraph unit is permanently connected at each end of each cable as a repeater of telegraph signals between the submarine cable and a land circuit. The four units at the right of Fig. 18 are the direct-current telegraph panels, one being a spare unit. A schematic diagram of the direct-current telegraph circuit arranged for repeating between the submarine cable and subscriber's loops, is shown in Fig. 20. This figure shows the arrangment for full-duplex operation over the cable.

In this telegraph circuit the separation of the sending and receiving branches is accomplished by the main-line receiving relay, which in its relation to these branches functions like a bridge transformer. Outgoing signals to the cable divide at the points T, half the current passing through coils 1 and 2, and the other half passing through coils 3 and 4. These coils are wound so that with a good balance between the balancing network and the circuits on the opposite side of the relay, the armature A is not actuated by the sending currents. It is evident, however, from Fig. 20 that incoming signals from the cable will produce an additive effect in passing through the relay coils and operate this relay.

The network K balances, for the frequencies involved in direct-current telegraph operation, the impedance between the points S and S'. Reference to Figs. 10 and 20 shows that this includes the two halves of the filter G in parallel, the cable and the cable balancing network as well as the impedance at these frequencies of the telephone and carrier apparatus. The network contains a fixed portion to balance the filter G and an adjustable portion to balance the cable and the associated equipment just mentioned. The balance can be tested by observing the differential milliammeter C (Fig. 20) as signals are transmitted from the sending branch.

Signals coming from the subscriber's sending loop operate the sending relay which acts as a pole-changer to reverse the polarity of the 10-volt battery applied to the cable, in conformity with these signals. The low-pass filters F and G transmit freely all frequencies below about 80 cycles but practically prevent the passage of higher frequencies. They thus allow free passage of those components of the sending currents which are necessary for the operation of this system, but suppress those which might cause interference in the telephone and carrier channels.

A feature of the receiving branch is the tandem connection of receiving relays. Incoming signals from the cable actuate the sensitive receiving relay No. 1 and, as shown, in Fig. 20, the operation of this relay in turn actuates the receiving relay No. 2. The armature of receiving relay No. 2 acts as a pole-changer to transmit signals to the receiving loop. The larger energy available for the operation of this relay enables it to commutate successfully the comparatively heavy currents which are transmitted into the land line. The networks connected between the armature and the contacts of receiving relay No. 2 operate to suppress sparks at break. The purpose of the transformer B is to quicken the action of the receiving relays.

The circuit as shown in Fig. 20 and described above is adapted to working into two loops for a local telegraph subscriber. Apparatus equivalent to a standard duplex set is provided in the telegraph panel so that by throwing a switch, the set may be adapted to duplex operation over a land line. This is the condition at Key West where all the telegraph circuits are continued northward. Switches are also provided in the panel for adapting the circuit to half duplex operation instead of full-duplex operation.

The sending loops, the receiving loops and the 120-volt batteries of the land sides of the direct-current telegraph units are connected through jacks in the standard Morse Boards so that they may be available for cross-connecting or testing.

Auxiliary Equipment

A jack panel and two testing panels in each terminal office provide means for testing the circuits and terminal apparatus and for changing their connections. The jack panel contains a system of jacks to which all circuits are connected and on which are terminated all important pieces of equipment such as amplifiers, filters, networks and bridge transformers. The testing panels contain an oscillator for supplying testing currents

of telephone and carrier frequencies, transmission measuring apparatus for testing the telephone repeaters and circuits, apparatus for testing the balance of the networks and lines, thermocouples and meters for measuring the carrier currents, a frequency meter for testing their frequencies and apparatus for testing the efficiency of the carrier terminal sets. In Fig. 15 the jack unit is at the middle of the row of panels, with a testing unit on each side.

A 24-volt storage battery furnishes current for the filament circuits of all the vacuum tubes in the telephone repeaters, carrier telegraph panels, ringer circuits and testing apparatus. Positive and negative 120-volt batteries are provided for the standard duplex sets and for the local circuits of the carrier and direct-current telegraph sets. The positive 120-volt battery also furnishes plate current for all vacuum tubes. Grid potentials for the vacuum tubes are derived from a small capacity 60-volt storage battery. A number of 10-volt batteries are provided for the direct-current telegraph circuits over the cables. All batteries are charged from the local power mains through mercury arc rectifiers, with gas-engine-driven generators for charging in case the electric power supply fails. Battery circuits for supplying the terminal equipment pass through control apparatus mounted on the relay rack shown in Fig. 17. On the two sections at the left are rheostats for adjusting the filament currents of the vacuum tubes, with associated relays and resistances in these circuits, and also meters for measuring the filament and space currents and the voltages used. Another rack, not shown, carries the fuses and other protective equipment associated with the power supply.

Operation

The relation between the total transmission equivalent of the telephone channel over the cables, the available gains in the terminal amplifiers and the balance obtained between the cables and the balancing equipment was such that this channel could be operated at an efficiency materially higher than that required for connections terminating in Havana and Key West and also over a large range of current levels. As the cables were to be used in general as links in long circuits, the operating adjustments which were finally adopted were set rather by the circuits as a whole than by the cables. One of the cables was connected at Key West to a land line to form a direct New York-Havana circuit, a second cable to form a direct Jacksonville-Havana circuit and the third was arranged for a Key West-Havana circuit.

The New York-Havana circuit was set to have a transmission equivalent of 12 miles of standard cable. As the New York-Key West section has an equivalent of 10 miles, the net equivalent of the cable and terminal apparatus is only two miles. The Jacksonville-Havana circuit was set at 11 miles and the Key West-Havana at 10 miles. Switching through New York, operating equivalents are obtained for Havana-Chicago connections of approximately 16 miles and for Havana-San Francisco[17] of 20 miles. In addition to the submarine cables, the Havana-Chicago circuit contains 2453 miles (3940 km.) of land line and the Havana-San Francisco 4790 miles (7700 km.)

With these equivalents, satisfactory commercial connections can be established not only from Havana to points on the eastern part of the United States, but also to the Pacific coast. The application of repeaters to the Cuban toll lines makes it possible to establish commercial connections from points along the island to points in the United States. While the majority of the telephone connections over the cables have been for calls between New York and Havana, commercial calls have been handled satisfactorily to points all over the United States, such as Boston, Washington, Chicago, St. Louis, San Francisco, New Orleans and Atlanta, also to Toronto and Montreal in Canada, and to points in Cuba such as Matanzas, Sagua, and Santiago. The traffic between New York and Havana has been so large at times as to require two of the cables to be used in direct New York-Havana circuits.

The d-c. telegraph channels operate so well that their connection to land-line telegraph circuits from Key West to New York does not appreciably affect the maximum speed of the circuit. The carrier-current telegraph channels are good enough for the operation of four channel multiplex printers if it should be desired to use them for such service.

In planning this cable system it was intended that a demand for more telegraph facilities would be met by increasing the number of carrier channels per cable. As has been noted, the initial apparatus and land connections provided for the commercial operation of only six telegraph channels, one d-c. and one carrier channel per cable, on the basis that this number would meet the initial service requirements. In order, however, to obtain information regarding the operation of additional carrier channels and to provide spare telegraph facilities in case of cable failures, a fifth carrier telegraph set was provided at each terminal, together with special receiving selective circuits. With this apparatus three carrier telegraph channels were successfully operated over one cable, using frequencies up to 4200 cycles, for which the equivalent of the circuit between the terminal offices is 48 miles. It is possible that this number of channels can be further increased. The present arrangement of the carrier telegraph apparatus makes it possible, therefore, to carry six telegraph channels over two cables or four over one cable. This will prove very useful in maintaining service in case of cable failures.

---

17. The transcontinental line has been improved since the publication of the paper "Telephone Repeaters," Gehrardi and Jewett, TRANS., A. I. E. E., 1919. The transmission equivalent of the New York-San Francisco circuit is now approximately twelve miles.

At the time of the opening of service over these cables under the auspices of the Pan American Union, greetings were exchanged between the President and other officials of the United States at Washington and the President and officials of the Cuban government at Havana. In connection with this demonstration, the circuit was extended through New York and San Francisco to the Island of Santa Catalina, off the coast of California, in the Pacific Ocean. As this island is connected to the mainland by radio telephone[18], this connection, 5470 miles (8800 km.) in length, involves the radio connection through the air, a 5322-mile land line across the United States and the submarine cable from Key West to Havana. This circuit containing twenty-five telephone repeaters illustrates the possibilities of the present state of development of telephony.

The work described in this paper involved the application of ideas from practically all branches of the telephone and telegraph fields and from a number of organizations. The Western Electric Company was retained by the Cuban-American Telephone and Telegraph Company as engineers and purchasing agents for the cables and to manufacture and install the terminal apparatus. The Cuban Telephone Company retained as consulting engineer Sir William Slingo, who also assisted the Western Electric Company in the inspection of the cable during the manufacture and laying. The electrical design of the cables, the method of operation, the design and arrangement of the terminal apparatus and the adjustment of the system for operation were the work of the engineers of the American Telephone and Telegraph Company and the Western Electric Company. The Telegraph Construction and Maintenance Company, Limited, of London, which manufactured and laid the cables, was largely responsible for the mechanical features of the cables, such as the design of the armoring for the different depths of water involved and the arrangement of the copper tapes. The recommendations of the engineering firm Clark, Forde and Taylor, retained by the Western Electric Company, were obtained on many of these matters including the routes to be followed.

Discussion

Bancroft Gherardi: The two questions that required much care and thought in the design of this cable were, first—shall the cable be continuously-loaded or coil-loaded, and, second, shall it be a single or a multi-conductor construction? There were serious questions involved in each. In the first place, as to the loading. Coil-loading is in many respects more efficient than continuous-loading, because with coil loading, you can get practically any inductance per mile that you desire, and so you can, within very considerable limits, increase the efficiency of the circuit. With continuous-loading, however, there are very sharp limitations on the possible inductance per mile that can be attained with any practical contruction. As we saw the problem at that time, and as we still see it, the coil-loading would have been chosen, for electrical reasons, but it presented most formidable mechanical difficulties. In the first place, the making of a cable of that kind, interrupted periodically by coil cases and coils, and laying it in deep water was a very formidable matter. In the next place, the maintenance of the cable would necessarily be complicated by having points of discontinuity. The attachment of the cables to the coil cases and the coil cases themselves would necessarily be elements of weakness. This weakness is not serious in a land cable, as trouble, if it occurs in a land cable, can be cleared in a few hours. On the other hand, if trouble develops in a cable of the kind in question, it may be weeks and under bad weather conditions and unfavorable location of cable ships, it might be months before the trouble could be cleared. The coils were, therefore, excluded for mechanical reasons.

The other question was the one of the single-conductor versus the multi-conductor cable, and this brought up a related question that of one cable versus several cables.

These questions, as you see, are tied right up with each other. The single-conductor cable necessarily meant grounded-circuit operation. In the case of the metallic circuit cable, the obvious method of operation would be to build probably a cable of four wires and undertake to operate two physical metallic circuits, and possibly a phantom circuit, with a more remote possibility of getting a fourth circuit, that is, a grounded phantom circuit from the combination.

The choice finally was determined by the consideration that we could not afford to put all of our eggs in one basket, as we might lose the whole cable at one time. Therefore the alternative of three separate cables was chosen, although it required a great deal of study and investigation as to the general question of the grounded circuit operation of cables of that character, and their operation under the particular conditions existing between Key West and Havana. Our investigation satisfied us that we could safely count on that method of operation.

These investigations were very extensive and very carefully made. We satisfied ourselves that the cable itself, and the service from it with any degree of amplification we would wish to place on it, would be satisfactory.

William McClellan: What effect is long distance wireless communication going to have on long distance telephone? At present there is a certain lack of secrecy which our customary long distance lines give in part at least.

Bancroft Gherardi: I will be glad to say a word in answer to the question which has been asked. The matter of utilizing wireless in that connection was very carefully considered at the time the cables were being considered and it has been reconsidered recently in this form—if we were to do the job again, would we do it by means of wire or wireless? In each case the answer has been the same. Most of the communication has been on business, matters—particularly last spring, and to a certain extent this fall, there were a number of very serious financial failures avoided by the use of the cables. These were matters which required prompt communication with a considerable number of different institutions, and if action was not taken in twenty-four hours there would be a financial failure, and there was a situation in Cuba in which a few failures might start things going and create a very much more serious state of affairs than the one which actually existed.

Obviously, wireless communication, certainly in the present state of the art, would have been entirely unsuited for such service.

The mere mention of such topics in the air, the broadcasting of such questions as were discussed in these communications would create the effect which it was desired to avoid. But excluding altogether the matter of secrecy, and excluding altogether the matter of interference, atmospheric or otherwise, we have thus far been unable to figure out how we could give an equally extensive and dependable service and give it as cheaply by means of radio across that distance, as we can by means of the cables.

Submarine Cable Telegraphy

BY J. WILLARD MILNOR
Associate, A. I. E. E.
Research Engineer, The Western Union Telegraph Company

The history of the development of the subject is first outlined, and methods of operation of cables are described. The technical side is introduced with a statement of the various conditions whi h limit operation of cables, and a general method of analysis is developed, based upon an extension of ordinary alternating-current theory. The theory is made use of to analyze the action of cable types and of apparatus which at this time can be regarded as standard. The fundamental theory of the method of analysis, with information on the calculation of transients in electrical circuits, is given in the Appendix.

HISTORICAL

THE feasibility of submarine cable telegraphy was suggested by Salva, a Spaniard, as early as 1795. The first actual experiment seems to have been made in 1803. In the period covered by the next forty years, numerous experiments were carried on in different parts of the world for the purpose of demonstrating the possibility of submarine telegraphy. In 1842, Morse transmitted signals over a short section of insulated wire laid in the New York Harbor. The conductor used in this experiment was insulated by covering it with hemp soaked in tar and pitch, and surrounding this with india-rubber. The introduction of gutta-percha as an insulator and the invention of a machine for applying it to wire, gave a decided impetus to the experiments being carried on.

The first commercial attempt to establish electrical communication by submarine cable was in 1850, when a cable was laid between England and France. This cable was broken, however, shortly after communication was established. The cable used in this attempt consisted of a No. 14 copper wire surrounded by gutta-percha to a thickness of one-half inch. The failure of this cable due to its physical weakness led to the design and laying of an improved type between Dover and Calais in 1851. This cable consisted of four No. 16 copper wires, each covered with two layers of gutta-percha to the size of No. 1 gage. These insulated wires were armored with ten No. 1 galvanized iron wires wound spirally. This cable proved to be successful, and in the next few years a number of cables was laid between England and adjacent shores, between Denmark and Sweden, and in the Mediterranean Sea.

The first attempt to lay a cable across the Atlantic was in 1857. This attempt ended in failure when the cable broke in 2000 fathoms of water, at a point about 350 miles west of Valentia, Ireland. As at that time there were no means of recovering a cable in deep water this project was abandoned. In August 1858 the same company, The Atlantic Telegraph Company, completed the laying of a cable. This cable was operated for about three months, when it became interrupted, and no attempt was made to repair it. In the years 1865 and 1866 The Atlantic Telegraph Company laid two new cables. The first cable broke when it was about two-thirds laid. The second cable was then successfully laid, and soon afterward the end of the first cable was picked up with much difficulty and its laying was completed. These cables were operated with no competition until 1869 when the French Atlantic Telegraph Company opened a cable for traffic. With the success of the Atlantic cables established, the growth of submarine cable systems was rapid, until in 1914 there were seventeen cables across the Atlantic between North America and Europe alone, and there was then an aggregate of about 2000 cables in the world, comprising a total length of over 300,000 miles.

The use of gutta-percha as an insulator was adopted at the very inception of submarine cables, and it is still almost universally used for long cables.

The necessity for a protective armor for submarine cables was demonstrated by the failure of the first cable laid in the English Channel. Since that time cables have been provided with a protective armor consisting of a number of iron or steel wires wound spirally around the core. The design of the armor was, of course, changed from time to time as experience demonstrated the desirability of improvement.

Even before the first Atlantic cable was laid it was realized that a very sensitive instrument would be necessary for the successful reception of signals on long cables. Early in 1858 Prof. William Thomson, later Lord Kelvin, perfected an invention that was destined to fill this need. This instrument known as the mirror galvanometer, consisted of a small permanent magnet, with a small mirror fixed to it, suspended by silk fibers and surrounded by a coil of fine wire. By reflecting a light from the small mirror to a screen, a greatly magnified image of the coil movement was obtained. When the 1858 cable was completed, tests showed that signals transmitted with a battery of Daniell cells could be successfully received with the mirror galvanometer. However, when the cable was turned over to the electrician for working, he, believing that a high voltage was best suited for signaling, used a large induction coil, excited by a battery, which yielded a potential estimated at about 2000 volts. Under the strain of this voltage, the insulation began to break down and the signals gradually failed. The mirror galvanometer and Daniell cell battery were then substituted and the cable was successfully worked for a

Presented at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

short time until the cable finally failed completely. It was the opinion at that time that the high voltage used at first had partly broken down the insulation of the cable, and that the faults thus opened gradually became worse until the insulation failed completely.

The mirror galvanometer, with improvements from time to time, was used universally on long cables for a number of years. In 1867 the siphon recorder was invented. This instrument, which had the advantage of supplying a permanent record of the signals as received, gradually replaced the mirror galvanometer, and in its improved forms it is now largely used in the operation of long cables. Previous to 1871 cables were operated in one direction only, but in that year the duplex system was introduced, which permits the use of the cable for simultaneous transmission in both directions. Other more recent developments of operating apparatus include cable relays, automatic transmission, and cable magnifiers, the latter being introduced about 1908. These developments will be described later.

The maximum operating speed of the 1858 cable before it failed was about 15 letters per minute. When the cable was first opened it required about thirty hours to transmit a message of 150 words from President Buchanan to Queen Victoria. It is interesting to note that at that time the minimum rate on a message from New York to London was £20 for a twenty-word message and £1 for each additional word. From that time until the present, improvements in the cable systems have been such that it is now possible to duplex a good Atlantic cable with an operating speed of 300 letters per minute each way; and the operating economies effected have been such that the maximum cable rate between New York and London is now twenty-five cents per word.

Construction and Laying of Cables

The make-up of a typical deep-sea submarine cable is shown in Fig. 1. The conductor is made up of stranded copper wires, or of copper strips. The actual size of the conductor and of the insulation is determined by the operating characteristics desired.

As previously stated, the insulation generally used in submarine cables is gutta-percha. Gutta-percha is derived from the milky sap of gutta trees. The sap of several different species of trees is suitable for converting into gutta-percha, the quality of the gum from some species being better than that from other species. These trees are found principally in the Malay Islands and Peninsula and in Borneo. The sap is collected from incisions in the bark of the living tree, or by stripping the bark. The gutta is roughly cleansed after its collection, and is coagulated into solid cakes in which form it is imported. In the manufacture of the finished product, the gutta must be further purified and treated before it is suitable for use as insulation.

Another form of insulation, known as "balata" or "gutta-balata," is derived from the sap of a species of trees found in some parts of South America. This has been used in combination with gutta-percha in short telephone cables, and possesses distinct advantages for that purpose. The possibility of using balata for long submarine telegraph cables has been suggested.

Rubber has also been used for insulation of submarine cables, notably for the cable connecting the United States and Alaska. This material is somewhat inferior to gutta-percha for the purpose.

It is necessary to protect the gutta-percha from damage by the iron sheathing by placing some sort of a cushion between them. In modern cables this cushion is generally made up of several layers of jute. Jute consists of the bark fibers of two plants called the "chouch" and "isbund," extensively cultivated in Bengal. The jute is usually tarred or tanned before being used on a cable.

In order to protect the core of the cable from damage after being laid, it is necessary to provide a layer of sheathing or armor wires. These wires also serve to support the cable while being laid, and in case it is later necessary to lift the cable for repairs. The design

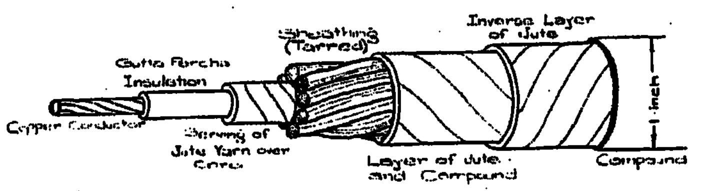

Fig. 1—Typical Section of Cable

depends upon the type of cable—whether deep-sea, intermediate, or shore-end—and in general consists of a number of galvanized iron or steel wires wound spirally. The shore-end types of cables may have two layers of sheathing wires. As a preservative, the sheathing is covered with a layer of jute.

The route for the cable is so far as practicable chosen to avoid deep water, sudden changes in depth, and rocky bottoms. The greatest depth of transatlantic cables is 2.9 statute miles; across the Pacific the cable depth reaches 3.4 miles.

The manufacture of submarine cables has been largely a British industry due to their early interest in and need of a communication system between the various parts of the Empire. The Alaskan Cable is the only long submarine cable that has been manufactured in the United States.

Modern Operation and Apparatus

The following description of apparatus used in regular operation of cables does not aim at being complete. Many devices are developed from time to time for application to cables; some of these are of permanent value and others are of only passing interest. It is the purpose to describe here only some of the important appliances which may be regarded as standard.

Duplex Operation. Generally speaking, a greater output can be obtained by duplex operation of a cable

than by operating in one direction only. Accordingly, cables are ordinarily worked duplex except in cases where it is impossible to maintain a satisfactory duplex balance.

In order to duplex a cable, it is necessary to provide some arrangement by which the receiving instrument is not responsive to outgoing signals, while at the same time it must respond to signals coming from the distant end. There are two common methods of duplexing a communication circuit, both of which involve the use

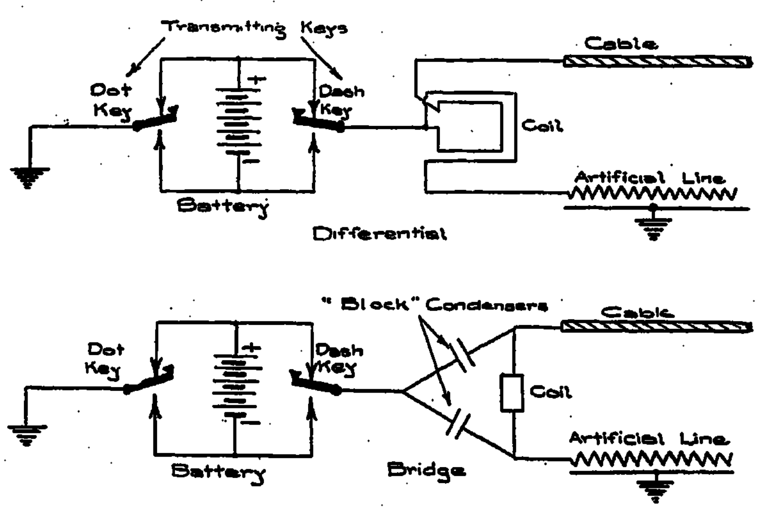

FIG. 2—DUPLEX TERMINAL SETS

of an artificial line. These two methods are illustrated in Fig. 2.

In the differential system of duplexing, the coil of the receiving instrument has two separate windings. These are so joined to the cable circuit that in transmitting, the currents in the two windings are equal in magnitude and opposite in direction, thus causing no effect in the local receiving instrument; while currents from the distant station pass through the two coils in the same direction, and cause the receiving instrument to respond.

The bridge method of duplexing employs the principle of the Wheatstone bridge, and is almost universally used for cable working. There is some latitude in the arrangement of the bridge; thus the two condensers

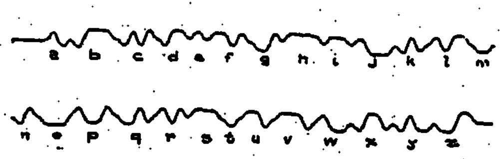

FIG. 3—LETTERS OF THE ALPHABET RECEIVED ON SIPHON RECORDER

may be replaced by resistances or by inductances—the latter arrangement being used by some cable companies. Another plan is to use condensers shunted by high resistances. The use of condensers appears to have advantages for high-speed working of cables, in that it results in better shaped signals.

The Standard Cable Code. The continental Morse code is mostly used for operation of submarine cables. The method of distinguishing dots and dashes is ordinarily different, however, from that in land-line or wireless telegraphy. In land-line or wireless operation the difference between dots and dashes is one of duration, the dash being about three times as long as the dot. In submarine telegraphy the dots and dashes are of the same duration but of different polarity. Dots are formed by applying positive potential to the cable; dashes by applying negative potential. The spacing intervals are obtained by earthing the cable, the zero interval between letters being one unit, and between words usually three units. Fig. 3 shows the alphabet as received on a siphon recorder tape.

Transmitting Apparatus: The Cable Key. For signaling on the cable it is necessary to apply positive, negative or zero potential to the sending end of the cable in various combinations as explained above. In manual signaling a special double-lever key known as the cable key is used. This is shown in theory in Fig. 2. In the normal position of the cable key, both levers are up, thus grounding the cable. When the dot lever is depressed, positive potential is applied to the cable, and when the dash lever is depressed negative potential is applied to the cable.

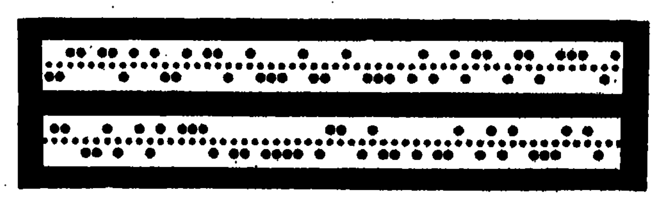

FIG. 4—TRANSMITTING TAPE WITH LETTERS OF THE ALPHABET

Manual transmission is employed chiefly in conversations between stations relative to the operation of the circuit.

The Automatic Transmitter. In handling commercial messages a motor-driven automatic transmitter is commonly used in place of manual transmission.

A paper tape is first prepared with perforations corresponding to the message to be transmitted. A sample of this tape with perforations corresponding to the letters of the alphabet is shown in Fig. 4. The tape is passed through the automatic transmitter at the desired speed. The keys shown in Fig. 2 are controlled magnetically from contacts in the transmitter, these contacts in turn being operated in correspondence with the perforations in the tape.

A device known as a perforator is used in preparing the paper tape. The modern perforator has a keyboard similar to an ordinary typewriter and is operated similarly. An electrical solenoid furnishes the power for punching the holes, and the tape is automatically stepped forward.

Receiving Apparatus: The Siphon Recorder. This instrument is generally used in the recording of received cable signals. It is in principle a D'Arsonval galvanometer, with a moving coil suspended between the poles of a strong magnet (Fig. 5). The coil is in the form of a rectangle, a common size being 6 cm. long and 1.8 cm. wide. The coil may be wound to have 500 to

800 ohms resistance. The coil controls the movement of a fine glass siphon pen supplied with ink. The movements of the pen are recorded on a paper tape drawn at uniform speed beneath the siphon. The coil and siphon are separately mounted, and are connected by

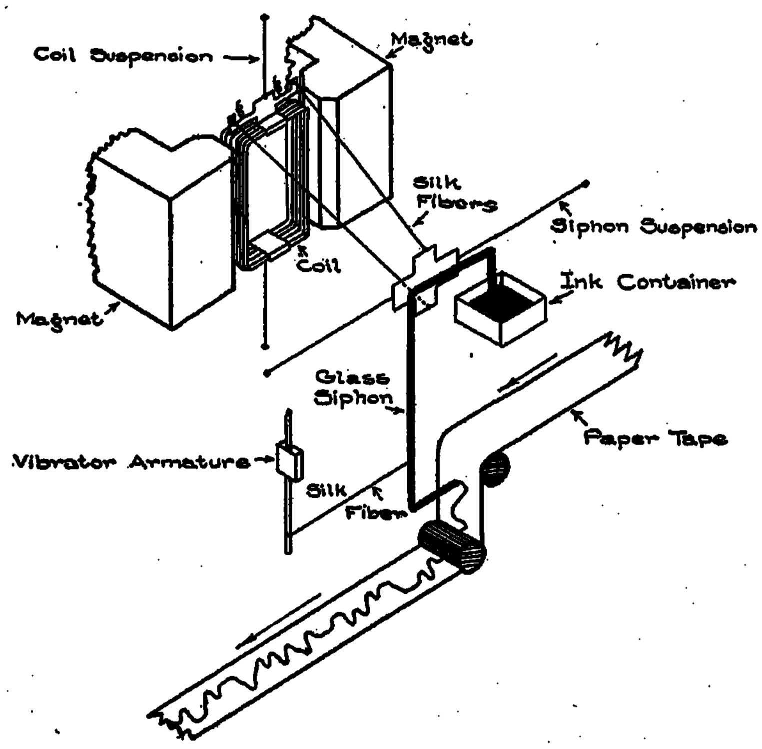

Fig. 5—Moving Elements of Siphon Recorder

silk fibers arranged to magnify the motion of the coil. To reduce friction between the siphon and the tape, the siphon is vibrated vertically with respect to the tape. This is accomplished by an electric buzzer arrangement, the armature of which is connected to the siphon by a silk fiber.

The coil and the siphon are suspended by fine wires the tension of which may be varied, thus permitting the natural period of the moving system to be adjusted according to the speed of the incoming signals. For the recording of well-shaped, undistorted signals, it is necessary that the coil return to its zero position quickly when the current flow ceases, and it is also necessary that the coil shall not swing beyond its zero position. It is sometimes necessary to provide damping for the moving system, which may be accomplished electromagnetically by having the coil shunted with a high resistance, or may be secured by having a small aluminum vane attached to the coil and moving in oil.

A siphon recorder gives a readable signal when actuated by from 30 to 100 microamperes, (0.000030 to 0.000100 ampere).

Magnifiers. In order to increase the speed of a cable above a point where satisfactory operation can be obtained with a siphon recorder alone, it is necessary to magnify the weakened signals before passing them through the recorder. With the magnifiers described below, good signals may be obtained when the current in the magnifier coil is as small as from two to fifteen microamperes.

The Heurtley Magnifier. One type of magnifier extensively used was patented by E. S. Heurtley. This magnifier (Fig. 6) is similar in principle to a siphon recorder, with the coil controlling the movement of two fine platinum wires. Associated with the two moving wires are two similar fixed platinum wires, the relative positions of which are indicated in the figure. The platinum wires are heated by battery current. When the relative positions of the wires are changed by movement of the coil from its mid-position, the mutual heating effect between the fixed and moving wires is altered. Thus the temperature and hence the resistance of the wires in one arm of the bridge are increased, the values being decreased in another arm. The resulting bridge unbalance causes a current to flow in the siphon recorder.

The Selenium Magnifier. The selenium magnifier, also used in operation of long cables, was developed by T. B. Dixon, K. C. Cox and others. It is also of the moving-coil type, the coil carrying a small mirror. This mirror reflects a strong beam of light on to a bank of two or four selenium cells, which form either two or four arms of a Wheatstone bridge. Battery is connected across one diagonal of the bridge and the ordinary siphon recorder is placed in the other diagonal. The electrical resistance of selenium cells varies inversely with the strength of light to which they are subjected. When a movement of the magnifier coil causes a movement of the light beam on the selenium cells, the bridge is unbalanced and current flows in the siphon recorder.

The Vacuum-Tube Magnifier. Some experimental work has been done on the application of vacuum-tube magnifiers to cable operation and fair results have been obtained. There has not been a large incentive to

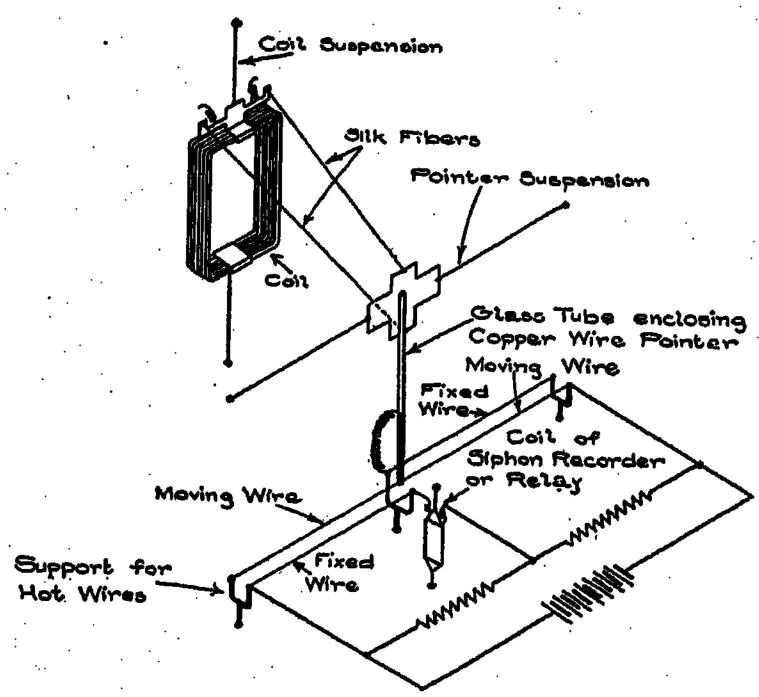

Fig. 6—Heurtley Magnifier

developing the vacuum-tube magnifier, because of the condition that other fairly satisfactory magnifiers were already available.

Cable Relays. In some cases it is desirable to repeat signals automatically from one section of cable into

another rather than to record them. It is essential that a cable relay used for this purpose shall have a reliable form of electrical contact. All of the standard types of cable relays employ the principle of the D'Arsonval moving-coil galvanometer, and differ only in the method of making contact. A relay may be used with or without a magnifier in circuit, the relay alone being approximately as sensitive as a siphon recorder.

The Brown drum relay has an iridium-pointed platinum wire, the movement of which is controlled by the relay coil, making contact on the insulated silver rings of a rotating drum. With very little pressure the iridium point makes good contact on the moving silver, and the friction resisting the lateral movement of the contact point is small.

In the Muirhead gold wire relay, the coil controls the movement of a gold wire between two platinum contacts. The gold wire is maintained in rapid vibration by an electric buzzer arrangement, for the purpose of securing better contact.

The Bruce relay contact scheme consists of a fine nickel wire controlled by the moving coil, which makes contact in drops of mercury. The nickel wire is rapidly vibrated vertically with respect to the contact surfaces, thus reducing frictional resistance to its lateral motion.

Shaping of Signals. In addition to apparatus previously mentioned; various auxiliary devices are used in order to shape properly the received signals. Such devices comprise coils known as "magnetic shunts" connected in parallel with receiving equipment, condensers in series with receiving equipment, and various special pieces of apparatus. The use of condensers in the bridge arms (Fig. 2) has a very beneficial effect in improving signal shape. The action of these devices will be taken up later. A complete cable circuit is shown in Fig. 10.

In relay reception of signals, it is necessary to pay attention to the tendency of signals to have a slowly wandering zero position. This effect is caused by the block condensers, and if conditions are otherwise correct it may be eliminated by providing the condensers with high-resistance shunts. The latter expedient, however, is not always considered desirable, and in order to correct a slowly wandering zero in relay reception, there have been various ingenious devices developed which need not be described here.

Cable Printers. A very promising development, likely soon to be in commercial form, is the application of printing systems of reception to long cables. The code that can be used in a printing system has fewer characters per word than the ordinary cable code. In addition to the economies made possible by the use of a shorter code, a cable printer is also likely to effect economies in operation due to the fact that fewer attendants will be required than with the present system.

Eastern Telegraph Company's System. The Eastern Telegraph Company has recently patented a system of operation which is quite different from conventional methods of operation. In this system the original—not the modified—continental code is used. The original continental code would ordinarily be less efficient, but some special apparatus has been developed which largely overcomes this objection. The system has the advantage that it can be operated through relays directly to the land lines, using land-line apparatus already standard.

Limiting Conditions of Cable Operation

The object of submarine cable engineering is to provide cables which give greatest operating speed and greatest reliability at least cost, and to develop operating methods which make use of the cable to its utmost capacity. A further object of almost equal importance is to reduce operating expenses.

The cost, in place, of a single section of submarine cable of modern type 2000 miles in length is in the neighborhood of $4,000,000. This represents an annual charge of approximately $400,000, to cover interest, maintenance, etc., of the cable itself. The cost of efficiently operating such a section of cable is likely to be in the neighborhood of $200,000 per year, for salaries of men and apparatus directly used in handling traffic. From these figures it is evident that considerable engineering can be justified to obtain highest working efficiency of cables.

A cable of modern type 2000 miles long would have approximately 3000 ohms resistance and 800 microfarads electrostatic capacity to ground. The operating speed, or the message capacity, of a cable is directly limited by its resistance and capacity. The resistance and capacity can be reduced in designing a cable only by increasing the size of the cable, which proportionately increases its cost.

Besides the constants of the cable itself, there are other factors which act in different cases to control the ultimate speed of a cable. These factors are enumerated below.

1. *Sensitiveness of Receiving Apparatus.* If a cable is worked at a very low speed, it is possible to transmit sufficient energy through it to operate receiving apparatus which is substantial in construction. When the speed is increased the current transmitted through the cable falls off very rapidly, due to the effect of resistance and capacity. The decrease in received current is met as far as practicable by providing receiving apparatus of increased sensitiveness. If the apparatus is not sufficiently sensitive, the operating speed may be definitely limited thereby—in fact it may be said that previous to ten or fifteen years ago, cable speeds were definitely limited by the lack of sensitiveness of available receiving equipment. Since that time, however, cable magnifiers, to which reference was previously made, have been developed to a point where they are practically as sensitive as is desired. While there is still some room for improvement the sensitiveness of

available magnifiers is such that other factors, given below, now largely limit the speed.

2. *Duplex Balance.* Due to small but unavoidable errors in the artificial line necessary for duplex working, there is likely to be some degree of off-balance, causing extra currents in receiving apparatus which act to limit the speed. The duplex balance is probably the most important limitation upon speeds of the majority of cables, for even if the cable is once correctly balanced, the balance is subject to change due to variations caused by small temperature changes of the ocean. Much can be accomplished by careful engineering in decreasing balance troubles. Some of the possibilities of improvement will be taken up in detail later.

3. *Extraneous Current.* Although not generally known, it is a fact that ocean cables are subject to continuous interference from extraneous currents in much the same way that interference is caused to wireless telegraph operation. The extraneous currents which affect ocean cables are probably partly caused by electric railway systems. Possibly part may be due to the operation of wireless systems. The greater part of the extraneous currents are, however, of unknown origin, and are doubtless akin to the "static" so familiar to wireless operators. The current is very irregular in nature and may be considered to contain currents of all frequencies. In practise it is usually found that extraneous currents are smaller in magnitude than the currents present due to slight errors in the duplex balance, although in some cases the extraneous currents are the larger. If the balance is improved extraneous currents become of increased importance, and they must be regarded as forming an ultimate limit to further increase in speed of a cable.

It is customary to make use of an earth connection for cable working which is extended several miles from shore. By this means disturbances from electric railway systems are largely reduced. Currents from other sources may be somewhat decreased by the same expedient, although they can not be eliminated. Extraneous currents may be picked up at any point along the cable and conveyed into the receiving apparatus, although the greater part is introduced by slight unsteadiness of the sea-earth connection, of amounts ranging from 0.0001 to 0.005 volt or higher.

4. *Sending Voltage.* The amount of voltage used for operating the cable has a bearing upon the operating speed. A short section of gutta-percha cable is capable of withstanding as much as 40,000 volts before being punctured. A long cable, however, is likely to contain weak spots, which may be punctured at a much lower voltage. In fact, there are instances where cables have been broken down by a few hundred volts. The cost of making repairs to a cable which has been damaged is large, and it is therefore customary to keep operating voltages down to a conservative value.

A potential of 50 volts is commonly used for operation. Due to the effect of the sending condenser, the strain caused to the cable is somewhat increased, so that the insulation near the end is subject to a maximum strain of about 75 volts. In the center of the cable the maximum strain on insulation is very much lower.

5. *Magnetic Storms.* Fortunately, magnetic storms occur only at comparatively wide intervals, otherwise cable engineering might have developed along entirely different lines. Magnetic storms are ordinarily, if not always caused by conditions on the sun. Slight effects from this source are fairly common, but severe magnetic storms occur only rarely, sometimes years apart. Whenever a severe storm occurs, there are displays of the aurora borealis in the sky, the compass needle is affected, and voltages ranging up to several hundred volts are induced in cables. The voltages alternate from one direction to the other in an irregular manner and at a low speed. The period of the reversal may be a few seconds or it may be as long as a half hour. A severe storm may make cable operation impossible for several hours and its effect may not entirely disappear for three or four days.

The Arrival Curve

If a direct-current voltage is suddenly impressed upon a cable grounded at the far end, a current flows into the cable according to the upper curves of Fig. 7. At the distant end of the cable, the current builds up according to the middle curve. The shape of this curve was originally worked out by Lord Kelvin in 1855. The strength of current received through the cable finally reaches a value many times stronger than that necessary to operate the usual receiving apparatus. The rate of increase of current is so slow, extending as it does over several seconds, that rapid signaling with a simple cable circuit is impossible. The various condensers and magnetic shunts introduced in the cable circuit for shaping signals act to remove the greater part of the received current, while retaining the sharp initial rise of current. The result is that the current in the receiving coil is approximately of the shape of the lower curve.

A curve such as one of the lower curves of Fig. 7, which shows the current received over a cable due to a suddenly impressed voltage, is known as an "arrival curve." Any combination of signals may be built up by algebraically adding a succession of arrival curves, in the manner illustrated in Fig. 8.

In studying cable operation, it is convenient to think in terms of the arrival curve. It is essential that the arrival curve be of proper shape, within certain limits, in order that all signal combinations may be legible. In Fig. 9 are shown various shapes of arrival curves, and also the shapes of the first three letters of the alphabet, built up by proper addition of a succession of arrival curves of the shapes given.

The Dot Frequency. By *dot frequency* is meant the normal frequency of operation when a succession of reversals is sent without spaces between them. Thus

the letter *a*, consisting of one dot above, and an equal deflection below the zero line, is considered to be one cycle. The letter *c* is considered to be two cycles. In Fig. 9, the base line of each arrival curve is shown divided into equal spaces. Each of these spaces represents the length of one dot, that is, one-half cycle.

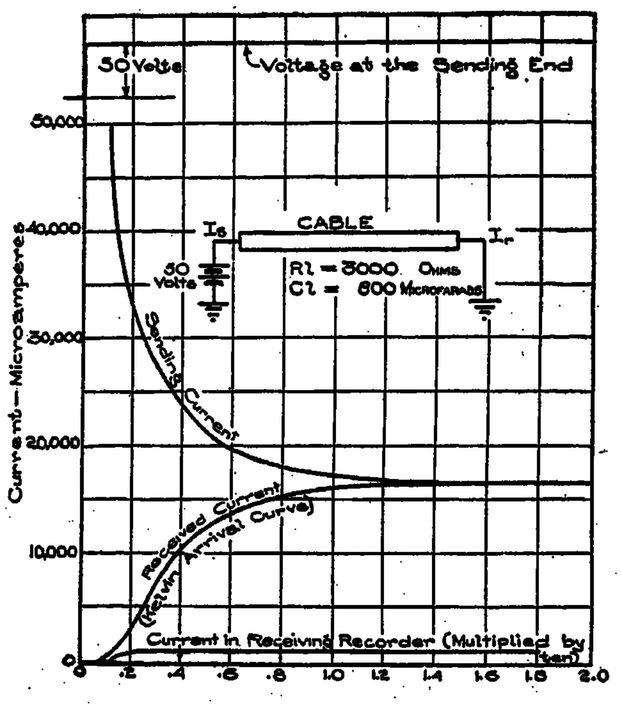

FIG. 7—SENDING AND RECEIVED CURRENT OVER CABLE

A cable such as that previously referred to, with 3000 ohms and 800 microfarads, could be commercially worked at a speed of 54 words per minute, or 324 letters per minute, under favorable conditions. By analyzing the standard cable code, it is found that this is equivalent to an average dot frequency of approximately ten cycles per second.

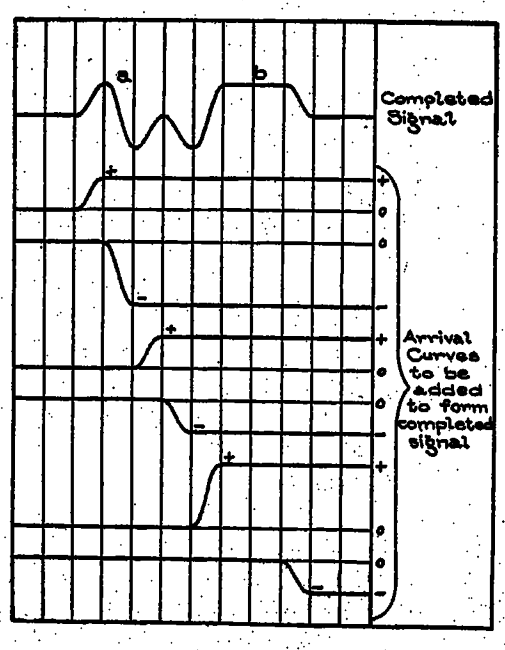

FIG. 8—ADDITION OF ARRIVAL CURVES TO FORM COMPLETED SIGNALS

THEORY OF CABLE OPERATION

The theory to follow is based upon the use of ordinary alternating-current theory. *A knowledge of the behavior of the cable and its associated apparatus under the influence of a sine wave of current throughout the proper range of frequencies, is sufficient to enable the shape of received signals to be predicted.* The action of any equipment may be determined by investigating its behavior through a range of frequencies. The frequencies which must be considered in cable investigations are those from zero frequency to a frequency two or three times the so-called "dot frequency" of operation, as explained later.

The fundamental theory of this method of analysis is developed in the Appendix. It is shown there that in general any transient curve may be considered to be composed of the sum of an infinite number of pure sine waves, of frequencies varying from zero to infinity. Each of these sine waves is attenuated in the cable circuit in accordance with well-known laws. Even the mechanical motion of receiving coils may be approximately or exactly solved by applying methods such as are used in solving alternating-current circuits.

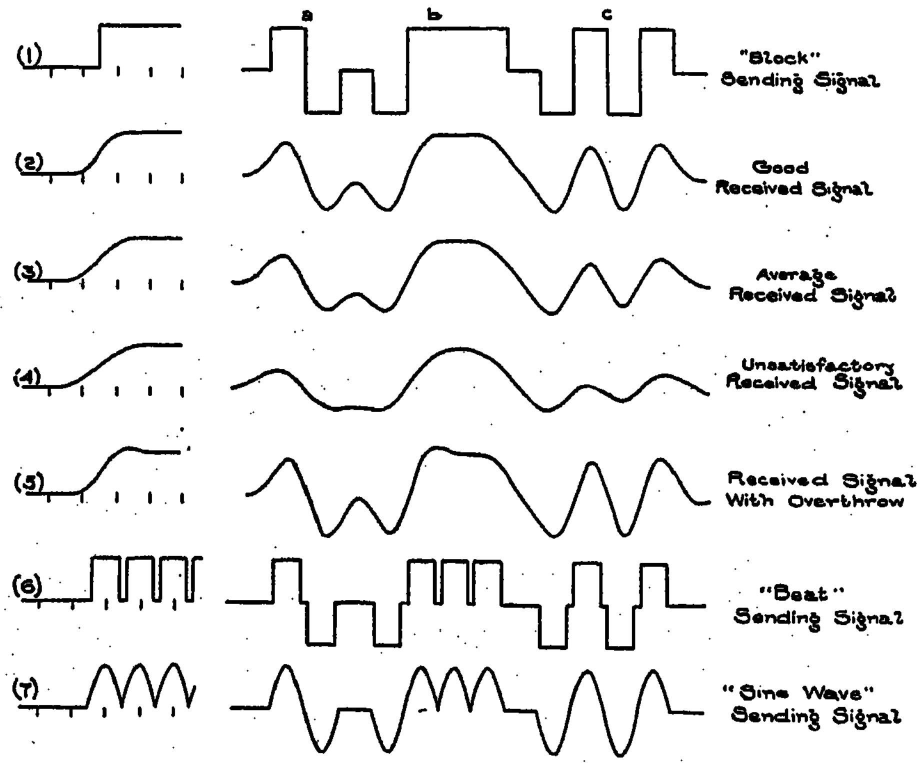

FIG. 9—TYPES OF ARRIVAL CURVES

While this method of analysis is of quite general application, it will be illustrated by applying it to the cable of standard present-day type previously referred to, and to simple apparatus used for operation.

The Frequency Characteristic. This term is used to designate a pair of curves which show how sine wave currents are changed in magnitude and in time lead or lag, by the cable circuit or by a part of the circuit, at various frequencies.

Notation.

E = battery voltage.

E_s = sending voltage as modified by type of signal used.

R = cable resistance per mile (inductance and leakage of cable are ignored).

C = cable capacity per mile.

l = cable length in miles.

f = frequency in cycles per second.

F = dot frequency in cycles per second.

Z_0 = surge impedance of cable $= \sqrt{\dfrac{R}{j\,2\,\pi\,f\,C}}$[1]

P = complex attentuation constant

$= \sqrt{j\,2\,\pi\,f\,R\,C}$[1]

I_s = current at sending end of cable.

I_r = current at receiving end of cable.

Z_s = impedance offered to outgoing current by apparatus at sending end.

Z_r = impedance of complete receiving system.

D = deflection of receiving instrument. The maximum deflection (neglecting a momentary overthrow) is taken as unity, the deflection at any frequency being expressed as a fraction of the maximum.

M = magnification of complete receiving set at any frequency = ratio D/I_r.

Solution with Single-Frequency Alternating Current. A standard expression for current received through a cable is the following:

$$I_r = \frac{E_s\,Z_0}{(Z_0^2 + Z_r\,Z_s)\sinh P\,l + (Z_0\,Z_r + Z_0\,Z_s)\cosh P\,l} \qquad (1)$$

This may readily be put into the form

$$D = \frac{E_s}{Z_0 + Z_s}\cdot \epsilon^{-Pl}\cdot \frac{2\,Z_0\,M}{Z_0 + Z_r} \cdot \frac{1}{1 - \dfrac{(Z_0 - Z_r)\,(Z_0 - Z_s)}{(Z_0 + Z_r)\,(Z_0 + Z_s)}\,\epsilon^{-2\,Pl}} \qquad (2)$$

The first term of the right-hand member of equation (2) gives the current flowing into the cable, as modified by apparatus at the sending end. The second term shows how the current is modified by the cable itself, and the third term shows how the current is modified by the receiving apparatus as a whole. The fourth term takes into account multiple reflections between the ends of the cable. The latter term may for all practical purposes be considered equal to unity, and may be ignored, as it has no effect except at speeds far below the usual signaling speed.

Analyses of Arrival Curves. If a voltage is impressed at the sending end of a shape corresponding to curve 1, Fig. 9, and the cable circuit as a whole, including apparatus, attenuates all frequencies equally, the wave as received at the distant end will be of exactly the same shape. Under these conditions, all signals would be reproduced at the receiving end exactly as they were sent.

If the characteristics of the cable circuit are such that the higher frequencies are lost in transmission, then the tendency is to round off the corners of the wave in a definite manner, so that a more or less rounded signal is the result. Such rounding-off is not objectionable providing it is not carried too far. It becomes then of the utmost importance to determine just what frequencies it is necessary to transmit through the cable in order to obtain a received signal that is sufficiently legible. Since the higher frequencies are most difficult to transmit through the cable, it will be obvious that the ideal shape of arrival curve is one which, while giving good signals, requires the transmission of the smallest possible amount of the higher frequencies. In order to determine what frequencies it is necessary to transmit, a theoretical analysis was made of a large number of possible arrival curves, using methods given in the Appendix, and tests were also made of working cable circuits.

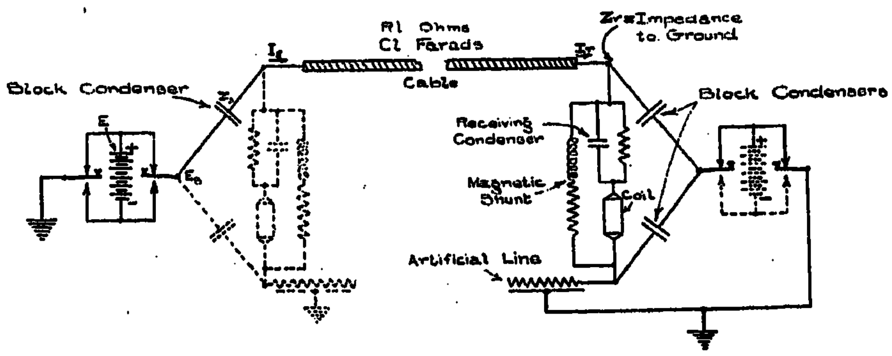

Fig. 10—Complete Cable Circuit

In order to obtain a received signal which, while somewhat rounded, may be regarded as perfect in shape, it is found necessary to transmit frequencies through a cable up to approximately 2.4 times the dot frequency. Fortunately, however, a received signal of such quality is not necessary for commercial operation, since the rece ving operator becomes so familiar with signals that he is able to read signals which are moderately distorted. It has been found that for recorder reception, with or without a magnifier in circuit, it is necessary to transmit frequencies only up to about 1.5 times the dot frequency in order to obtain a signal which is suitable for traffic.

For relay reception a somewhat better defined signal is necessary, and it is necessary to transmit frequencies up to about 1.65 times the dot frequency. Relay reception is facilitated by permitting a small overthrow of the arrival curve. It can be shown that such an arrival curve can be built up with smaller amounts of the higher frequencies.

Examples of signals which have been chosen to represent the approximate limits of good transmission, for recorder and relay reception respectively, are shown

1. In the general case, with inductance L and leakage G present, these become,

$$Z_0 = \sqrt{\frac{R + j\,2\,\pi\,f\,L}{G + j\,2\,\pi\,f\,C}}$$

$$P = \sqrt{(R + j\,2\,\pi\,f\,L)\,(G + j\,2\,\pi\,f\,C)}$$

opposite curves 3 and 5 of Fig. 9.[2] These arrival curves are redrawn to a larger scale in Fig. 11.

In Fig. 12 are shown the frequency characteristics corresponding to the above arrival curves. These

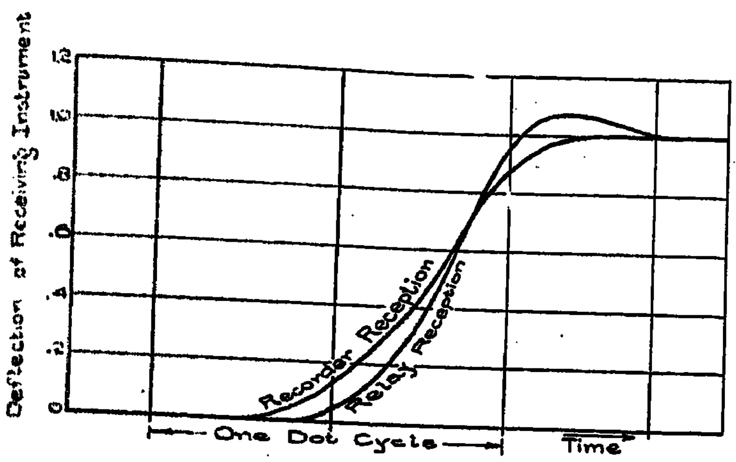

FIG. 11—IDEAL ARRIVAL CURVES

characteristics show the approximate deflection and time lag which the receiving instrument must have at any frequency, when a sine wave of voltage is impressed at the sending transmitter. The portion shown solid is considered to represent the *working frequency*, which is of importance in determining the shape of the received arrival curve. The precise shape of the portion shown dotted is unimportant as regards transmission through the cable, both because the energy transmitted through the cable is small at these frequencies, and because due to the nature of the equations of this theory as given in the Appendix, the higher frequencies are of less importance.

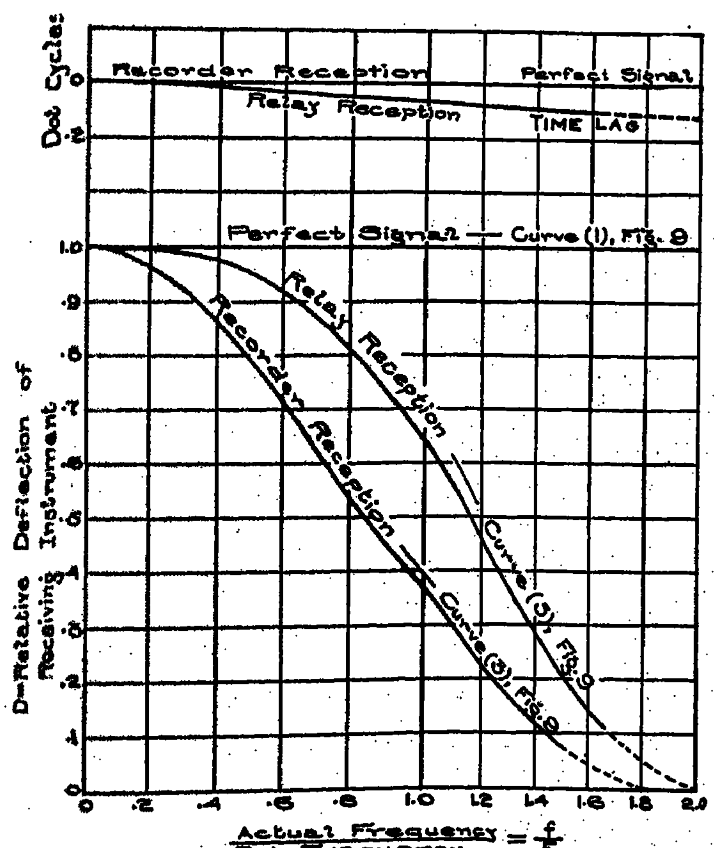

FIG. 12—IDEAL FREQUENCY CHARACTERISTICS OF COMPLETE CABLE CIRCUIT

It will be recognized that there may be some dif-

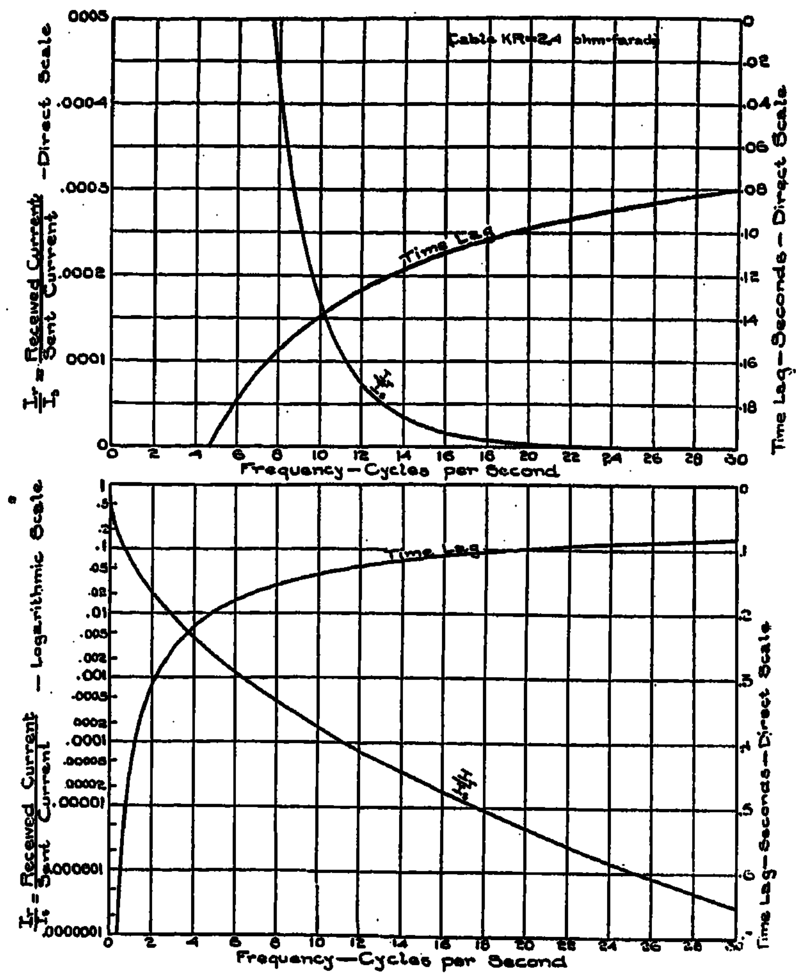

FIG. 13—FREQUENCY CHARACTERISTICS OF CABLE

ference of opinion as to when the received signal is legible. For this reason there is some variation in the frequency limits required for reception by different cable operators. The limits given, however, may be

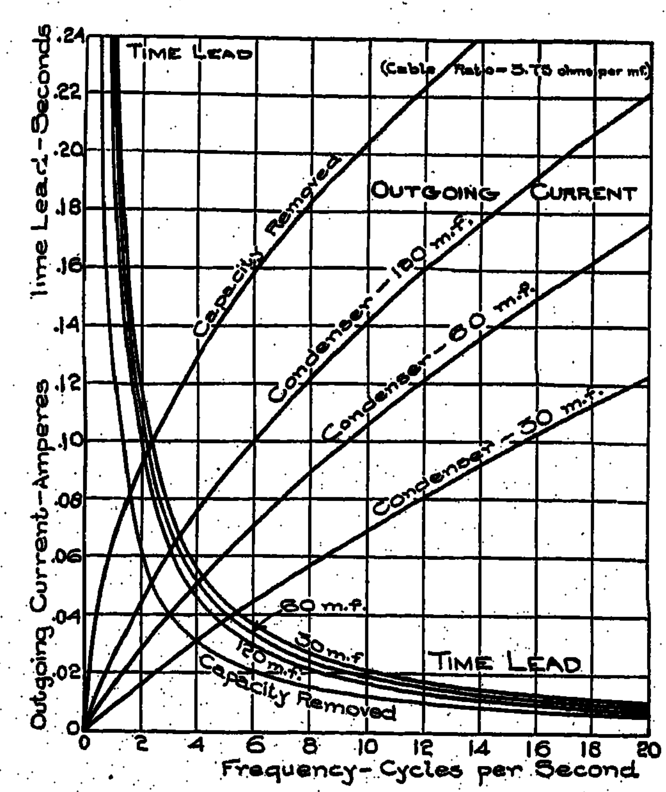

FIG. 14—FREQUENCY CHARACTERISTICS OF SENDING APPARATUS

taken to represent average values, and are of the highest importance in studying cable problems.

Frequency Characteristic of Cable. The frequency

2. The following table gives the range of frequencies contained in each curve of Fig. 9:

Curve 1, 6 and 7—zero to infinity
" 2—zero to 1.9 times the dot frequency
" 3— " " 1.5 " " " "
" 4— " " 1.1 " " " "
" 5— " " 1.65 " " " "

characteristic given in the preceding section was the characteristic of the entire cable circuit, from transmitter to recorder, necessary for proper reception. It is now the purpose to determine the separate frequency characteristics of different parts of the system.

The frequency characteristic of the cable itself is shown in Fig. 13. This characteristic applies to the cable referred to previously. It is shown plotted both to a logarithmic and to a direct scale. The characteristic was determined by calculating real and imaginary values of the second term of the right-hand member of equation (2)

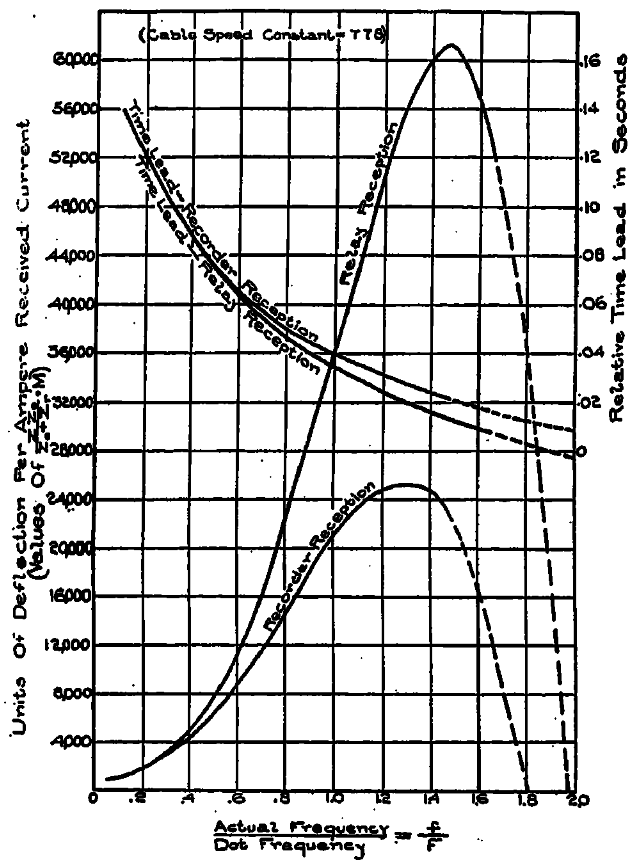

Fig. 15—Frequency Characteristics of Complete Receiving Set

Frequency Characteristics of Sending Apparatus. In Fig. 14 are shown frequency characteristics of the current entering the cable, for three different sizes of the condensers at the sending end, and also with the condenser removed. The values in this figure were obtained from the first term of the right-hand member of equation (2), the sending voltage being taken at fifty volts.

This figure clearly shows the beneficial effect of the sending condenser in decreasing currents of the lower frequencies. The condenser also reduces, in a less degree, the amount of energy flowing into the cable at higher frequencies—an effect which in itself is undesirable, but which can be compensated for by increasing the sending voltage or the sensitiveness of receiving apparatus.

Frequency Characteristics of Receiving Apparatus. By combining the frequency characteristics shown in Figs. 13 and 14,[3] the frequency characteristic of the current at the receiving end of the cable may be obtained. Now since Fig. 12 shows the frequency characteristics of the cable circuit as a whole, necessary to produce properly shaped signals for reception, it is possible by combining these characteristics with the characteristics referred to above, to obtain characteristics which show the necessary behavior of the receiving set. Such characteristics are shown in Fig. 15.

The characteristics of the receiving set show that this apparatus must be comparatively insensitive to low-frequency currents. It must have its highest sensitivity to currents about 1.3 times the dot frequency for recorder reception, or about 1.45 times the dot frequency for relay reception. The working ranges of frequency, which are important in determining shapes of received signals, are shown as before by solid lines. There are decided advantages from the standpoint of freedom from interference, in having the receiving apparatus insensitive to frequencies higher than the working frequencies.

It is interesting to consider the manner in which the receiving set is made to have characteristics of the shape given. The receiving set is composed of a number of condensers and shunts as shown in Fig. 10. While it is entirely practicable to calculate the frequency characteristic of each part of the circuit, it appears unnecessary to give such calculations here, and a statement will simply be made of the general characteristics of different parts of the receiving set.

The receiving characteristics in Fig. 15 are in fact plots of the quantity

$$\frac{2\,Z_0\,M}{Z_0 + Z_r}$$

taken from equation (2). In this quantity, the factor

$$\frac{2\,Z_0}{Z_0 + Z_r}$$

does not greatly vary from unity. The characteristic may therefore be considered to be an approximate plot of the quantity M, which is the ratio of the deflection of the receiving instrument to the current in amperes at the receiving end of the cable. The largest deflection shown is 61,000 units per ampere—that is, full deflection is obtained with 1/61000 ampere = 16 microamperes.

The magnetic shunt, Fig. 10, tends to cause a characteristic which rises with frequency, that is, the shunt tends to absorb currents of lower frequencies, while throwing the higher frequencies into the receiving coil. The condenser in series with the coil has an effect similar to that of the magnetic shunt, and tends to increase further the slope of the characteristic of the complete set.

The block condensers at the receiving end are in effect shunted around the receiving coil and tend to shunt or absorb currents of the higher frequencies. An additional condenser is sometimes placed in shunt with the receiving coil. The values should be such that these condensers mainly absorb only currents

3. The 60 μf. curve of Fig. 14 was used.

above the working frequencies. Such a characteristic may be very beneficial, as it reduces balance troubles and interference from outside sources. The condensers

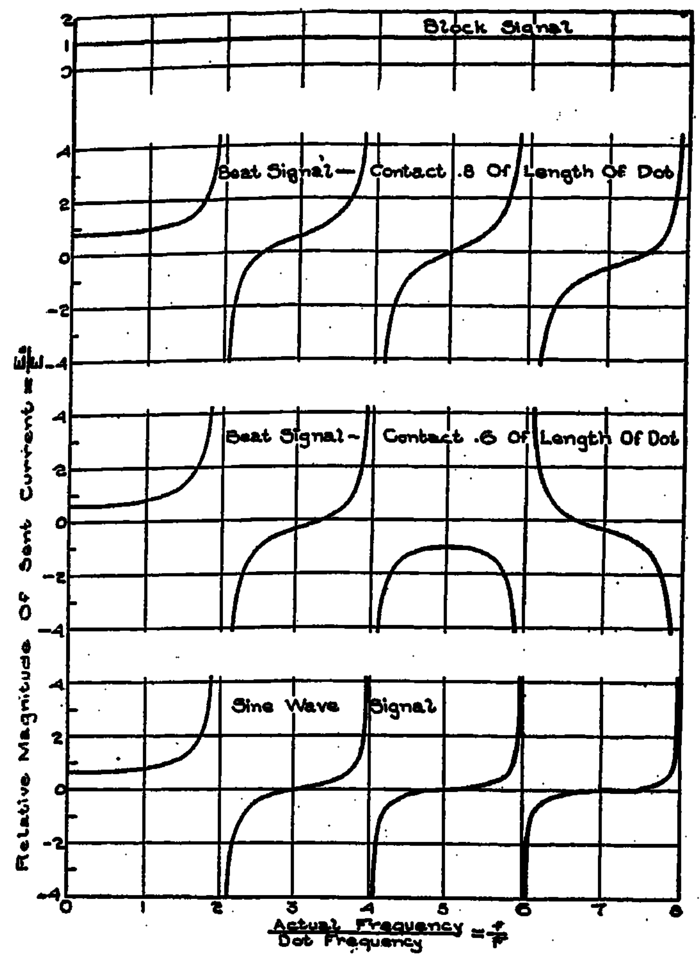

FIG. 16—FREQUENCY CHARACTERISTICS OF SENDING SIGNALS

may be semi-resonant with the magnetic shunt, at a frequency between 1.2 and 1.5 times the dot frequency.

The recording coil has inertia which tends to make it relatively insensitive to the higher frequencies. The

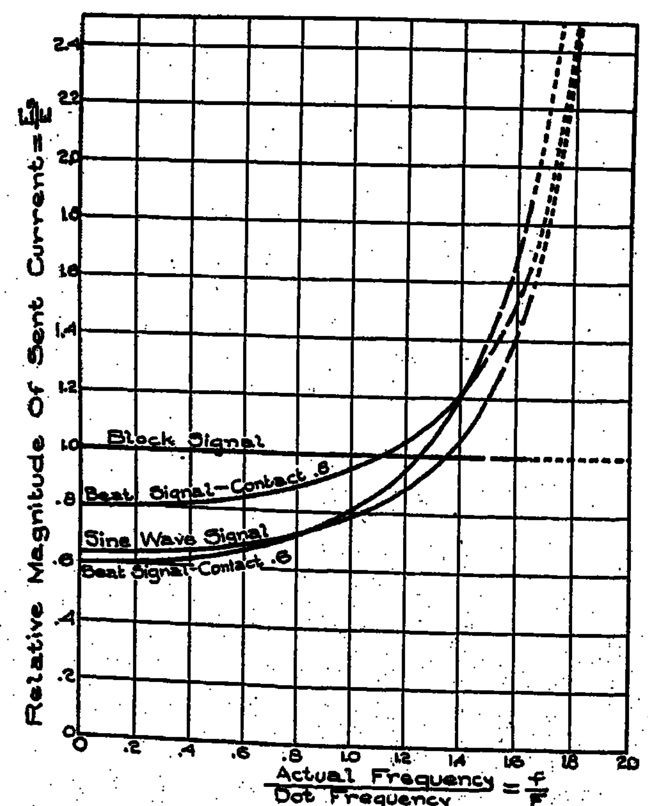

FIG. 17—FREQUENCY CHARACTERISTICS OF SENDING SIGNALS

coil may be adjusted to have a free period of its own, the period being between 1.2 and 1.5 times the dot frequency.

If a magnifier is used of the Heurtley or selenium type, the hot wire of the former, or the selenium cell of the latter, has a certain amount of sluggishness which may have a decidedly beneficial effect in absorbing currents of the higher frequencies.

Frequency Characteristics of Sending Signals. Up to this point it has been assumed that the signal sent is of the so-called "block" type, as shown in curve 1, Fig. 9. There is another type of sending signal which is used to a considerable extent, namely the "beat" type of signal, curve 6, Fig. 9. Still another type has been proposed by Major-General G. O. Squier, namely the sine wave signal, curve 7, Fig. 9.

The characteristics of such signals may be studied in the same manner as parts of the circuit are studied. Frequency characteristics of these types of signals are shown in Figs. 16 and 17,[4] the latter figure being to a larger scale.

No general rule will be given as to which type of sending signals is best, the preference in any case being dependent upon a knowledge of the particular conditions which limit transmission. With beat signals smaller amounts of low-frequency currents are transmitted, so that the associated condensers and magnetic

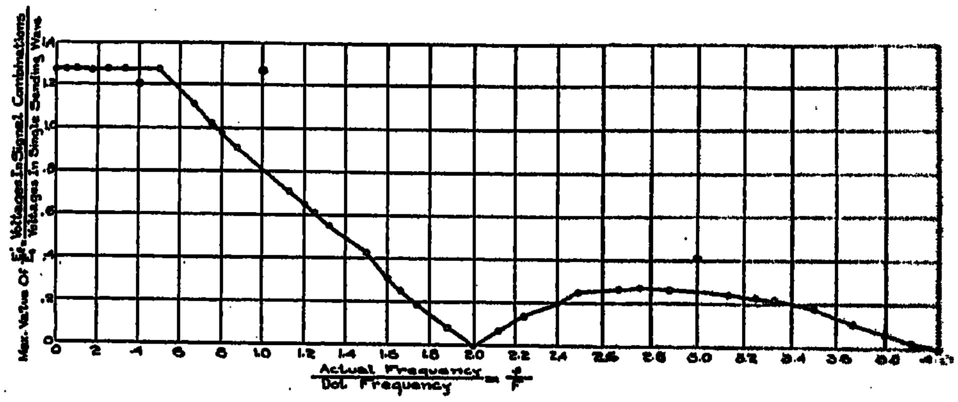

FIG. 18—ANALYSIS OF SENDING SIGNAL COMBINATIONS

shunt need not absorb as much of such currents. Block signals have advantages from the standpoint of duplex balancing, as will be evident later.

THE DUPLEX BALANCE

Theory. Since cables are usually operated duplex and the balance is often the condition which limits operation of the cable, it is important to consider the theory and practise of balancing.

If there is present a small error in the balance, its effect is in general most severely felt when some irregular combination of signals is sent. In order to analyze this condition, the combination of signals may be considered to recur at regular intervals, and may then be broken up by the standard Fourier method into the sum of a number of separate sine waves. By

4. The development of these is given in the Appendix. The curves show only the *transient* characteristics of the signal. In the beat and sine wave signals, there is also a non-transient component which contains frequencies of 2, 4, 6, etc., times the dot frequency. Such frequencies may in general be neglected in studying transmission through the cable, for reasons given previously.

choosing various possible combinations of signals and analyzing them in this manner, we may determine what the maximum sine wave value of the sending voltage may be at any frequency. This maximum value will be designated E_s'.

Let it be assumed that the impedance of the cable is Z_o, and that the artificial line is so adjusted that the system would be perfectly balanced if the cable impedance were $Z_o(1 + \Delta)$ where Δ is a very small quantity. It can then be shown[5] that the deflection of the receiving instrument will be given by the expression

$$D_b = \frac{E_s' \, Z_o \, M \, \Delta}{(Z_o + Z_r)(Z_o + Z_r)} \qquad (3)$$

Now equation (2) gives the deflection of the receiving instrument at any frequency, when the sending battery is replaced by a sine wave of voltage of value E_s. By combining equations (2) and (3) we have,

$$D_b = 1.2 \cdot \frac{E_s'}{E_s} \cdot \epsilon^{rl} \cdot D \cdot \Delta \qquad (4)$$

A plot of the ratio E_s'/E_s, calculated by setting up various recurring combinations of signals as described above, is given in Fig. 18.[6] Plots of the quantity D under ideal conditions, and of $1/\epsilon^{rl}$, were given in Figs. 12 and 13.

In order that duplex operation may be satisfactory, it is necessary that any deflection of the receiving instrument caused by off-balance, will be small as compared with the size of the signal itself. The precise amount permissible depends to some extent upon the individuality of the operator, so that no exact limit can be given. It may, however, be said that an approximate limit for deflection due to off-balance is 0.2 of the size of the dot signal. Now since each of the various combinations of signals contains several different frequencies, the effects of which are aggregated at times, it is necessary to apply a "factor of safety," which will here be assumed equal to 2. Taking these considerations into account, equation (4) may be put into the form

$$1/\Delta = \frac{E_s'}{E_s} \cdot \frac{D \cdot \epsilon^{rl}}{0.094} \quad \text{for recorder reception.} \qquad (5)$$

$$1/\Delta = \frac{E_s'}{E_s} \cdot \frac{D \cdot \epsilon^{rl}}{0.16} \quad \text{for relay reception.} \qquad (6)$$

Plots of values of $1/\Delta$ are given in Fig. 19. This figure shows the approximate degree of accuracy which the balance must possess at all frequencies, in order to permit operation of the cable previously referred to, at a dot frequency of ten cycles per second. It should be noted that the curves in Fig. 19 have been built up on the basis of having apparatus which eliminates the higher unnecessary frequencies. With unfavorable operating apparatus far greater accuracy of the balance may be necessary.

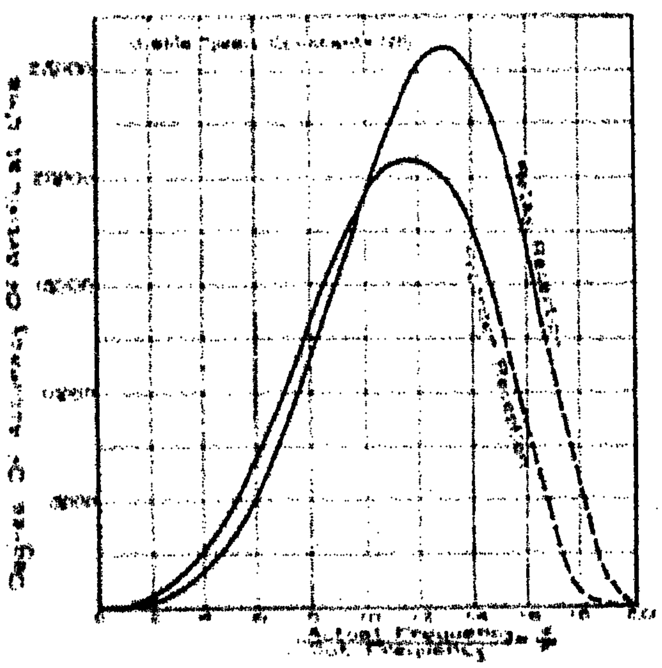

FIG. 19—ACCURACY REQUIREMENTS OF DUPLEX BALANCE

Balance difficulties are an inherent property of a cable system operated duplex, for even if the cable is once balanced correctly, the balance is subject to change due to variations that occur in the temperature of the ocean bottom. In practise it is usually necessary to readjust the balance at least daily, in some cases several times daily. As shown above, a change in the impedance of the cable of one part in 25,000 is sufficient to be important. To maintain a balance correct at one frequency only to this degree of accuracy might not be especially difficult. The chief difficulty is, in fact, the maintenance of a balance correct to the required accuracy throughout a considerable range in frequency.

5. This equation may be readily proved for any special terminal circuit, by obtaining an expression for the current in each branch of the circuit when a sending voltage E_s' is impressed at the apex. A general proof may be obtained by breaking the impressed voltage into two parts, of which one part causes a current I_s to flow in line and in artificial line. The remaining part then acts to cause a current I_b, due to off-balance, to flow from the line into the receiving circuit. The deflection $= M$ times I_b. It is assumed throughout that circuit conditions at the two ends of the cable are similar.

6. As examples of combinations chosen are the following. (1) Reversals; (2) Dot, dash, dash, dot, dash, dash, etc.; (3) Dot, dot, dash, dash, dot, dot, dash, dash, etc. A large number of other combinations was used. The curve in Fig. 18 is, of course, discontinuous. There are two points separate from the curve at $f/F = 1$ and at $f/F = 3$. (Balance disturbances from these particular frequencies are not likely to be more severe than from others, because it happens that these frequencies occur only together, and do not occur in combinations with the numerous other frequencies.) The above signal combinations may be assumed made up of "block" signals, or they may be assumed made up of "beat" or other shaped signals. If the latter, it will be found on trial that the values of E_s' are changed in amount, for any signal combination, by a ratio given by the ordinates of Figs. 16 and 17. But the value of E_s is also changed by the same amount, and the ratio E_s'/E_s is therefore independent of the type of signal. It should not be inferred from this that the type of sending signal has no influence on balance. The actual value of D in equations (4), (5), and (6), may be altered by changing the signal type, which may thus materially influence balance troubles. We are here concerned with the maximum values of the quantities in the equations, and it is not necessary to consider the angle of ϵ^{rl}.

From the theory and curves given above, three important conclusions may be drawn regarding balancing, as follows:

(1) The effect of a given balance error upon the receiving instrument is dependent upon the *actual* shape of the frequency characteristic (Fig. 12) of the entire cable circuit. The actual shape of the characteristic becomes of rapidly increased importance at the higher frequencies.

(2) If there is a certain error in the balance, there can be nothing done *throughout the working range of frequencies,* to decrease its effect upon transmission, by altering the apparatus at either the sending or receiving end, excepting insomuch as the alterations change the shape of the useful transmitted signal.

(3) Any change in the apparatus at either the sending end or the receiving end of the cable, which decreases the magnitude of current transmitted through the cable *at frequencies higher than the working range,* without unduly affecting frequencies within the working range, is a distinct advantage in decreasing balance disturbances.

Artificial Lines. Every submarine cable, in addition to having resistance and capacity, has a certain amount o' self-inductance and leakage. The latter factors are ordinarily too small to affect transmission through the cable, but are of considerable importance in balancing. The effective resistance and inductance vary with frequency, due to the characteristics of the sea-water return circuit,[7] and the capacity and leakage also vary with frequency, due to the behavior of the gutta-percha insulation.

The artificial line for balancing such a cable consists of a network of resistance and capacity, to which inductance may be added if desired. The network must be adjusted to have electrical characteristics that closely match those of the cable. The original adjustment may be a very tedious process, there being records of cases where as much as three months' work was done in obtaining a duplex balance for a single cable. Much of the early balancing was done without fully understanding the theory of balancing, and some ingenious appliances to artificial lines were developed by workers in the field, at a time when the electrical properties of the cable itself were incompletely understood. Fortunately, the theory is now better known so that the time required in balancing has been greatly cut down.

Artificial lines of any type are more or less sensitive to temperature changes, and are, therefore, usually placed in heat-insulated cabinets, sometimes located in rooms having special heat-insulated walls. In order to provide for convenient minor daily adjustments, it is customary to provide in addition a few small adjustable condensers and resistances, located near the receiving apparatus, and connected in the artificial line or in the bridge circuit.

7. See J. R. Carson and J. J. Gilbert: "Transmission Characteristics of the Submarine Cable." *Journal of the Franklin Institute,* Dec. 1921.

The earliest type of artificial line was of the lumped variety, Fig. 20, used by Stearns. This artificial line was not successful, due probably to defects in design and construction.

Shortly afterwards, in 1875, the smooth type of artificial line was patented by Taylor and Muirhead.

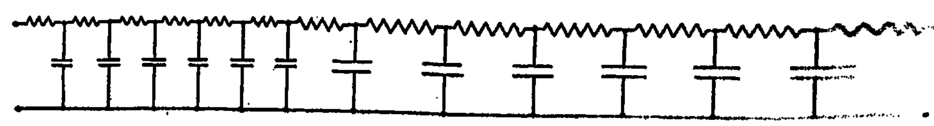

FIG. 20—STEARNS TYPE OF ARTIFICIAL CABLE
Capacity and resistance of each section adjustable

In this line (Fig. 21), the resistance of the line is made up of a zig-zag strip of tinfoil. This is insulated from the solid ground sheet of tinfoil by paraffined paper. thus forming the capacity of the line. The line is mounted in wooden boxes, having 10 to 21 microfarads per box, with terminals brought out which divide the line into sections of from one to three microfarads each. This type of line is especially sensitive to temperature changes.

A more recent type of artificial line has been patented by Dearlove. This line is made up of a large number of very small units of resistance and capacity, the latter being from 1/30 to 1/15 microfarad each. Neither the resistance nor the capacity is adjustable. The resistance and capacity are mounted together in boxes, similar to the type previously described.

With either of the types just described, the artificial line must be specially designed and constructed to match the cable with which it will be used, since the

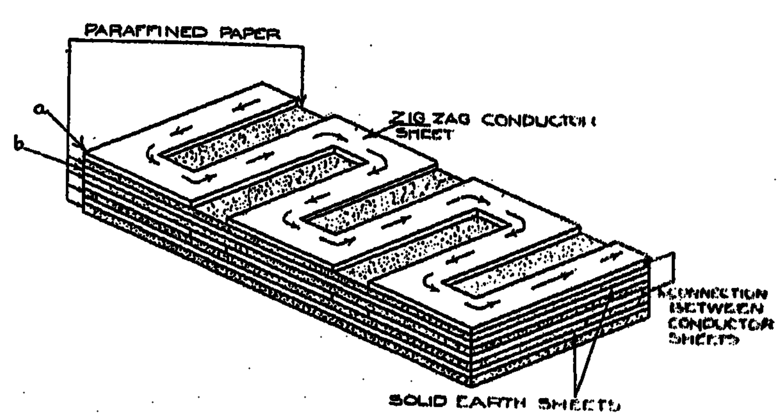

FIG. 21—DIAGRAM OF MUIRHEAD TYPE OF ARTIFICIAL CABLE

constants can be adjusted only in an indirect manner which introduces irregularities in the artificial line that have no duplicate in the cable.

A new type of artificial line[8] has been developed by the writer, w th the object of overcoming the disadvantage of the types previously described. This artificial line is shown diagrammatically in Fig. 22, and contains resistances and condensers in fairly large lumps.

While it might seem that a lumped line of this type could not be made to ba'ance a cab'e with constants

8. Patents pending.

uniformly distributed, the actual condition is that the lumped arrangement is utilized to aid in balancing the inductance of the cable. It may readily be shown that the impedance of such network having a large number of resistances and condensers is

$$= \sqrt{\frac{R'}{j\,2\,\pi\,f\,C'} + R'\,R'' + R'^2/4} \qquad (7)$$

The surge impedance of a submarine cable with resistance, capacity and inductance is

$$Z_0 = \sqrt{\frac{R}{j\,2\,\pi\,f\,C} + L/C} \qquad (8)$$

From these it is apparent that a balance which is correct for all frequencies may be obtained if

$$R'/C' = R/C, \quad \text{and} \quad R'\,R'' + R'^2/4 = L/C \qquad (9)$$

An artificial line of this type has the additional advantage that it is readily constructed to be completely adjustable throughout its length. In practise the resistances and condensers are mounted in separate boxes, and the resistance of the line is made continuous with taps brought out at intervals. The resistance steps are small near the head of the line, and become increasingly larger away from the head. For adjustments a movable connector is used which is reliable and convenient to handle, and which does not introduce appreciable contact resistance. It is found that an adequate balance can be obtained with condenser units of two microfarads near the head of the line, and with considerably larger units toward the rear of the line. The resistances in series with the condensers need little if any adjustment, and are only necessary near the head of the line.

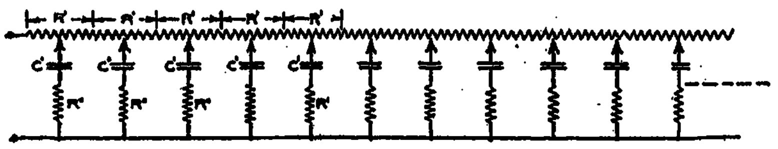

FIG. 22—ADJUSTABLE TYPE OF ARTIFICIAL LINE

KELVIN'S *KR* LAW

This law, formulated early in the history of the science, states simply that the operating speed of the usual type of cable is inversely proportional to the product of its capacity times its resistance, the letters "*KR*" being an old symbol for this product. Expressed in another way, the law states that the product of speed times the "*KR*" is a constant. With speed expressed in letters per minute, cable resistance in ohms, and capacity in farads, this product is termed the "speed constant" of the cable, and is widely used.

That the *K R* law is approximately true is immediately evident from the preceding theory [see equation (2)]. The amount of energy which is transmitted through the cable is directly dependent upon the product of frequency times resistance times capacity, and if there is a definite minimum permissible amount of received energy, then there must be a definite value of the above product.

Obviously, the above does not take into account the fact that different conditions may in different cases act to limit the speed of a cable. The "speed constant" is therefore not a definite fixed value, but varies in different cases, and is in fact a measure of the efficiency of operation. With recorder reception a speed constant of 500 to 550 is usual. With magnifier reception and duplex operation, speed constants from 600 to 800 or higher are regularly obtained. A speed constant as high as 1200 has been commercially attained over a cable which was operated in one direction only, and was therefore free from balance troubles.

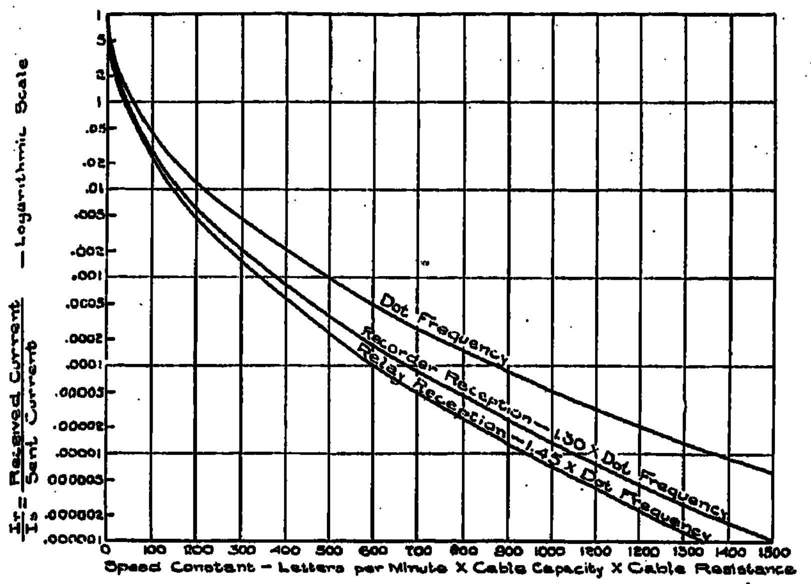

FIG 23—DECREASE OF CURRENT IN CABLE

In order to examine further the validity of the *K R* law, the effects of the different limiting conditions to cable operation will be considered separately.

(1) If conditions are such that the speed of a cable is limited only by the sensitiveness of available receiving equipment, the *K R* law forms an approximate guide only. This condition is not now of sufficient importance to justify a detailed discussion. It may be said, however, that of two cables of unequal length a somewhat higher speed constant (although a lower speed) will in general be obtained over the longer cable, for the reason that a given receiving instrument can be adjusted to have higher sensitiveness when used for operation at low speed.

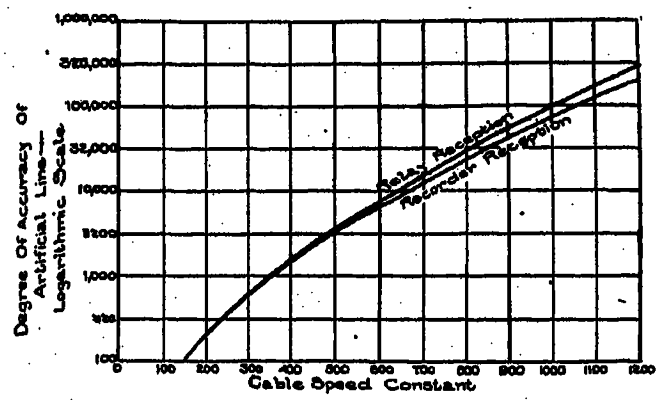

FIG. 24—RELATIVE ACCURACY REQUIREMENTS OF DUPLEX BALANCE

(2) If the speeds of two cables are limited only by

the duplex balance, and the cables are subjected to the same percentage balance variations and have equally efficient terminal equipment, then the $K R$ law is an accurate guide to their relative speeds. This is evident from equations (5) or (6), for with any given value of f/F, each term of the equation is constant, and the quantity $P l$ is therefore constant.

(3) If the speeds of two cables are limited only by the presence of extraneous current caused by small equal extraneous voltages impressed at the end of the sea-earth, then it will also be found that the $K R$ law accurately applies. It is again assumed that equally efficient terminal equipment is used. Two such cables subjected to the same extraneous voltage will have the same speed constant, while if the two cables are subjected to different amounts of extraneous voltage, then the one subjected to the smaller extraneous voltage will have the higher speed constant.

The ratio of received current to sent current in cables operated at different speed constants is shown in Fig. 23. It will be noted that a small change in the speed constant requires considerable increase in the sensitiveness of receiving equipment. The approximate degree of accuracy that the duplex balance must possess with different speed constants, assuming favorable terminal apparatus, is shown in Fig. 24.

In conclusion the writer desires to acknowledge the valuable assistance which he has received in the preparation of this paper, from Mr. C. H. Cramer and Mr. W. D. Cannon.

Appendix

In this Appendix is given the fundamental theory of the method of analysis used in the body of the paper. While the general plan has previously been to assume the shape of the received current to be known, and to determine the frequency characteristic from the known current, the method also provides for determining the received current or voltage when the frequency characteristic is known, as shown below. The most useful case is to determine the received current caused by the application of a suddenly impressed steady voltage, yet the method is applicable for determining effects caused by any general transient shape of voltage or current, in cable or other electrical circuits.

The frequency characteristics have previously been considered to be functions of the frequency, and to show the magnitude and the time lead or lag of the wave. In the Appendix the frequency characteristics will be considered to be functions of $p = 2\pi f$, and will show the sine and cosine components of the wave separately.

In order to calculate the received current or voltage, the transient source is assumed replaced by a continuous sine wave source, and a calculation is in general made of the received voltage or current for all values of frequency from zero to infinity. The real and imaginary components are calculated separately, and are denoted respectively by u and v. A formula for the received voltage or current caused by a suddenly impressed continued voltage is given in equation (10).

In difficult cases the necessary integrations are too complicated to be solved analytically, and it is necessary to resort to a graphical or mechanical method of integration. A form of harmonic analyzer is especially applicable.

Notation

t = time
$p = 2\pi \times$ frequency
y = height of transient curve (function of t)
s = sine component of frequency characteristic (function of p)
c = cosine component of frequency characteristic (function of p)
u = real component of received sine wave (function of p)
v = imaginary component of received sine wave (function of p)
$j = \sqrt{-1}$
$a, b, g, k, m, n, A, P, T$, constants
R = resistance
L = inductance
E = voltage
I = current

Theory

The method is a development of Fourier's series. Referring to Fig. 25, the Fourier expression for a single valued continuous curve of any shape between the limits of $-2k$ and $+2k$ is,

$$y = a_1 \sin\frac{\pi t}{2k} + a_2 \sin\frac{2\pi t}{2k} + a_3 \sin\frac{3\pi t}{2k} + \ldots$$

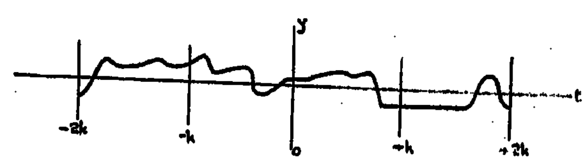

Fig 25

$$+ b_0 + b_1 \cos\frac{\pi t}{2k} + b_2 \cos\frac{2\pi t}{2k} + b_3 \cos\frac{3\pi t}{2k} + \ldots \quad (1)$$

A curve such as shown in Fig. 26 may be expressed by the simpler form,

$$y = a_1 \sin\frac{\pi t}{2k} + a_3 \sin\frac{3\pi t}{2k} + \ldots$$

$$+ b_0 + b_1 \cos\frac{\pi t}{2k} + b_3 \cos\frac{3\pi t}{2k} + \ldots \quad (2)$$

$$= \sum_{1,3\ldots}^{\infty} a_m \sin\frac{m\pi t}{2k} + b_0 + \sum_{1,3,\ldots}^{\infty} b_m \cos\frac{m\pi t}{2k} \quad (3)$$

In Fig. 26, the two halves of the curve are similar in shape, but inverted. The portion between $-k$ and $+k$ is the part in which we are especially interested. The value of k may be made as large as desired, so that in practise any shape of continuous curve may be expressed by (**3**).

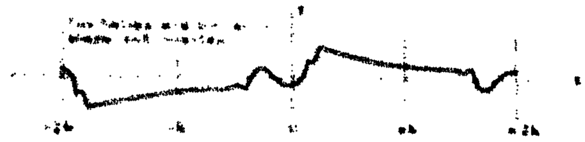

FIG. 26

An additional limitation upon the curve will now be made in order to simplify further the mathematics. It will be assumed that the curve is horizontal, as shown in Fig. 27, excepting for a small portion in the neighborhood of the vertical axis. The value of k will later be assumed increased indefinitely, as in Fig. 28. In the remainder of this theory, it is assumed that the transient under investigation is of the general type shown in Fig. 28. This limitation does not prevent the investigation of those types of transients in which we are interested, as is shown later.

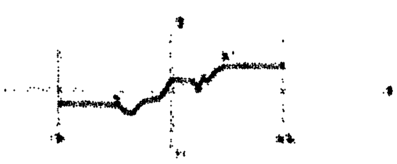

FIG. 27

Referring to equation (**3**), the value of m takes every odd integer value from one to infinity. By assuming k increased indefinitely, (**3**) may be replaced by an equation containing integrals, and becomes of the form

$$y = 1/\pi \int_0^\infty s \sin pt \, dp + 1/\pi \int_0^\infty c \cos pt \, dp + b_0 \quad (4)$$

in which $\frac{m\,\pi}{2\,k}$ has been replaced by p, $k\,a_m$ has been

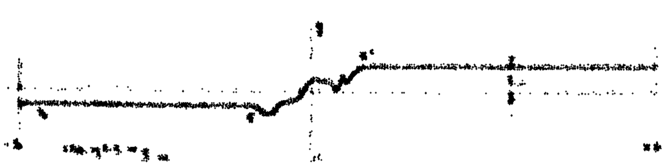

FIG. 28

replaced by s, and $k\,b_m$ has been replaced by c. The quantities s and c are functions of p, and constitute the *frequency characteristic* referred to previously.

For each type or shape of transient curve there is a pair of quantities s and c, which correspond to the one transient curve only. The frequency characteristic is independent of the actual value of k, provided that k is large. Equation (**4**) enables the transient to be determined when the frequency characteristic is known. Equations (**8**), below, enable the frequency characteristic to be determined when the transient itself is given. Equations (**4**) and (**8**) are the fundamental equations of this theory.

To develop the latter equations, we have the well-known equations for determining the constants of Fourier's series,

$$\begin{aligned} a_m &= \frac{1}{2\,k} \int_{-2k}^{2k} y \sin \frac{m\,\pi\,t}{2\,k}\, d\,t \\ b_m &= \frac{1}{2\,k} \int_{-2k}^{2k} y \cos \frac{m\,\pi\,t}{2\,k}\, d\,t \\ b_0 &= \frac{1}{4\,k} \int_{-2k}^{2k} y\, d\,t \end{aligned} \quad (5)$$

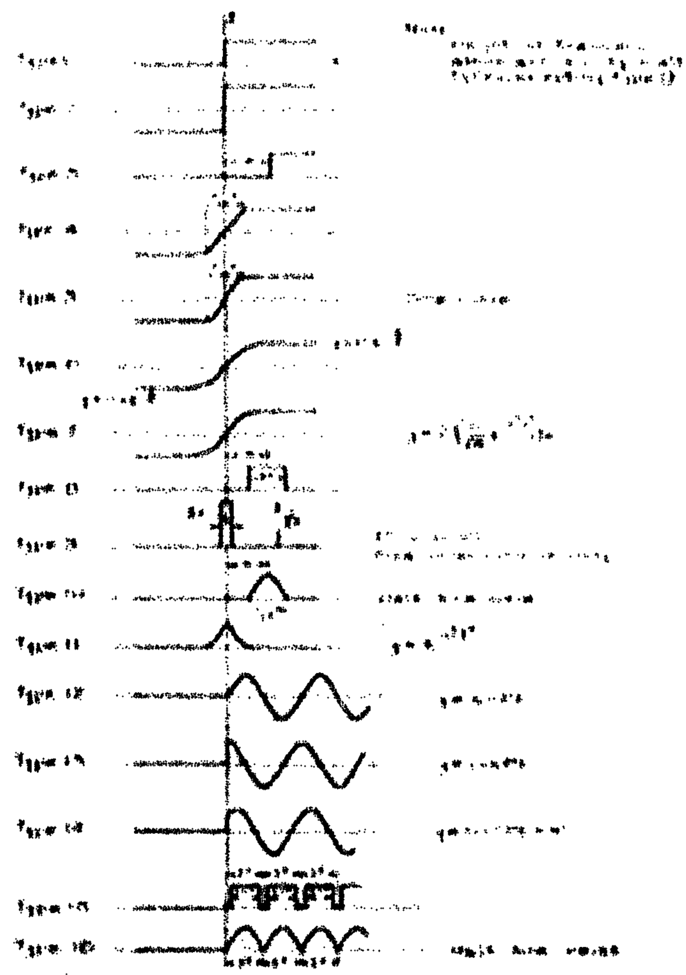

FIG. 29—TRANSIENT TYPES

Now since we are considering only odd harmonics, the first of these may be written

$$a_m = 1/k \int_{-k}^{k} y \sin \frac{m\,\pi\,t}{2\,k}\, d\,t \quad (6)$$

In evaluating the limits, it will be noted that the sine is at its highest or at its lowest value at each limit. It is not necessary to carry the limits to the values of $-k$ or $+k$; instead it is only necessary to begin the integration from some point at the left of t', Fig. 28, and carry it to some point to the right of t''—providing that in each case the integration is stopped at a point where the sine is at its maximum or at its minimum, *i. e.*, at a point where the cosine is zero.

A similar simplification might be made directly of the second of equations (**5**) for the special case where $b_0 = O$. In the case where $b_0 \neq O$, the case is less

simple. It may, however, be shown that in general, when k is large

$$b_m = 1/k \int_{-k+k/m}^{k-k/m} y \cos \frac{m \pi t}{2k} \, dt \qquad (7)$$

At each of these limits the sine is zero, and it is again necessary only to carry the integration from some point at the left of t', to some point at the right of t''. As k is increased indefinitely, the above equations take the form below, where substitutions as before have been made

$$\left. \begin{aligned} s &= \int y \sin pt \; dt \text{ between limits where } \cos p\,t = O, \\ c &= \int y \cos pt \; dt \text{ between limits where } \sin p\,t = O, \end{aligned} \right\} \qquad (8)$$

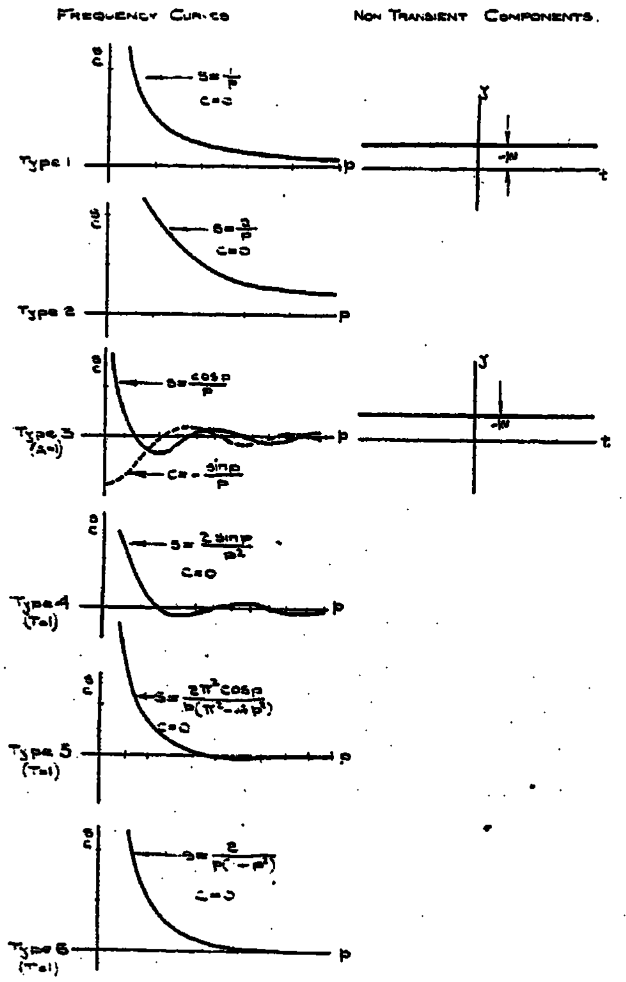

FIG. 30—FREQUENCY CHARACTERISTICS

each integration to be carried *through* the transient.

$$b_0 = \frac{y_{-\infty} + y_{\infty}}{2}$$

In Fig. 29 are shown examples of a number of types of transients, and in Table I are given formulas for the frequency characteristics for the various types. These formulas were calculated with the aid of equations (8). If the values given in Table I are substituted in equation (4) and the integration is carried out, the original transient will be obtained. Plots of a number of the frequency characteristics are given in Figs. 30 and 31.[9]

Further explanation is necessary in connection with transient types 12 to 16 inclusive. In calculating the frequency curve of type 12, the transient is assumed to be built up as shown in Fig. 32. The upper part is

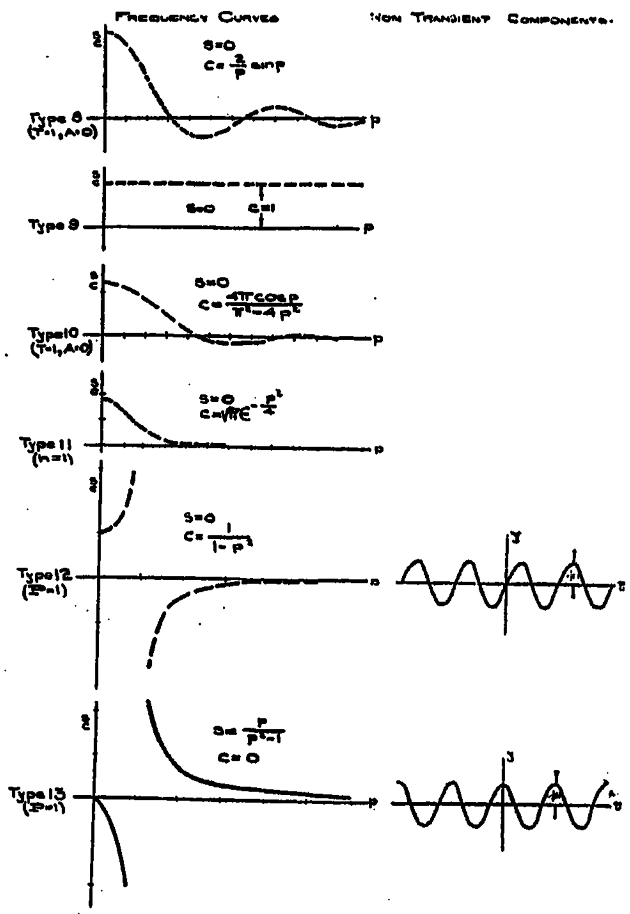

FIG. 31—FREQUENCY CHARACTERISTICS

TABLE I
CONSTANTS OF FREQUENCY CHARACTERISTICS FOR VARIOUS TRANSIENTS

Transient Type	s = sine component	c = cosine component	Non-transient component
1	$1/p$	0	1/2
2	$2/p$	0	0
3	$(1/p) \cos p\,A$	$-(1/p) \sin p\,A$	1/2
4	$\dfrac{2 \sin p\,T}{p^2\,T}$	0	0
5	$\dfrac{2\,\pi^2 \cos p\,T}{p\,(\pi^2 - 4\,p^2\,T^2)}$	0	0
6	$\dfrac{2}{p\,(1 + p^2\,T^2)}$	0	0
7	$(2/p)\,\epsilon^{-p^2/4h^2}$	0	0
8	$\dfrac{2 \sin p\,T}{p} \sin p\,A$	$\dfrac{2 \sin p\,T}{p} \cos p\,A$	0
9	0	1	0
10	$\dfrac{4\,\pi\,T \cos p\,T}{\pi^2 - 4\,p^2\,T^2} \sin p\,A$	$\dfrac{4\,\pi\,T \cos p\,T}{\pi^2 - 4\,p^2\,T^2} \cos p\,A$	0
11	0	$(\sqrt{\pi}/h)\,\epsilon^{-p^2/4h^2}$	0
12	0	$\dfrac{P}{P^2 - p^2}$	$(1/2) \sin P\,t$
13	$\dfrac{p}{p^2 - P^2}$	0	$(1/2) \cos P\,t$
14	$\dfrac{p \sin \alpha}{p^2 - P^2}$	$\dfrac{P \cos \alpha}{P^2 - p^2}$	$(1/2) \sin (P\,t + \alpha)$
15	$\dfrac{\sin n\,p\,T}{p \sin p\,T}$	0	Continuous, similar in form to right-hand part of original, and half the height.
16	$\dfrac{2\,\pi\,T \cot p\,T}{\pi^2 - 4\,p^2\,T^2}$	0	

9. It should be noted that the characteristics shown in Figs. 12, 16 and 17 of the body of the paper are comparative rather than absolute characteristics. They show the ratio at each frequency of the characteristics of the transient under consideration, to the characteristic of transient type 1.

the transient component; the lower part is a non-transient component consisting of a continuous sine wave of half amplitude. The height of the transient component is assumed to be a double exponential curve as shown. The frequency characteristic of this transient is first calculated, after which the value of g is increased indefinitely. At the same time, g must be considered to remain small as compared with k. In this manner the limiting value given in Table I was obtained. The values in Table I for transient types 13, 14, 15, and 16 were calculated in a similar manner. The non-transient components of types 15 and 16 are themselves irregular in shape, and may be broken up by the standard Fourier method into the sum of a series of continuous sine waves. Thus the non-transient component of type 15 is equivalent to

$$n/2 - \frac{\sin n\,\pi}{\pi}\cos\frac{\pi\,t}{T} + \frac{\sin 2\,n\,\pi}{2\,\pi}\cos\frac{2\,\pi\,t}{T} - \ldots$$

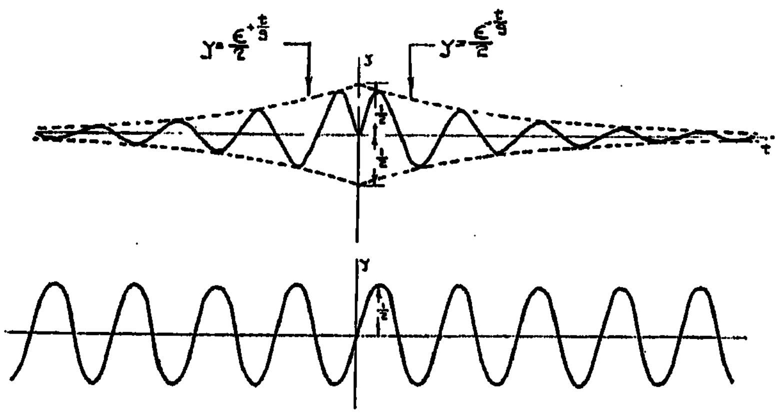

Fig. 32—Development of Transient Type 12

Application to Electrical Problems

Referring now particularly to transient type 1, the preceding theory shows that it may be regarded as the sum of an infinite number of sine waves, of heights equal to $1/p$, added to a non-transient component of height 1/2. The sine waves are individually attenuated in the electrical circuit in a manner which can be calculated by ordinary alternating-current theory, thus obtaining the frequency characteristic for the resultant effect at the receiving end. Then from equation (4) the shape of the received current is obtained.

Let it now be assumed that the transient source is replaced by a sine wave of voltage of frequency $p/2\,n$. At the receiving end, let u be the component in phase with the impressed wave, and let v be the component at 90 deg. Then the frequency characteristic of the received current will be

$$\left.\begin{aligned} s' &= u/p \\ c' &= v/p \end{aligned}\right\} \qquad (9)$$

Substituting in equation (4), we have the formula for the received current caused by an initial transient of type 1

$$y = 1/\pi\int_0^\infty \frac{u}{p}\sin\,pt\,dp + 1/\pi\int_0^\infty \frac{v}{p}\cos\,pt\,dp + u_0/2 \qquad (10)$$

The effect of the non-transient component of the initial transient has been calculated separately, and included in the formula.

In the general case, applicable to any initial type of transient, let s and c represent the initial frequency characteristic. Then the characteristic of the resultant transient will be

$$\left.\begin{aligned} s' &= s\,u - c\,v \\ c' &= c\,u + s\,v \end{aligned}\right\} \qquad (11)$$

Substituting in equation (4), we have the formula for the resultant transient caused by any initial type of transient

$$y = 1/\pi\int_0^\infty (s\,u - c\,v)\sin pt\,dp + 1/\pi\int_0^\infty (c\,u + s\,v)\cos pt\,dp \qquad (12)$$

If the initial transient is composed, in part, of a non-transient component, the effect of the latter must be calculated separately, and added to the result of equation (12).

The effect caused by suddenly impressing a continued sine wave (transient type 12) is given by the formu

$$y = -1/\pi\int_0^\infty \frac{P\,v\sin pt\,dp}{P^2 - p^2} + 1/\pi\int_0^\infty \frac{P\,u\cos pt\,dp}{P^2 - p^2} + u_P\frac{\sin P\,t}{2} + v_P\frac{\cos P\,t}{2} \qquad (13)$$

Examples

1. Let it be required to obtain the value of current in a circuit containing inductance and resistance, caused by impressing a voltage transient of type 1.

The current through such a circuit caused by a sine wave of voltage is

$$I = \frac{E}{R + j\,p\,L} = E\,\frac{R - j\,p\,L}{R^2 + p^2\,L^2} \qquad (14)$$

From this we obtain

$$u = \frac{R\,E}{R^2 + p^2\,L^2}, \qquad v = \frac{-\,p\,L\,E}{R^2 + p^2\,L^2}, \qquad u_0 = E/R \qquad (15)$$

Substituting in equation (10) gives

$$y = 1/\pi\int_0^\infty \frac{R\,E}{p\,R^2 + p^3\,L^2}\sin pt\,dp - 1/\pi\int_0^\infty \frac{L\,E}{R^2 + p^2\,L^2}\cos p\,t\,d\,p + \frac{E}{2\,R} \qquad (16)$$

$$= \frac{E}{2\,R}\,(1 - \epsilon^{-Rt/L}) - \frac{E}{2\,R}\,\epsilon^{-Rt/L} + \frac{E}{2\,R} \qquad (17)$$

$$= E/R\,(1 - \epsilon^{-Rt/L}) \qquad (18)$$

Equation (17) was obtained with the aid of a table of definite integrals.

2. The current through an inductance and resistance in series, caused by suddenly impressing a continued sine wave of voltage may be obtained by substituting

in equation (13) the values of u and v from equation (15). The result is

$$I = \frac{E}{R^2 + P^2 L^2} (P L \epsilon^{-Rt/L} + R \sin P t - P L \cos P t) \qquad (19)$$

Discussion

M. Sasuly (Communicated after adjournment): In regard to the theory of operation of cables as given in the paper, some qualifying remarks may be appropriate. The statement of the mathematical basis on which the character of signals can be predicted (p. 124) is likely to be misinterpreted. It implies that the mathematics of ordinary a-c. theory alone suffices for the determination of the "transient" as well as the "steady state" characteristics of cable and other circuits. This is correct only in the broad sense that the "transient" solution can be made to depend on the "steady state," or "periodic" solution because both are fundamentally of the same mathematical type, the general exponential function. But it is not to be inferred that the one solution can be derived from the other merely by the processes of ordinary a-c. mathematics. Also it must be noted that the identity in type of the two solutions is limited by certain conditions. These involve considerations of the invariability of the circuit "constants" with current and voltage, the linearity of the differential equations, and the "boundary" conditions applying in the given problem. The scope and importance of these restrictions must not be overlooked. In many practical problems they inevitably introduce considerable mathematical complexity.

The possibility of deriving the "telegraphy" solution of the cable problem directly from the a-c. solution has been a matter of controversy among a number of cable engineers. The issue does not concern merely the question of mathematical method. It is fundamental in the very practical problem of improved signalling through ocean cables by means of high-frequency currents. (Cf. Wagner, "E. T. Z." 1910, p. 163; 1912, p. 1289. Malcolm, Theory of the Submarine Telephone and Telegraph Cable, 1917, pp. 248-251). Consequently it is appropriate to call attention to what is perhaps the essence of the theoretical aspects of the problem.

Under the restrictions referred to previously the "transient" and "periodic" terms constitute the *general* solution. This is composed of a sum of terms of the type of the *particular* solution, the latter corresponding to the "periodic" solution. This fact is seen with little difficulty in the Fourier integral solution of the cable problem, first given by Kelvin about 1854 (Math. and Phys. Papers, II, pp. 48-49), and treated by a number of subsequent writers, with particular concreteness by Heaviside (*e. g.*, Electromagnetic Theory, II, p. 125 (1895)), Poincare (Théorie de la Propagation de la Chaleur, 1895, p. 134; L' Eclairage Electrique, 40, p. 162, 1904), and Wagner ("E. T. Z.," l. c.; Mitteil, Teleg. Vers., V-VI, 1909-1912). The applicability of the Fourier integral solution to circuit networks has been shown by several writers, especially by Wagner (*Archiv. f. Electrotechnik*, 4, p. 162, 1916), Carson (TRANS. A. I. E. E., 38, p. 359, 1919), and Fry (*Phys. Rev.*, 14, p. 118, 1919); also by Pomey (*Revue Gen. de l'Elec.*, 5, p. 204, 1919). In the solution of cable and network problems by Heaviside's Expansion Theorem (l. c., p. 127), the correspondence of the "transient" and "periodic" terms to the constituents of the general solution is no longer apparent. But the correspondence has been explicitly established in the very lucid and direct analytical proof of the Expansion Theorem given by Carson (Phys. Rev., 10, p. 217, 1917).

It is true then that the general solution of ordinary circuit problems can be formally derived from the same type as the a-c. solution. But this fact must not lead to under-estimating the complexity of the process of actually constructing the solution. The use of integral equations, Bessel series, (*e. g.*, Carson, Fry, l. c.) and other advanced mathematical processes is not merely a matter of elegance. Advanced methods are unavoidable in all but very simple and certain special types of circuit problems. Moreover, certain important aspects of the solution are entirely outside the scope of ordinary a-c. methods. These relate to the properties of the *indicial impedance function* (Cf. Carson, l. c.) associated with a circuit system. The roots of this function determine the "natural modes of motion" of the system. A study of these would appear not only to facilitate the solution of given circuits, but also to admit the possibility of designing circuits of predetermined characteristics.

J. W. Milnor: The foregoing discussion indicates that the scope of the paper has been somewhat misunderstood by the writer of the preceding communication, and it may be misunderstood by others. An original method of calculating transients is developed in the Appendix, and it is clearly shown that a transient may be directly determined from a knowledge of the behavior with continued sine wave alternating currents, of the electrical circuit under investigation. The amount of labor involved in the solution is of course by no means nil, since it is necessary to know the behavior of the circuit with alternating currents throughout a range of frequencies; and to take the step from alternating-current theory to the transient solution, it is necessary to make a definite integration which must be performed either analytically, graphically or mechanically. However, the method is straightforward, and does not involve Bessel series, operational methods, or a determination of roots of a function. The results are summed up in equations (10), (12) and (13) of the Appendix. This general method should not be confused with the subject of "transient oscillations" or "high-frequency signaling," which has been covered by different writers.

There are certain restrictions to the method of calculating transients given in the Appendix which while ordinarily not important, should perhaps be specifically mentioned. It is assumed throughout the mathematics that the circuit parameters are invariable with current and voltage,—although it is permissible that they might change with frequency. If the method is used in the solution of a circuit (of academic interest only) which contains no resistance, misleading results will in general be obtained. This condition follows from the fact that the method of development assumes that the quantity k although large, is finite. It is possible to apply the method for solving electrical circuits containing inductance and capacity only, by taking certain precautions, although it appears inadvisable to discuss such considerations here because of their complication. There is a slight omission relative to equation (7) of the Appendix; it should have been stated that this equation is valid *for values of m greater than one*, when k is large.

The suggestion has been previously made at different times that there might be some direct relation between the "telegraph" solution of the cable problem and the alternating-current solution or that it might be possible to derive one from the other. As far as the author knows, however, this is the first time that a mathematical justification for such a relationship has been published.

While the use of this method for calculating general transient effects in an electric circuit involves the performance of an integration,—such an integration may usually be avoided in investigations of ocean cable lines and apparatus. This simplification is made possible by the expedient of determining once for all what *frequency characteristic* a cable circuit must have in order to transmit satisfactory signals. Examples of such frequency characteristics are shown in Fig. 12 of the paper. A certain degree of variation from these is of course possible in practise, since a certain amount of variation in the shape of received signals is permissible. The behavior of an ocean cable or of its apparatus may therefore be directly determined by investigating its behavior with alternating currents,— *i. e.*, its frequency characteristic,— throughout the range of frequency from zero to about twice the dot frequency.

Printing Telegraph Systems Applied to Message Traffic Handling

BY A. H. REIBER

Associate, A. I. E. E.

Manager of Sales & Engineering, Kleinschmidt Electric Co., Brooklyn, N. Y.

Review of the Subject.—*Ever since the building of the first practical automatic telegraph instruments by Vail in America in 1837, and Wheatstone in England in 1841, an ever-increasing amount of the world's high-speed communication has been carried on by the printing telegraph. While these early machines were built primarily for the use of the European Government Telegraphs or the large American telegraph companies, the developments of the last few years have produced an instrument which is a practical working tool for the service of modern commercial and industrial enterprises.*

This paper discusses some of the economic principles which determine the applicability of the automatic printing telegraph to present-day communication problems. Examples are given of the application of this type of apparatus to modern business conditions and the fundamental fact is demonstrated that whenever speed is essential in communication, consideration should be given to the automatic printing telegraph.

The discussion is limited to those forms of light traffic load printing telegraph systems which have been developed particularly for linking together the departments of the factory, the terminal points of the railroad, the branches of the banking, the brokerage or the selling organization or the units of any other large corporation.

A description is then given of the principle of operation of three such systems, somewhat in detail, as there is very little literature on the subject.

CONTENTS

OBJECT AND SCOPE OF THE PAPER

In transmitting intelligence from one point to another, the requirements of one case differ widely from those of other cases. Sometimes speed of service is the important item, while under certain other conditions speed may be sacrificed for the sake of economy, or perhaps both speed and economy may have to be sacrificed for some other consideration—for instance, the transmission of original documents.

To meet the needs of these different problems, various types of communication systems are now in operation and it is becoming more and more of a problem to choose the system that will best meet the requirements of a given case. The business executive instinctively turns to the systems he is used to, and in many instances does not take the time to find out what other methods of communication are available. Too often a messenger service is used where mechanical conveyors of some kind should be in operation, or additional telephones are pressed into service where a printing telegraph system might be installed to advantage. Perhaps one of the most direct causes of this condition is a lack of literature on the subject.

It is the object of this paper, therefore, to point out very briefly some of the advantages of a branch of the communication art which is not very well-known to the average business man or industrial plant engineer and to describe briefly the operation of a few systems in this class.

The systems referred to are automatic printing telegraph systems. These may be divided into two classes:

1. Heavy traffic load systems.
2. Light traffic load systems.

Where the traffic load is approximately 80 words per minute or over, the volume may be handled with heavy traffic load systems. Smaller loads do not, as a rule, warrant the installation of an elaborate heavy traffic load system, but may best be handled with light traffic load systems. Of course, such conditions as fluctuations in traffic, speed of service or other considerations may justify the installation of a heavy traffic load system in cases where the average traffic load is less than 80 words per minute, for instance, where the traffic often fluctuates far above normal and where speed of service is important. For a general discussion, however, the above division may be taken as applying to a majority of cases.

Heavy traffic load systems have been described in various other papers[1] presented before the Institute but very little mention has been made of the light traffic load system. The following discussion will therefore be limited to three light traffic load systems developed within the last five or six years, namely:

1. The Morkrum "green code" system.
2. The Western Electric "start stop" system.
3. The Kleinschmidt system.

APPLICATIONS OF PRINTING TELEGRAPH EQUIPMENT TO COMMERCIAL CONDITIONS

The three most important savings effected with printing telegraph systems are savings of time, line wire and labor.

The distance between the sending and receiving station does not necessarily have to be as great for the sake of economy, as is often assumed. A printing telegraph system will often pay for itself by the saving of time alone. Take, for instance, a concern where orders are received at a central point, to be filled, part at one department and part at other departments in the same plant. Ordinarily such orders are sent to the first de-

Presented at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

1. John H. Bell, "Printing Telegraph Systems." A. I. E. E. TRANS. Vol. XXXIX, Part 2, 1920.

partment where certain items are placed on a truck together with the orders. The truck is then sent to the next point, where additions are made, and so on until the truck passes through all stations involved. This method requires a considerable amount of time which may be saved by using a printing telegraph system. If a receiving set is installed in each department, that part of an order which applies to the first department may be sent by wire to the first department, and that part which applies to the second department may be sent to the second department, etc. All this may be done automatically while making out the invoice. In one operation, therefore, the invoice is made out and the order is sent to the proper sections of the plant. All departments receive their parts of the order at practically the same time, and each may therefore start work immediately without having to wait for the others. The items are then brought together in the shipping room where they are checked against the original order and sent out. This is one instance where the saving of valuable time justifies the installation of a light traffic load printing telegraph system.

To illustrate a condition where line wire may be saved, we may assume a problem where there is a need for rapid transmission of a fairly large volume of traffic from New York to Chicago. Let us consider that speed is an important factor, and that, during the busy hours, the traffic load is over 40 words per minute. If Morse operators were placed at each point, an average of between 30 and 40 words per minute would be the most that could be handled, and to handle the traffic two line wires would have to be leased. The cost of the wires with two Morse operators at each end would be approximately as follows:

Two leased wires (approximately)	$40,000	per year
Four Morse operators at $1800 per year........................	7,200	" "
	$47,200	" "

The installation of a light traffic load system makes the second line wire unnecessary. The annual charges under this arrangement would be approximately as follows:

One Leased wire (approximately)..	$20,000	per year
Two Operators at $1200 per year...	2,400	" "
*Two Maintenance men at $1800 per year......................	3,600	" "
Annual charges on equipment figuring a depreciation over a period of 8 years, interest, taxes, administration and repair parts (approximately)	1,000	" "
	$27,000	" "

*This figure is kept high for purposes of illustration. A still greater saving would be shown in an actual case, as the maintenance men would either be free most of the day to do other work, or would act as operators, thus wiping out the $2400 operator charge.

By using automatic equipment, the speed may be very materially increased at a saving of approximately $20,000 per year over what it would cost to increase the speed by adding additional Morse operators. This is an instance where a saving of line wire more than justifies the installation of a light traffic load printing telegraph system.

Perhaps the best illustration of how a saving of labor can be effected, by the installation of automatic equipment, is the case of press associations. At one time a well-known press association employed as many as 100 messengers to deliver news to various newspapers scattered throughout a city. Light traffic load printing telegraph systems are now giving these papers far better news service, and, by means of periodic inspections, just a few maintenance men keep the equipment in order. At each newspaper office a receiving set is installed, and one transmitting set at the central bureau sends news to all of the newspapers simultaneously. The editors at the various newspapers tear off the printed copy from time to time but, as paper is fed into the printers automatically, no other attention is necessary.

These are only a few of the cases where automatic equipment may be used to advantage. Many others might be mentioned. Line wire plays but a small part in the first example, and in the second example this system of communication will still prove advantageous even if no saving in labor is shown. In all three cases, however, speed is essential and automatic equipment offers a promising solution of the problem.

The system chosen must be capable of operating at rates of speed slightly higher than that required for handling the average traffic load. At first glance it might appear that to increase the speed of a set above the point where it can handle the traffic under normal conditions would be destructive to the machines. Such is not the case, however. With equipment designed for a range of between 40 and 80 words per minute, the wear is the same for every 1000 words printed, no matter whether that 1000 words is printed at a speed of 40 words per minute or 80 words per minute. On long or poor lines, speed is limited by the carrying capacity of the line, but for shorter distances the speed should be regulated, not from the standpoint of wear on the machines, but in accordance with the traffic load. It has even been found practical to speed up above the sending capacity of one operator and to employ two operators at the sending station during the busy hours.

Methods used in Common by Systems to be Described

All three of the systems to be described make use of the following basic methods:

Messages are first prepared as perforations in a paper tape by typists familiar with a standard typewriter keyboard and the tape is then fed through a

transmitter which translates the perforations into line signals and steps the tape forward one character at a time. At the other end of the wire the message is automatically received on a printer in page form.

Each system employs a different type of perforator but the perforated tape prepared by any one of them

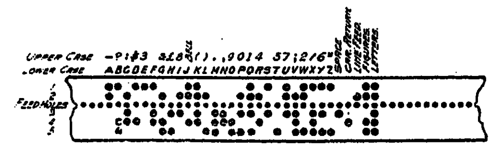
Five-unit code.



Specimen of tape with all characters perforated.

Fig. 1—Combinations of Positive and Negative Impulses Representing the Different Characters

may be used on any of the three systems and also on the multiplex system used by the Western Union Telegraph Company.[2] Likewise each system employs a different type of printer but certain standards are adhered to so that any one of them may be used inter-

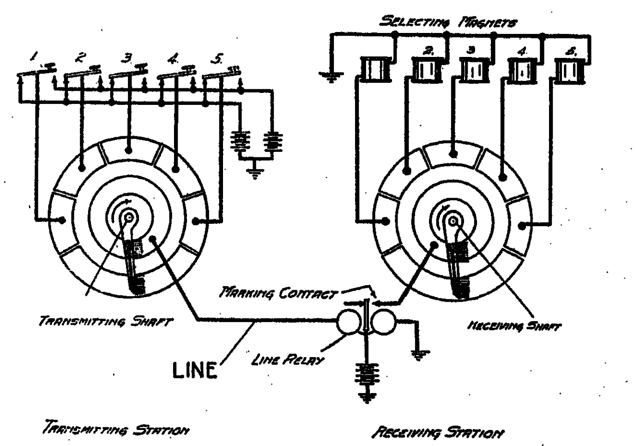


Fig. 2—Schematic Wiring Diagram of Transmitting and Receiving Apparatus

changeably with the printers used in the multiplex system.[2]

A five-unit code provides 32 combinations of positive and negative impulses as in the multiplex system. These impulses are used to operate five selecting magnets in the printer. For every character selected, one or more of the selecting magnets is operated. This makes it possible to select any one of the 26 letters of the alphabet or any one of the functions such as "space," "carriage return," "line feed," "figure shift," or "letter shift." Counting both the upper and the lower case positions, 52 letters, numbers or other characters are possible. Fig. 1 shows the various combinations of positive and negative impulses that represent each of the different characters.

Motor-driven distributors are employed at both the sending and the receiving stations to transmit the line signals from the sending station at a uniform rate of speed and to receive and interpret these signals at the receiving station. The speed of the motors at each end of the line is maintained uniform by governors.

Fig. 2 is a schematic wiring diagram showing the principle involved in sending and receiving.

The speed at which signals are sent over the line depends on the speed of the transmitting shaft at the sending end. As the line relay at the receiving end

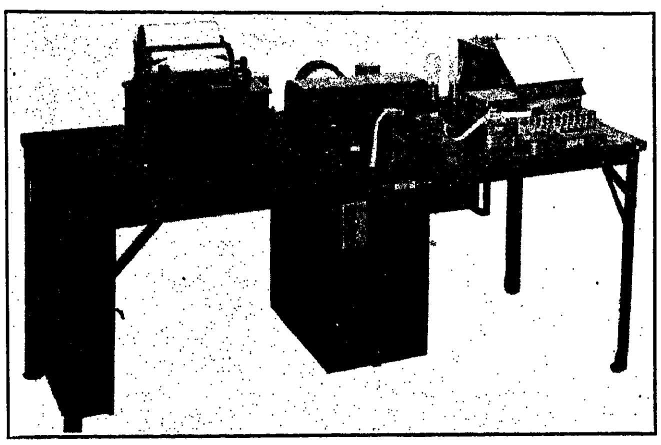

Fig. 3—Morkrum Terminal Set

operates in accordance with these signals, in order to select any one of the five selecting magnets in the printer, the receiving brush arm must pass over the corresponding receiving segment at the same time that a marking impulse is sent over the line and the line relay tongue is resting against its marking contact.

When the transmitting station stops sending, the receiving brush arm is held stationary by a magnet. At the beginning of each set of signals, a start impulse precedes the first selecting impulse and operates this magnet thereby releasing the receiving brush arm. The five selecting impulses follow and the proper selecting magnets are operated successively as the brushes pass over the receiving segments.

These fundamental features apply to all three systems but the method by which line signals are transmitted from the sending station and interpreted at the receiving end is quite different in each system.

Morkrum "Green Code" System

Fig. 3 shows a Morkrum terminal set. The perforator is shown at the right and the printer at the left with the transmitter and distributor between them.

2. John H. Bell "Printing Telegraph Systems," loc. cit.

Transmission. Fig. 4 is a schematic wiring diagram of the circuits involved in transmitting signals over the line.

The tape that is prepared by the perforator is fed through the transmitter and is stepped forward once for each revolution of the transmitting brush arm, Fig. 4, in the distributor. Fig. 5 shows the tape-feeding mechanism. When the contact *A B*, in the distributor, is closed, the transmitter magnet moves lever *A C* clockwise about its pivot *A D* and feeds

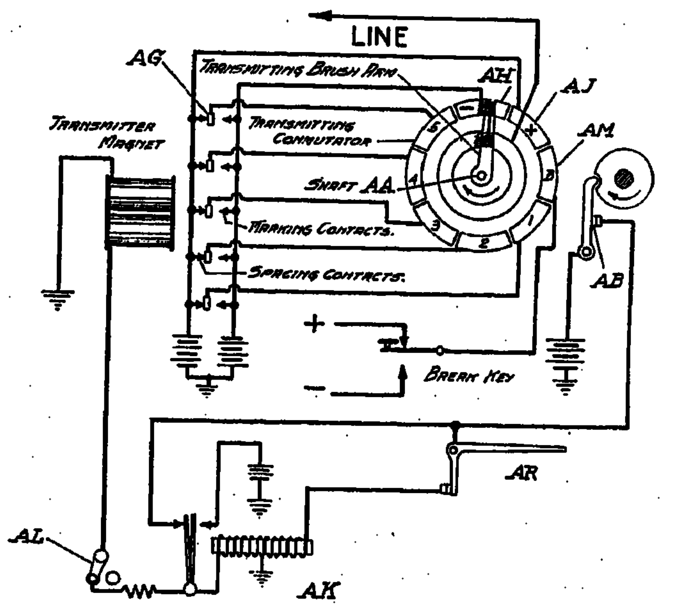

Fig. 4—Schematic Wiring Diagram of Transmitting Circuits

the tape forward. When the transmitter magnet is de-energized it allows the tape pin contact levers *A E* to move counter-clockwise about their pivot point *A D* until the pins *A F* reach the level of the tape. If a pin is blocked by the tape the contact tongue *A G* remains against its spacing contact. If the perforations in the tape permit a pin to go through the tape, however, the corresponding contact tongue *A G* moves over against its marking contact. There are five pins *A F* and five contact tongues *A G* and each contact tongue is connected to a segment on the transmitting commutator. Consequently when the transmitter magnet is de-energized each segment will be connected to marking or spacing battery according to the perforations in the tape. Segment *A H* is permanently connected to marking battery and segment *A J* is permanently connected to spacing battery. As the transmitting shaft *A A* revolves, the brush first sends a spacing signal which is called the start impulse and then the selecting impulses in accordance with the code combination set up in the transmitter.

The speed may be set so that transmission is carried on at any desired rate from 40 to 65 words per minute.

For every revolution of the transmitting shaft, eight impulses are sent to the receiving station. Two are for synchronizing purposes, one is for sending a bell signal to the distant station without interfering with the message being transmitted, and five are for selecting purposes. Communication is therefore carried on at a line frequency of eight units or 4 cycles per character. Sixty words per minute represents a line frequency of 24 cycles per second.

The transmitting shaft is not stopped after each revolution but continues to revolve until transmission is stopped by the raising of the arm *A R*. Normally when the transmitter cam contacts *A B* are closed, current flows through both windings of the differentially wound auto-stop relay *A K*. The transmitter magnet is therefore operated but as the current flows through the auto-stop relay windings in opposite directions, the latter will not be operated. If, however, the auto-stop arm *A R* is lifted and the transmitter cam contacts closed, current will flow through the transmitter magnet and through only one winding of the relay. This operates both the transmitter magnet and the relay— the relay locking itself in the operated position. The transmitter magnet remains energized until the auto-stop arm is again lowered. During this time the pins are held down and transmission of code combinations is stopped, but the transmitting brushes continue to revolve, sending out starting impulses once every revolution.

If for any reason, it is desired to repeat a character a number of times the switch *A L* may be opened, thereby opening the circuit to the transmitter magnet and allowing the tape to remain stationary with the proper marking and spacing battery combination set up at contact tongues *A G*. Inasmuch as the tape is not stepped forward, the same character is sent over

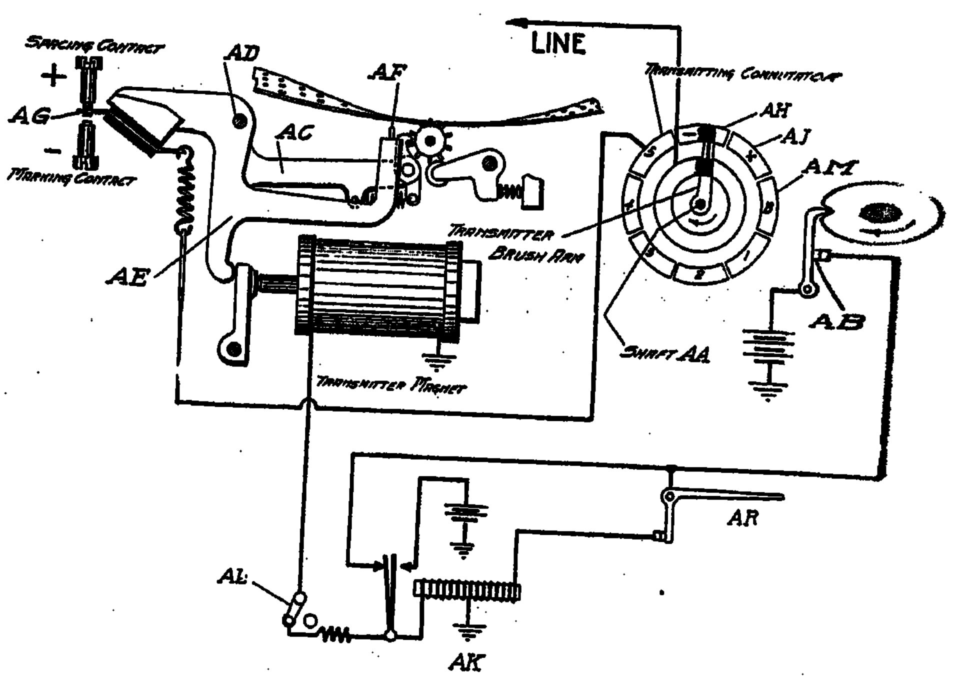

Fig. 5—Tape-Feeding Mechanism

and over again as long as the switch *A L* remains open and the brush arm continues to revolve.

In order to signal quickly to the distant station an extra segment *A M* (Fig. 4) is provided on the transmitting commutator. When the break key is held down, marking battery is connected to the segment *A M* and a marking impulse is sent over the line immediately after the start impulse. This impulse operates a bell at the receiving station in a manner which will be described later.

Reception. Fig. 6 shows the manner in which the receiving units are connected electrically.

The brush arm *A N* is mounted on a sleeve together with the start magnet cam *A S* the break circuit cam *A P* and the stop cam *A T*. A motor drives this sleeve through a clutch, at a speed slightly higher than the speed of the transmitting shaft at the sending end. This increased speed is compensated for by delaying

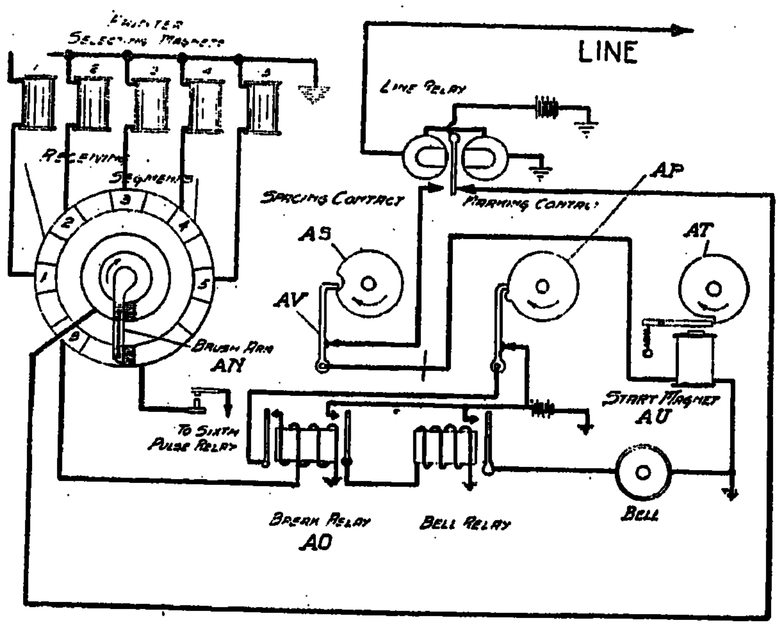

Fig. 6—Electrical Connections of Receiving Units

the brush arm after each character sufficiently to keep the sending and receiving stations in step.

Normally the brush arm is held stationary by the start magnet *A U* with the start magnet contact *A V* closed. When transmission is started a spacing impulse precedes the bell and selecting impulses, a circuit is completed through the spacing contact of the line relay, the start magnet is operated, and the brush arm is released. After the brush arm is released it revolves at a rate of speed slightly higher than that of the transmitting brush arm but the distance from center to center of the receiving segments is such that the time required for the brushes to pass from the center of one segment to the center of the next is equal to the time required for the transmission of one impulse of unit length. The brushes therefore, pass over the center of the receiving segments durng the middle of the incoming impulses.

Battery is connected to the solid ring of the receiving commutator whenever the line relay tongue moves over against its marking contact. Each one of the receiving segments is connected to a corresponding selecting magnet in the printer. If, therefore, the brush passes over receiving segment No. 1 while the line relay tongue is against its marking contact the first selecting magnet will be energized, and similarly with the second, third, fourth and fifth selecting magnets. As the brushes pass over each segment in turn they will or will not carry current to each successive selecting magnet according to whether or not the line impulse then being received is of marking or spacing polarity.

If a marking impulse is received directly after the start impulse the line relay tongue will be resting against its marking contact as the brushes pass over the bell segment *B* and the break relay *A O* will be operated. This relay in turn operates a bell through the bell relay. Attached to the brush arm sleeve is a break cam *A P* which breaks the locking circuit to the quick-acting break relay *A O* just before the receiving brushes reach the segment *B*. If the receiving brushes reach this segment before the break key at the transmitting station is released, the break relay will again be operated before the slow acting bell relay has time to open the circuit to the bell. Only one bell signal is transmitted no matter how long the break key is held down.

After the brushes pass over the bell segment and the five selecting segments they complete a circuit through the marking contact of the line relay to the sixth pulse relay in the printer.

The printer, Fig. 7, used with this system, prints from a typewheel, which rotates to the proper letter and is then thrown forward against the paper. After

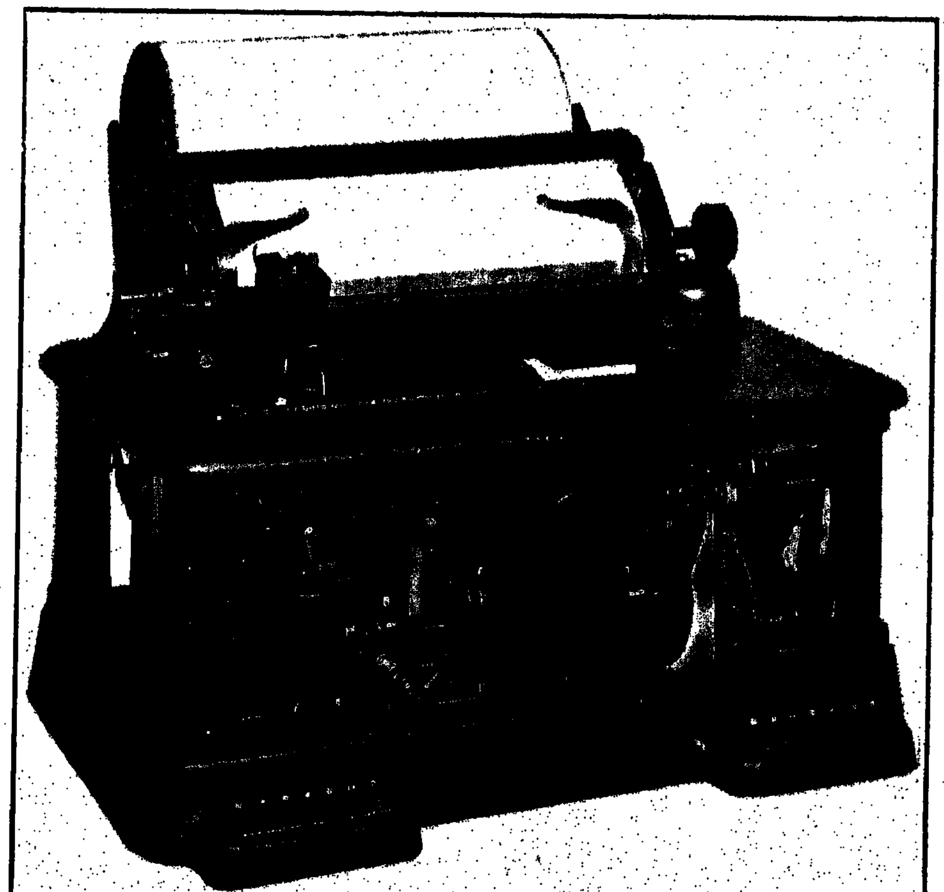

Fig. 7—Printer Used with Morkrum "Green Code" System

each letter is printed the typewheel itself is stepped to the right, the paper remaining stationary, and at the end of each line of printing the paper is moved upward.

When a selecting magnet is energized, a disk or interference plate is rotated as shown in Fig. 8. There are four interference plates controlled by the first, second, third and fifth selecting magnets. The fourth selecting magnet does not move an interference plate but operates the fourth-pulse relay which in turn decides the direction of rotation of the typewheel.

The arrangement of the five-unit code (Fig. 1) is such that there are exactly 16 combinations which contain the fourth pulse and 16 combinations which do not contain the fourth pulse. The printer is arranged, therefore, so that whenever a code combination containing the fourth pulse is received, the typewheel revolves counter-clockwise and when a code combination that does not contain the fourth pulse is received

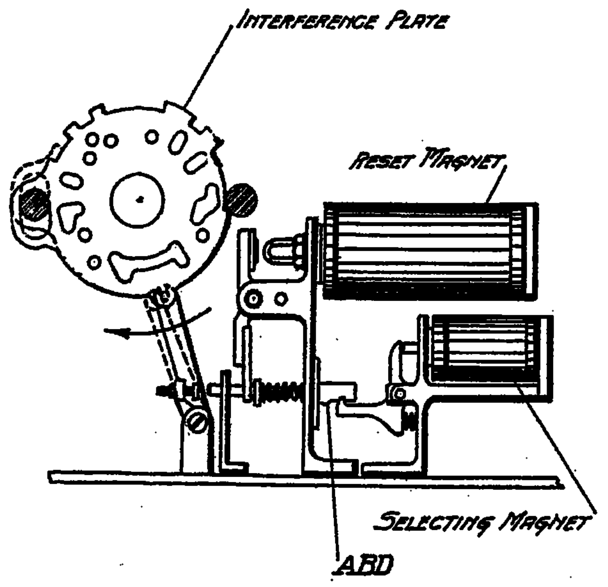

FIG. 8—ROTATION OF INTERFERENCE PLATE

the typewheel revolves in a clockwise direction. The degree of rotation of the typewheel, for any letter, is a fraction of one-half of a revolution of the typewheel in either direction depending on the character selected.

After the interference plates are moved, the sixth-pulse relay (Fig. 9) is operated and supplies battery to the drum magnet. When the drum magnet is energized it pushes a set of stop pins against the inter-

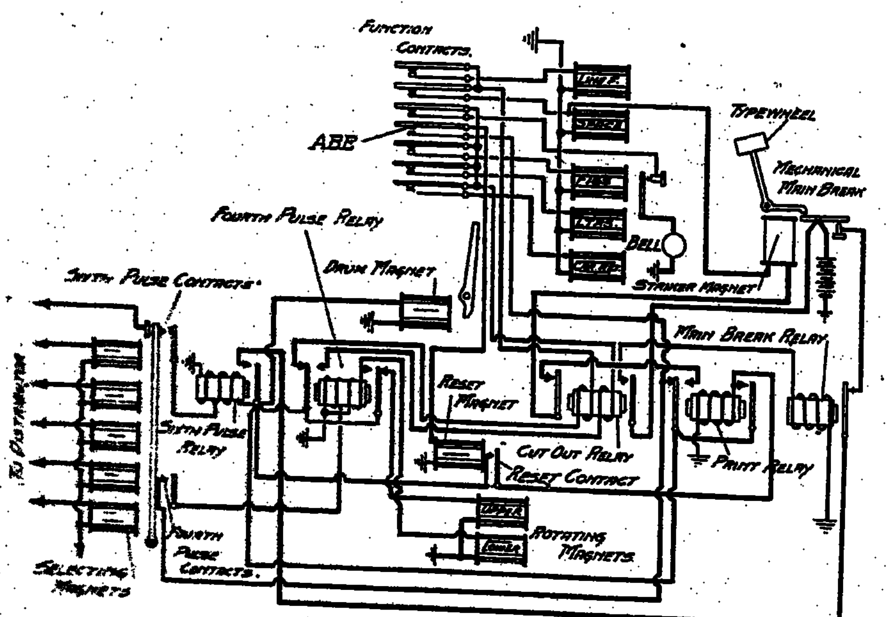

FIG. 9—DIAGRAM OF PRINTER CIRCUITS

ference plates. These plates (Fig. 10) are cut out in such a way that only two pins are allowed to go through all four plates at any one time.

If the letter "E" for instance is selected, the first interference plate is moved and the operation of the drum magnet pushes two pins through the interference plates. These pins *A Y* and *A Z*, are on opposite sides of an index arm *A W* which is connected to the typewheel by means of the square shaft *A X*. Inasmuch as the "E" code combination does not contain the fourth pulse, the fourth-pulse relay will not be operated and the operation of the sixth-pulse relay will connect battery to the *upper* set of rotating magnets thereby rotating the typewheel clockwise until the index arm *A W* strikes the pin *A Y*. If, however, the letter "D" is selected, not only the first selecting magnet but also the fourth selecting magnet is energized

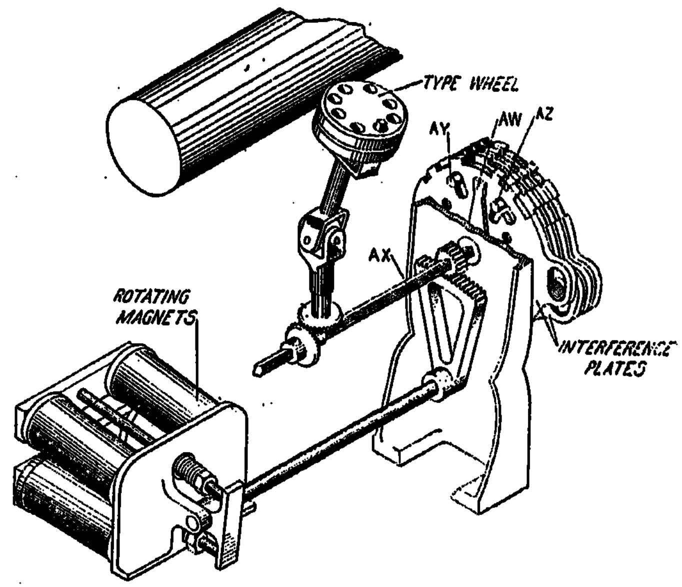

FIG. 10—OPERATION OF INTERFERENCE PLATES

thereby operating not only the first interference plate but also the fourth-pulse relay. In this case the same pins are pushed through the interference plates as for the letter "E" but in the case of the letter "D" selection, the operation of the fourth-pulse relay directs battery to the *lower* set of rotating magnets, when the sixth-pulse relay is operated. The typewheel is then rotated counter-clockwise until the index arm strikes the pin *A Z*.

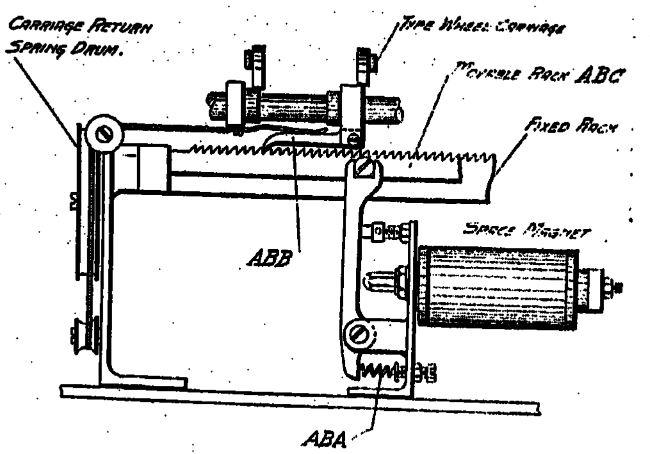

FIG. 11—OPERATION OF SPACE MAGNET

When the pins are pushed through the plates a contact *A B E* (Fig. 9) is closed and the reset magnet (Fig. 8) is operated. The operation of the reset magnet restores the trip rods *A B D* and closes the reset contact (Fig. 9). When the reset contact is closed a circuit is completed through the print relay contacts and the striker and space magnets are energized. The operation of the space magnet (Fig. 11) compresses a spring *A B A* which in turn spaces the typewheel carriage forward when the space magnet is released. The

striker magnet throws the typewheel against the platen thereby printing the selected character and opening the mechanical main break contact. The opening of the main break contact (Fig. 9) breaks the locking circuit to the sixth-pulse relay, and as the current to all of the magnets is routed through the sixth-pulse relay contact, battery is disconnected from the drum magnets, the rotating magnets, the striker magnet and the space magnet. The typewheel is spaced one space forward and the printer is again ready to gothrough the same cycle of operations for the next selected character.

Spacing between words, shifting to print figures, and the other functions, are controlled by function contacts (Fig. 9) located over notches cut in the top edges of the interference plates. When the "space" signal is received, for instance, the third interference plate is moved and a notch, under the space contact, allows the latter to close thereby connecting battery to the space magnet through one winding of the cut-out relay. When the space magnet is energized, the cut-out relay is also operated, closing a circuit to the main break relay. This relay opens the locking circuit of the sixth-pulse relay and disconnects battery from the space magnet. During this operation the reset magnet and the print relay are operated as usual but no printing occurs inasmuch as the circuit to the striker magnet is broken through the back contact of the cut-out relay.

FIG. 12—WESTERN ELECTRIC TERMINAL SET

On the under side of the typewheel carriage are mounted two pawls *A B B* (Fig. 11) which mesh with a fixed rack and a movable rack *A B C* located directly under them. When the spacing magnet is energized, the movable rack is moved to the left so that one of the pawls drops into the next tooth on the rack. When the spacing magnet is de-energized, the movable rack is returned to its normal position by the spacing spring *A B A* and moves the carriage forward one space.

When a "carriage return" selection is received, the carriage return function contact operates the cut-out relay and a carriage return solenoid. This solenoid raises a bar located between the two racks, lifting the pawls clear of the teeth. The typewheel carriage is then drawn to the left for a new line of printing by a cord wound around a spring-operated drum.

When the "figure shift" signal is received, the figures magnet is energized through the figures function contact and one of the windings of the cut-out relay. The figures magnet moves the typewheel upward, ready for the printing of numbers or punctuation marks.

When the "letter shift" signal is received the letters function contact is closed, thereby operating the letters magnet which releases the catch that holds the typewheel in its upper case position.

When the "line feed" signal is received, a line feed magnet is operated by the line feed function contact and, by means of a pawl and ratchet mechanism, feeds the paper upward ready for a new line of printing.

WESTERN ELECTRIC "START STOP" SYSTEM

Fig. 12 shows a Western Electric terminal set. The perforator is shown at the right with the printer directly behind it and the transmitter is shown at the left in front of the distributor.

Transmission. Fig. 13 is a schematic wiring diagram of the circuits involved in transmitting signals over the line.

The Western Electric system is equipped for either direct keyboard or perforated tape operation and may be operated at any desired speed from 40 to 65 words per minute.

The tape that is prepared when the perforator is used is fed through the transmitter and is stepped forward once for every revolution of the transmitting brush arm *B B* in the distributor. Fig. 14 shows the tape feed mechanism. When the brushes pass over the transmitter segment *B C* (Fig. 13) the transmitter magnet (Fig. 14) moves lever *B D* about its pivot *B E* and feeds the tape forward.

When the transmitter magnet is de-energized, the tape pins *B F* move upward until the tops of the pins reach the level of the tape. If a pin is blocked by the tape the contact tongue *B G* remains against its spacing contact. If the perforations in the tape permit a pin to go through the tape, the corresponding contact tongue *B G* will move over against its marking contact. There are five pins *B F* and five contact tongues *B G* and each contact tongue is connected to a sending relay (Fig. 13). Consequently when the transmitter magnet is de-energized and battery is applied to the marking contacts, the proper sending relays will be energized according to the perforations in the tape. Whenever a sending relay is energized, it closes a

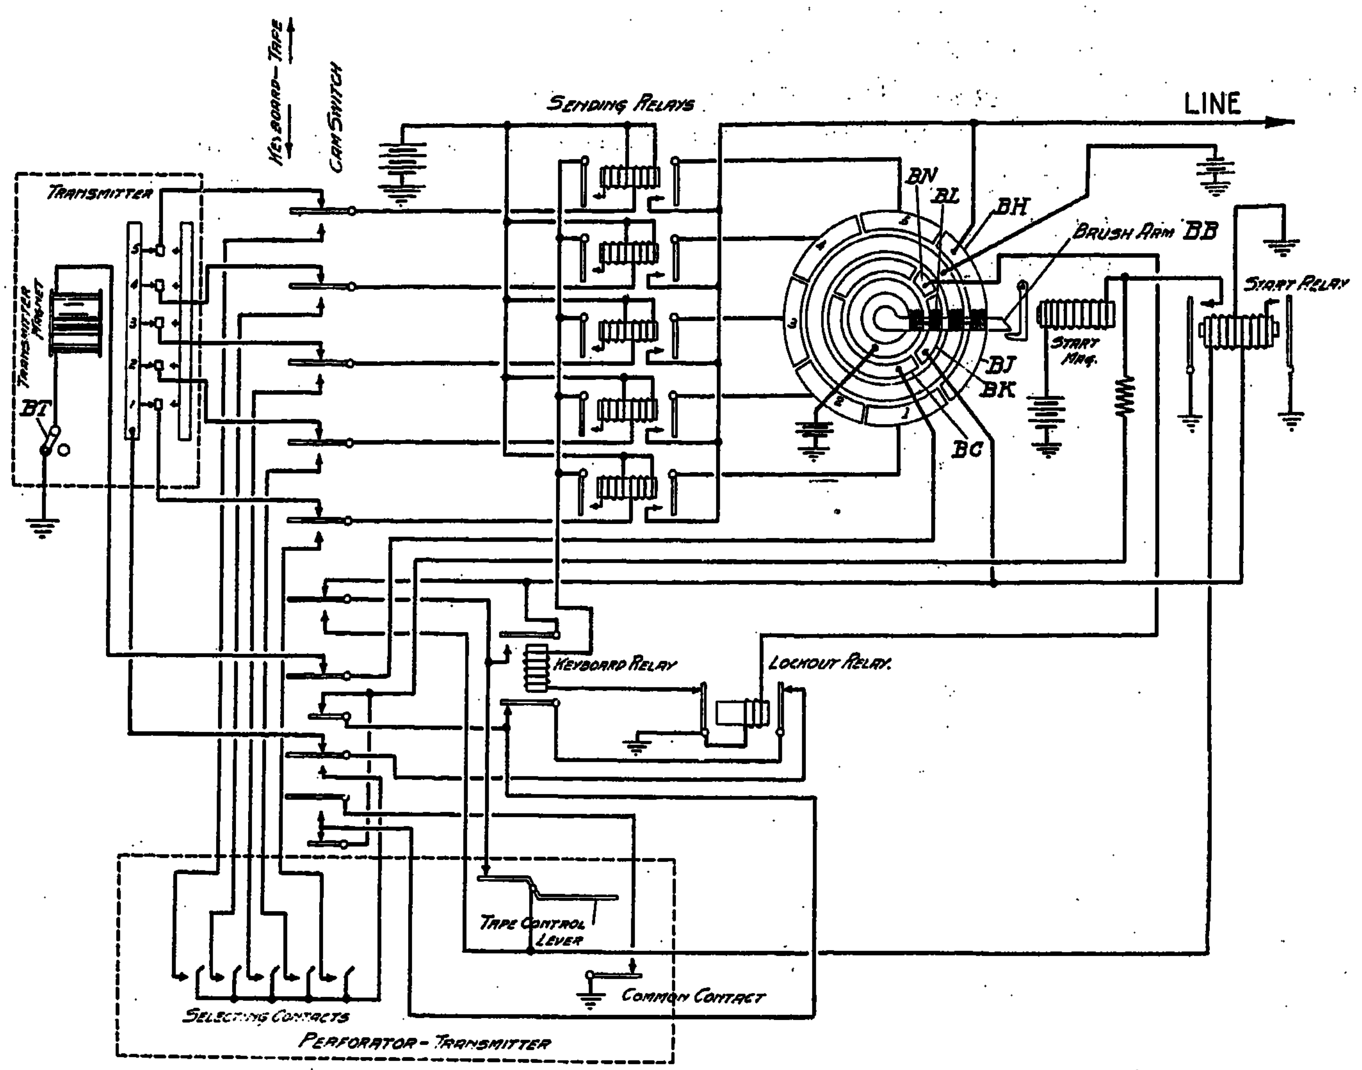

FIG. 13—SCHEMATIC WIRING DIAGRAM OF TRANSMITTING CIRCUITS

circuit to the corresponding transmitting segment and a locking circuit holds the relay operated.

To send a marking impulse, the line is closed, and to send a spacing impulse the line is opened. Segments *B H* and *B J* are wired so that when the brushes pass over segment *B H* the line will be closed and when they pass over segment *B J* the line will be opened. As the transmitting brushes revolve they first send out a spacing signal which is called the start impulse and then the selecting impulses in accordance with the code combination set up in the sending relays.

In order to send positive and negative impulses to the receiving station, a pole-changer may be operated from the transmitting segments. The signals are then sent over the line from the pole-changer.

For every revolution of the transmitting brushes, seven impulses are sent to the receiving station. Two are for synchronizing purposes and five are for selecting purposes but one of the synchronizing impulses is longer than the other. Communication is therefore carried on at a line frequency of between seven and eight units or between three and one-half and four cycles per character. Sixty words per minute represents a line frequency of a little over 21 cycles per second.

The transmitting brush arm *B B* is stopped once every revolution but is almost immediately released provided the tape control lever contact is closed. If, however, the tape control lever contact is open when the local brushes *B L* reach the segment *B K*, the circuit to the start relay will be open and the start magnet will not be operated. The brush arm will then come to rest so that the transmitting brushes rest on the segment *B H* thereby closing the line until transmission is again started.

When the tape control lever contact is again closed it completes a circuit through the local segment *B K*

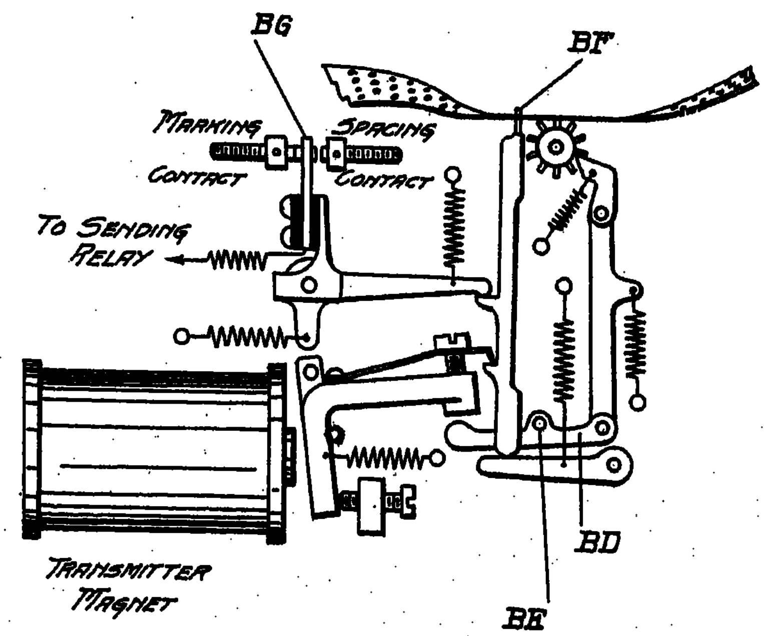

FIG. 14—TAPE-FEED MECHANISM

to the start relay and starts transmission. The start relay in turn operates the start magnet, the transmitting brush arm is released and circuits to the sending relays are closed through the marking contacts in the transmitter.

When the local brushes leave the segment *B K*, the locking circuit to the start relay is broken, the start

relay is de-energized and the circuit to the marking contacts in the transmitter is broken. During the time that the start relay is energized the selection is transferred from the transmitter to the sending relays ready to be sent to the receiving station one impulse after the other as the transmitting brushes pass over segments Nos. 1, 2, 3, 4 and 5.

Directly after the circuit to the marking contacts in the transmitter is broken the local brushes pass over segment $B\,C$ operating the transmitter magnet and stepping the tape forward so that the next character in the perforated tape is presented above the pins.

If it is desired to repeat a character a number of times the switch $B\,T$ may be operated to open the circuit to the transmitter magnet. Inasmuch as the tape is not stepped forward, the same character is sent over and over again as long as the switch $B\,T$ remains open and the brush arm continues to revolve.

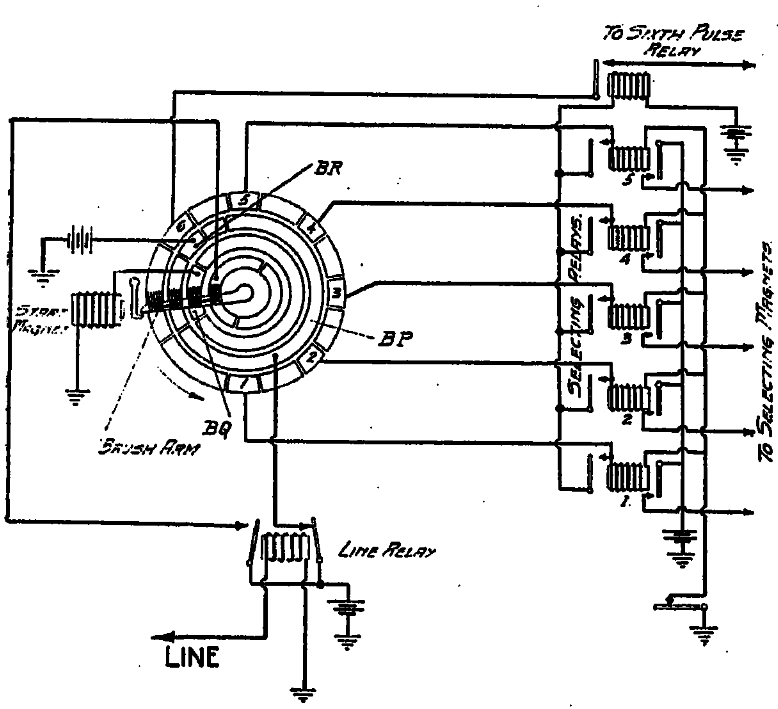

FIG. 15—ELECTRICAL CONNECTIONS OF RECEIVING UNITS

After the fifth selecting impulse is sent, the local brushes pass over segment $B\,N$ and the lockout relay is energized. The operation of this relay breaks the locking circuit to the sending relays and the relays are de-energized.

As long as the tape control lever contact remains closed, the start relay and start magnet will be energized whenever the local brushes pass over the segment $B\,K$ and the transmitting brush arm will therefore continue to revolve.

With direct keyboard operation the circuit to the transmitter magnet remains open and the selection that is set up on the selecting contacts in the perforator-transmitter, whenever a key lever is depressed, is transferred directly to the sending relays. From that point the operation of transmitting a character is practically the same as that described above.

In order to prevent sending a second selection to the sending relays before the first selection is sent over the line the common return wire from the keyboard selecting contacts is routed through the back contact of the keyboard relay which is in series with the locking circuit for the sending relays. When the sending relays are de-energized, by the operation of the lockout relay, the back contact of the keyboard relay is again closed permitting the next selection to be sent from the selecting contacts to the sending relays.

With keyboard operation a contact that is closed by the operation of the keyboard relay takes the place of the tape control lever contact described above. The transmitting brush arm stops, therefore, after every revolution and remains stationary until a key lever is depressed and the keyboard relay is operated.

Reception. Fig. 15 shows the manner in which the receiving units are connected electrically.

The light brush arm is clutch-driven and the speed of the shaft that drives the brush arm is the same as the speed of the transmitting brush arm at the sending end. When the start impulse is received the receiving brush arm is released and revolves at the same speed as the transmitting brush arm.

Normally the brush arm is held stationary by the start magnet with the local brushes resting on the start segment $B\,Q$. When the receiving brushes are at rest and the line is opened battery is supplied to the start magnet through the back contact of the line relay and the brush arm is released.

When the line is closed battery is connected to the segment $B\,P$ through contacts on the line relay, and when the line is opened battery is cut off. If the line is closed, therefore, when the receiving brushes pass over segment No. 1, the first selecting relay will be energized and similarly the second, third, fourth and fifth selecting relays. As the brushes pass over each segment in turn they will or will not carry current to each successive selecting relay according to whether the line is closed or open at that particular instant.

After the brushes pass over the five selecting segments a local circuit is completed through segment $B\,R$ and segment No. 6 to the sixth-pulse relay in the printer and the brush arm is again stopped by the start magnet armature.

The printer, Fig. 16, is of the movable-carriage type where the paper that receives the message is moved one space to the left after each character is printed. Printing is accomplished by pushing the paper against a type wheel which revolves in one direction on a vertical shaft and which may be raised or lowered for printing upper or lower case characters. This printer is described in J. H. Bell's Institute paper on printing telegraph systems and therefore needs no further mention.

KLEINSCHMIDT SYSTEM

Fig. 17 shows a Kleinschmidt terminal set. The perforator is shown at the right and the printer at the left with the transmitting and receiving distributors between them.

Transmission. Fig. 18 is a wiring diagram of the circuits involved in transmitting signals over the line. The transmitting mechanism is entirely mechanical and is like that of a Wheatstone transmitter.

The tape that is prepared by the perforator is fed through the transmitting distributor and is stepped forward by means of the cam *H* and the pawl *J*, once for every half revolution of the transmitting shaft *A* (Fig. 19). For every revolution of the transmitting shaft two characters are sent over the line.

The transmitting cam shaft *A* is motor-driven through a friction clutch at any desired speed from 40 to 80 words per minute. As the shaft *A* revolves, the cam *B* moves lever *C* about a pivot *D* allowing the spring *E* to draw the pin *F* upward. If a hole in the perforated tape presents itself above the pin *F*, the latter pin will pass through the tape and the contact

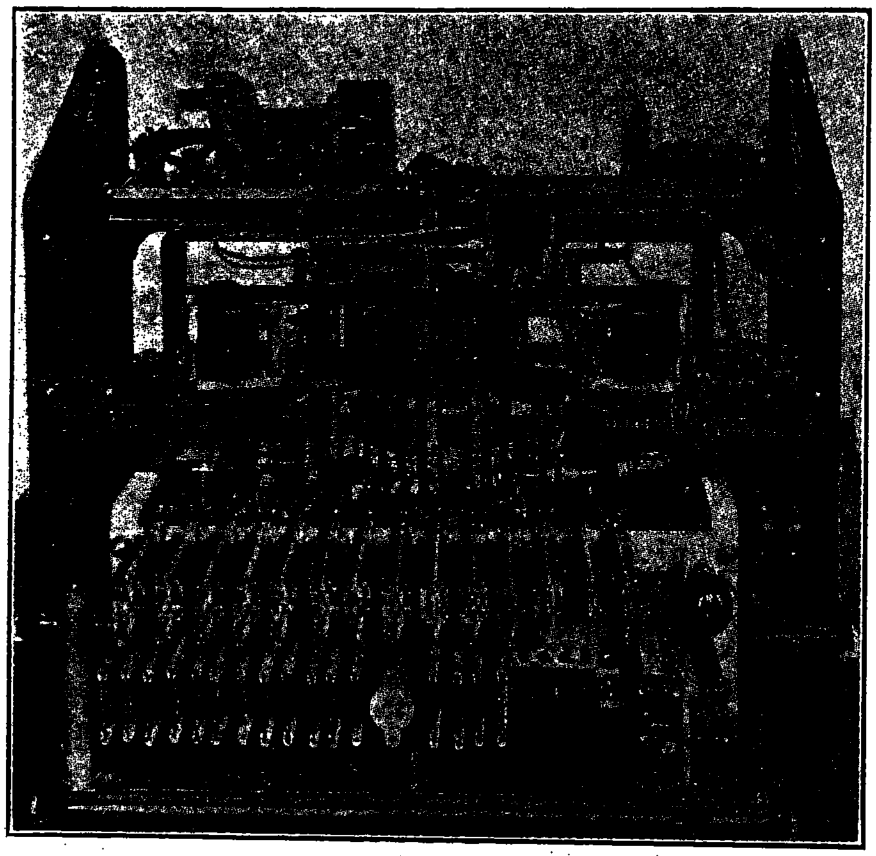

FIG. 16—WESTERN ELECTRIC PRINTER

tongue *G* will move over against its negative or marking contact as shown. If, however, the pin *F* is blocked by the tape, the contact tongue *G* will remain against its positive or spacing contact as illustrated in Fig. 20. Six cams *B*, six levers *C* and five pins *F* are located one behind the other and operate in succession.

The contact tongue is connected directly to the line. Positive and negative impulses are therefore sent over the line as the five pins *F* move upward, one after the other, and are blocked or are not blocked in accordance with the perforations in the tape.

At the beginning of every character one of the cams on the transmitting shaft *A* actuates a train of mechanism similar in every respect to that described above, except that no vertical pin *F* is included. At the beginning of each character the transmitting tongue moves to the right and sends out a marking impulse. This impulse is followed by the five selecting impulses and then a spacing impulse.

For every character transmitted, therefore, seven impulses are sent to the receiving station. Two are for synchronizing purposes and five are for selecting purposes. Communication is carried on at a line frequency of seven units or three and one-half cycles per character. Sixty words per minute represents a line frequency of 21 cycles per second.

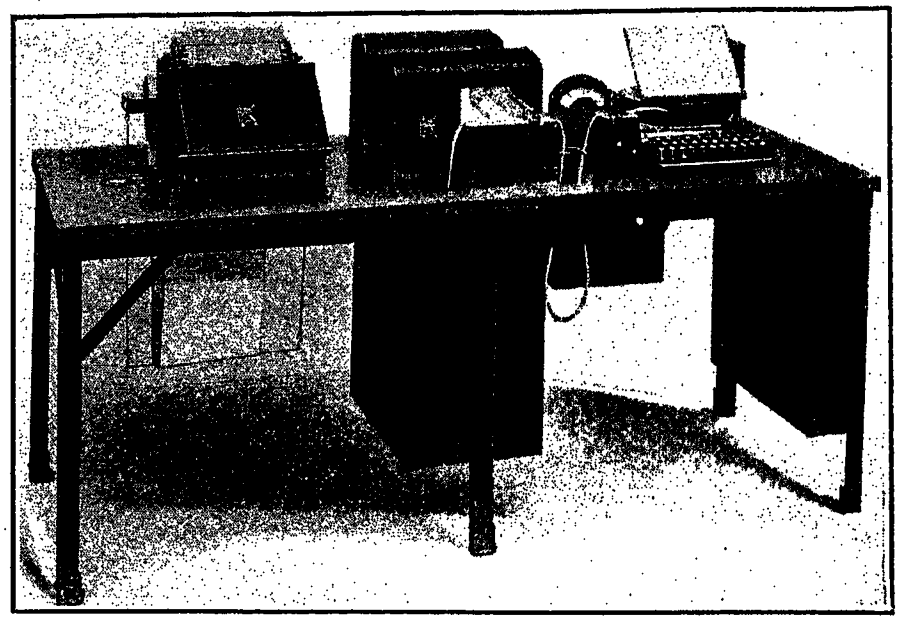

FIG. 17—KLEINSCHMIDT TERMINAL SET

The transmitting cam shaft *A* is not stopped after each character, but revolves constantly, sending out one character after another until the sending station wishes to stop transmission, which may be done at any time by moving a lever in the path of a stop arm attached to the transmitting cam shaft *A*. When the cam shaft *A* is stopped transmission ceases although the motor continues to drive the friction clutch through which the cam shaft is driven.

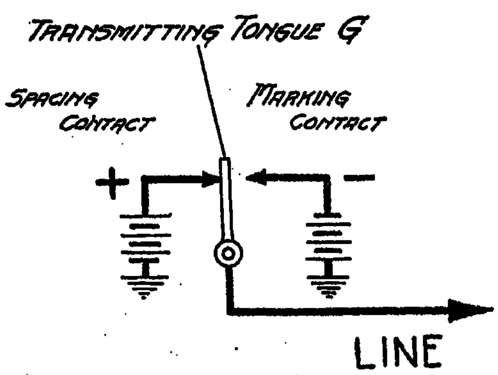

FIG. 18—DIAGRAM OF MARKING AND SPACING CONTRACTS

If, for any reason, it is desired to repeat a character a number of times, the button *O* (Fig. 20) may be depressed so as to hold the pawl *J* out of engagement with the tape feed wheel ratchet. In this way the tape will remain stationary and the same character will be sent over and over again as long as the transmitting cam shaft *A* continues to revolve and the button is depressed.

In order to signal quickly to the distant station, a bell signal mechanism is provided as illustrated in

Fig. 21. Shaft K is clutch-driven and revolves only when the bell handle L is moved to the right. When the handle L is moved to the right, and then released, the shaft K is released and the transmitting cam shaft A is stopped during one revolution of the shaft K. During this revolution the cam M moves the contact tongue G back and forth by means of the levers shown, sending the characters "figure shift," "J," and "letter shift" over the line. Whenever the letter "J" is selected

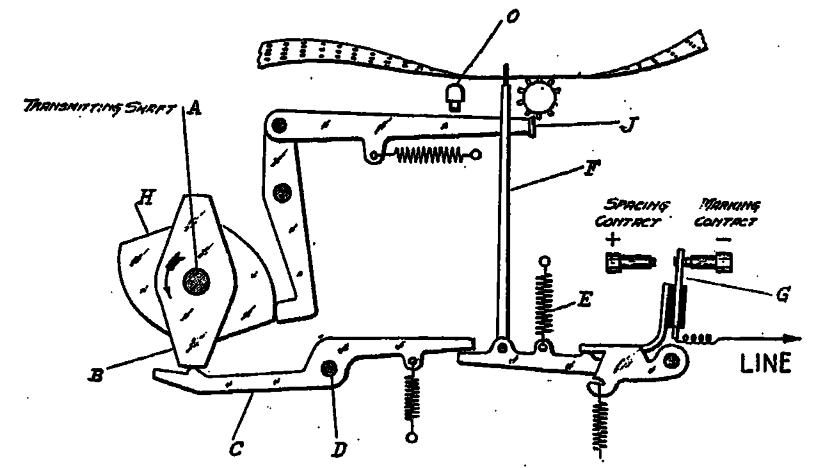

Fig. 19—Tape-Feeding Mechanism—Marking Contact

in the printer, while the carriage is in the upper case, a bell is rung and no printing takes place. If the bell handle L is held over to the right when the shaft K completes one revolution the latter will continue to revolve sending out a bell signal to the distant station once every revolution as long as the bell handle is held over. When the bell handle is released, however, the shaft K will be stopped and the transmitting cam shaft A will continue its motion. At the beginning of each revolution of the shaft K, a small mechanical

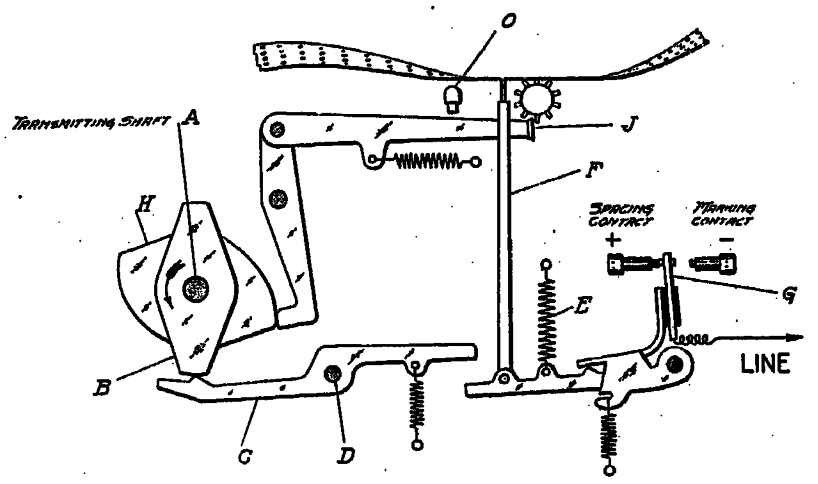

Fig. 20—Tape-Feeding Mechanism—Spacing Contact

bell is operated so that the operator at the sending station may know how long to hold the bell handle L to the right in order to send out any desired number of bell signals.

Reception. Fig. 22 shows the manner in which the receiving units are connected electrically.

The receiving distributor is entirely separate from the transmitting distributor. This necessitates two motors, but with this arrangement transmission may be carried on in opposite directions at different speeds and accurate speed adjustments are not necessary. The light brush arm N is clutch-driven at a speed slightly faster than the speed of the transmitting cam shaft at the sending end. This increased speed at the receiving station is compensated for by delaying the brush arm, after each character is received, sufficiently to keep the sending and receiving stations in step.

Normally the brush arm is held stationary by the

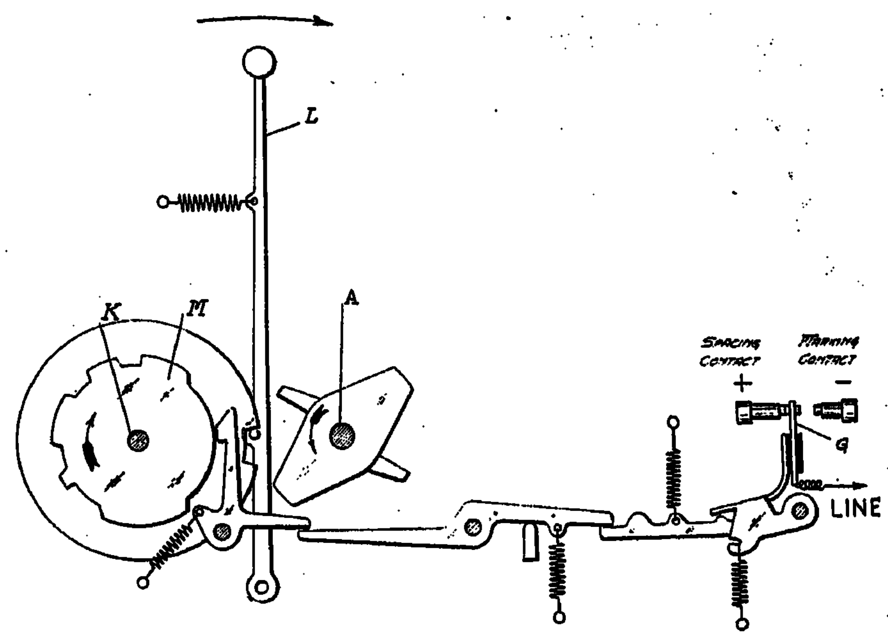

Fig. 21—Bell Signal Mechanism

start magnet armature with the brush resting on the start segment and the relay tongue held against its spacing contact. When a character is received a marking impulse precedes the first five selecting impulses and a circuit is completed through the marking contact of the line relay, the start magnet then is operated and the brush arm released.

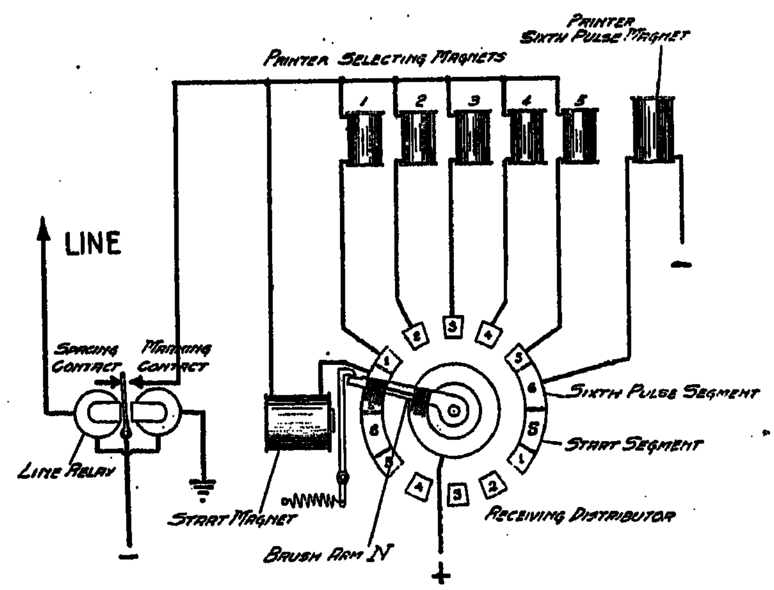

Fig. 22—Electrical Connections of Receiving Units

Positive battery is connected to the solid ring of the receiving distributor and the marking contact of the line relay is in series with the common return wire for the selecting magnets and the start magnet. Each one of the selecting magnets in the printer is connected to a corresponding receiving segment. If, therefore, the brush passes over receiving segment No. 1 while the line relay tongue is against its marking contact, the first selecting magnet will be energized and similarly the second, third, fourth and fifth selecting magnets. As

the brushes pass over each segment in turn they will or will not carry current to each successive selecting magnet according to whether or not the line impulse then being received is of marking or spacing polarity.

After the brushes pass over the five selecting segments they pass over a sixth-pulse segment, completing

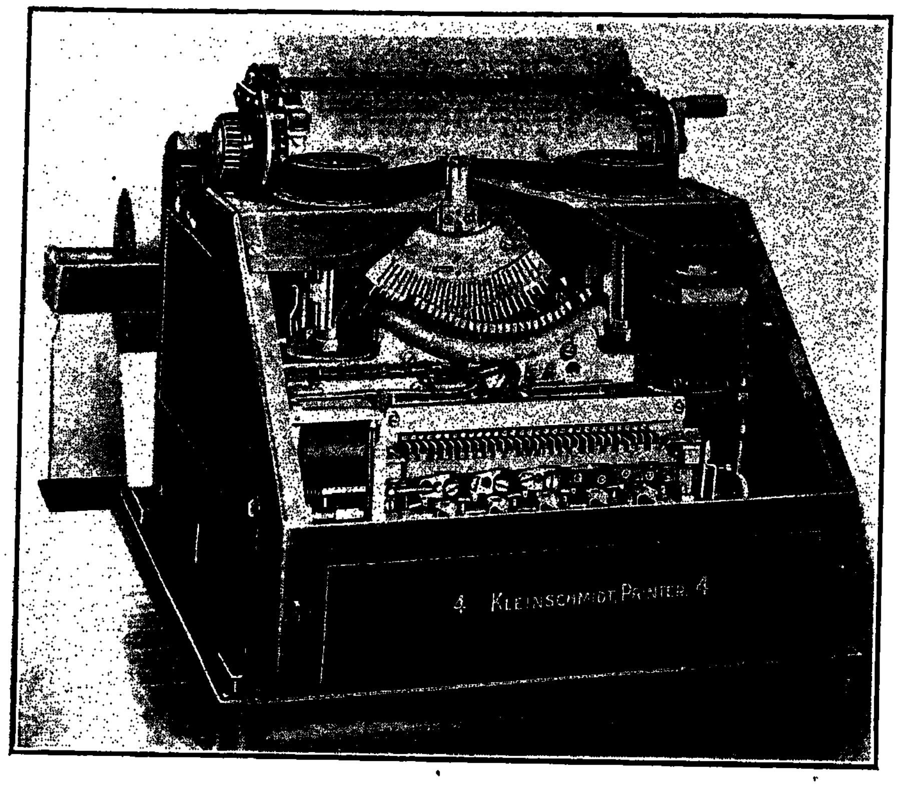

FIG. 23—KLEINSCHMIDT PRINTER

a circuit through the sixth-pulse magnet in the printer and then again come to rest on a start segment.

The printer, Fig. 23, is a type-bar printer of the movable-paper carriage type similar to a standard typewriter. The paper is moved to the left after each character is printed and is fed upward at the end of each line of printing.

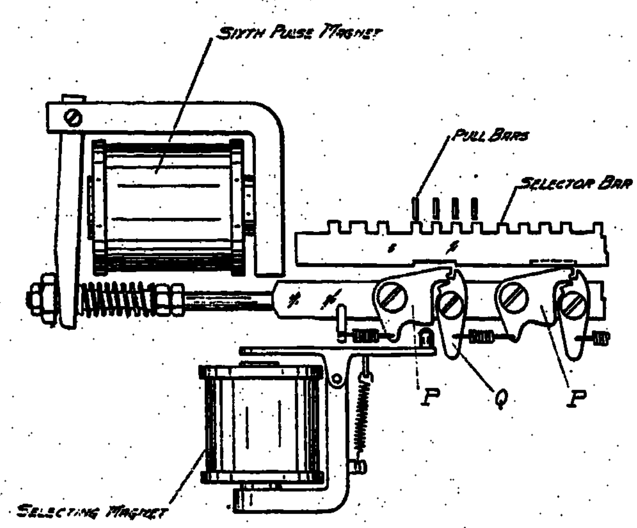

FIG. 24—OPERATION OF SELECTING MAGNET

When a selecting magnet is energized its armature lifts a pawl P (Fig. 24) in the path of a selector bar and a latch Q locks it in this position. Five pawls P are located on a bar that is moved by the sixth-pulse magnet. When the selection is stored up in the pawls on this bar, the sixth-pulse magnet is operated and the pawls that were lifted move the corresponding selector bars to the right.

Each type-bar (Fig. 25) is connected to a pull-bar mounted directly above and at right angles to the selector bars. When one or more of the selector bars is moved to the right a slot is presented under one of these pull-bars and the selected pull-bar drops so that a hook on the under side of the pull-bar is in the path of an operating bail R. This bail is moved by an operating solenoid whenever a pull-bar drops into a

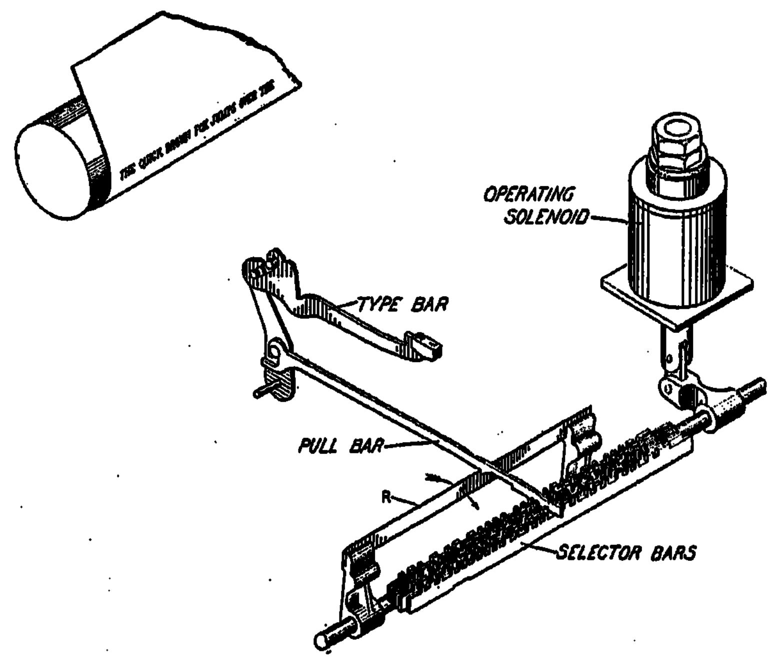

FIG. 25—OPERATION OF TYPE BAR

slot in the selector bars. In this way the selected type-bar is thrown upward and the proper character is printed.

Spacing after every letter is provided for by means of a spacing solenoid which is energized whenever a type-bar moves upward. Spacing between words is accomplished in a similar manner except that the type-

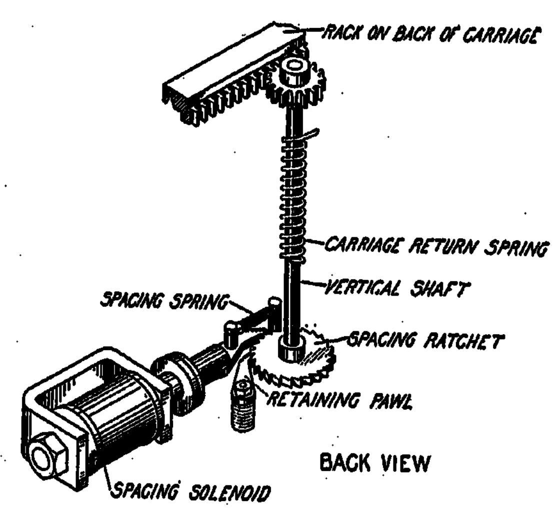

FIG. 26—OPERATION OF CARRIAGE

bar selected does not carry any type and therefore does not print.

On the back of the carriage a rack (Fig. 26) is mounted which meshes with a gear on top of a vertical shaft. The spacing solenoid turns the ratchet on the bottom of this vertical shaft, the motion being transmitted to the carriage by means of the vertical shaft, and the carriage is thus stepped forward after each character is printed. The spacing ratchet is not

rigidly attached to the vertical shaft, however, but drives it through a clutch (not shown). A carriage return spring is wound up as the carriage is spaced along and exerts a force on the vertical shaft tending always to return the carriage to the beginning of a new line of printing. When the clutch is in its normal closed position this force is held in check by a retaining pawl acting against the spacing ratchet. When the "carriage return" signal is received, the "carriage return" pull-bar drops into its notch in the selector bars and a contact is closed, thereby operating a carriage return magnet which disengages the clutch. The spring on the vertical shaft is released from the restraining action of the retaining pawl and returns the carriage to the beginning of a new line of printing. When the carriage reaches this position it opens the locking circuit to the carriage return magnet and the clutch is returned to its normal closed position, again connecting the spacing ratchet to the vertical shaft.

The various other functions are either performed mechanically directly from the pull-bars or are operated by means of solenoids controlled by the pull-bars.

When the "figure shift" signal is received, for instance, the "figure shift" pull-bar drops into its notch in the selector bars and a contact is closed thereby energizing the shift solenoid. The latter then lifts the front end of the carriage and a latch holds it in its shifted position so that figures or punctuation marks may be recorded. When a "letter shift" signal is received and the "letter shift" pull-bar is moved forward by the operating bail the latch is released mechanically and the carriage drops back to its normal position.

A ratchet that is operated by a pawl is mounted on the platen around which the paper is fed. This pawl is attached to a bail extending the length of the carriage and is operated by the line feed solenoid. When a "line feed" signal is received, the operation of the proper pull-bar energizes the line feed solenoid and the paper is therefore moved upward a distance of one line space to the next line of printing.

Discussion

R. E. Chetwood: At the present time, in the Western Union System, we have about 185,000 miles of trunk wires, equipped with automatic, printing telegraph apparatus. If the automatic apparatus had not been used it would have required approximately 460,000 miles of wire to handle the same amount of traffic. That shows a great saving in wire plant, due to the use of automatic apparatus.

Another figure that possibly would be of interest is that today approximately 75 per cent of the trunk line traffic is handled by automatic apparatus. By automatic apparatus, I refer to apparatus of the type described in the paper and also the heavy traffic apparatus which was described in Mr. Bell's paper of two years ago.

John H. Bell: The author has not mentioned that all three systems can be operated duplex. As a result of this omission the following sentence in the first column of page 89, towards the bottom which reads: "This necessitates two motors, but with this arrangement, transmission may be carried on in opposite directions at different speeds and accurate speed adjustments are not necessary," might lead one to think that in order to secure transmission in both directions, that is, to operate duplex, it is necessary to have two motors. Such is not the case. I think it was Mr. Reiber's intention to emphasize the fact that a different speed in each direction is obtained by the use of two motors.

He might have claimed for printing telegraphs the advantage of greater accuracy. In the majority of the operating rooms of one of the largest telegraph companies in this country, there are large notices reading: "Accuracy First." In the final analysis, the standard of accuracy depends upon the operator, but the use of printing telegraphs enables the operator to give so much more time to the checking of the messages that the standard of accuracy is considerably higher than with the old Morse instruments. As a matter of fact, I believe that the number of undetected errors in the case of printing telegraph systems is only about thirty to forty per cent of the number of undetected errors with Morse.

Just picture a telegraph organization in a position to print at the bottom of each message blank which goes out to the public—"There is no error in this message". The use of the printing telegraphs has made it possible to proceed a long way toward that high standard.

While on the subject of accuracy, I will mention one or two slight inaccuracies in the paper. Fig. 16 shows the Western Electric printer with relay box as arranged for multiplex operation, which is different from the arrangement for the start stop system as shown in Fig. 12. Fig. 15 shows the Western Electric receiving face plate with four rings. Four ring face plates have been abandoned and now only the two rings are used.

If the printer systems described by Mr. Reiber can successfully compete with the Morse system when operated by the skilled Morse operators in America—and they do—then there should be no difficulty in having them compete with Morse operators in other parts of the world.

G. D. Robinson: What is the possibility of applying the printing telegraph to wireless communication?

A. H. Reiber: I believe there will be developments along those lines in the future. In applying automatic printing telegraph equipment to wireless communication there is a condition, that of static, which is hard to overcome. Where the human element is involved, it is possible to receive signals even though they are badly mutilated but with automatic printing telegraph equipment, unless future developments correct the difficulty, static disturbances will occasionally cause unintelligible words.

On Deviations From Standard Practise in Lightning Arresters

BY E. E. F. CREIGHTON
Associate, A. I. E. E.
General Electric Company, Schenectady, N. Y.

Review of the Subject.—*This paper is an endeavor to answer questions of practise and criticism of arresters brought out by an investigation conducted by the Protective Devices Committee.*

For the most part practise in lightning arresters is standardized. In fundamental principles there have been no changes for many years. Improvements in details, especially of construction, are still being made. A new arrester, the oxide film arrester, gets rid of the oil and electrolyte and avoids the necessity of daily charging, but fundamentally it is designed along the same principles as the aluminum arrester. The important principle is the electric valve action—there are but a few milliamperes of discharge rate at normal line voltage, but at abnormal line voltages the discharge current rise to hundreds of amperes. In answer to criticisms made by a few prominent engineers, it is maintained as fundamental that a large discharge rate for an arrester is an absolute essential. The burden of proof falls on those engineers who use arresters of low discharge rate. These arresters cannot discharge the dangerous lightning surges on overhead lines. Since there are lightning arresters of low discharge rate in apparently satisfactory use, an explanation for this anomaly is found in the use of insulators of low arc-over voltage. Either the lightning potential is relieved locally at the insulator or the resultant traveling wave is of too low voltage when it reaches the transformer greatly to endanger the insulation. Poor line insulation is not a solution of the problem of continuity of service. Why not save the cost of the useless lightning arrester?

The current in such a traveling wave is about two amperes for every thousand volts of lightning potential, 600 amperes for 300 kv. One to twenty-five ampere discharge rate of arresters has little effect in reducing the lightning voltage.

How many arresters should be used to protect a six-feeder system? It depends on the conditions of insulation in circuit breakers and the importance of continuity of service. According to the conditions discussed in the body of the paper, from one arrester connected to the busbars to seven arresters with auxiliaries are needed.

The use of no arresters is discussed from three standpoints. 1. If it is contended that lightning is not of sufficient voltage to cause damage. 2. If it is considered a better investment to put lightning arrester money into spare transformers. 3. If it is considered good practise to so highly insulate a transformer as to give it immunity from lightning. The conclusion reached is that each of these three arguments is dangerously faulty.

A new method of inspection of aluminum arresters is proposed. The experiments given in the paper show that the power factor of the cells examined is very sensitive to their condition. There are promises of effecting economies in overhauling aluminum arresters and of lengthening their life. Experiences are given with a 33-kv. arrester in service thirteen years without overhauling. The plates are still in good condition. The usual damaging deposits of decomposed oil on the aluminum film were prevented by using an initial rush of charging current great enough to throw them off. The electrolyte is partially exhausted in strength and needs changing. The discharge rate is still high.

CONTENTS.

COMMITTEE SURVEY. For several successive years the Technical Committee on Protective Devices, Mr. D.W. Roper, Chairman, has voted to make a survey of practise in lightning arresters on transmission circuits (not distribution), but each year there have been other matters which took precedence.

Last year Mr. F. L. Hunt addressed a number of eminent transmission men with definite questions relating to specific cases designed to bring out views on advisable practise and to obtain adverse criticism. In general their answers represent standard practise. There are a few variations from, what seems to the writer, good practise. These variations will be discussed briefly by a presentation of definite reasons against them.

Object. Briefly the object of this paper then is to discuss: First, variations from good practise, and second, proper differences in standard practise, which will be treated under one heading; and third, improvements and economies in the maintenance of aluminum arresters.

Presented at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

Differences in Standard Practise

Status of Lightning Arrester Practise. Established practise in lightning arresters is firmly based on sound scientific principles. There is still a number of unknown conditions and even the best developed devices fall short in certain ideal functions, but engineering judgment is found in every step.

Horn-Gap Arresters and Any Other Type of High Series Resistance. The initial discussion will be on the extremes of differences from standard practise, such, for example, as the use of horn-gap arresters and the practise of using no arresters at all. A brief review of some of the factors relating to arresters not of the electric valve type follows: (1) Horn gap with high series resistance, (2) with medium resistance, (3) with no series resistance.

(1) If a horn-gap arrester has a discharge rate of the order of 10 *amperes* it is *insufficient to relieve the potential of any dangerous induced lightning stroke.*

(2) If the discharge rate is of the order of 100 amperes the arrester becomes more protective in proportion but the amount of power taken by the arrester from the circuit makes both a heavy draft on the

generators and a difficulty in the design of the arrester. If it is designed with generous proportions to avoid overheating of series resistance the cost will be high.

Commenting on these factors: The power taken by a three-phase discharge of horn gaps with currents limited to 100 amperes on a 60-kv. circuit is about 12,000 kw. The usual time required for the arc to rise on a horn is about 5 seconds. No such discharge rate is used on these arresters in general because the resistance would be overheated by the power current which follows the lightning discharge. This energy would heat 600 liters (150 gallons) of electrolyte through 100 deg. cent. In so doing the resistance would reduce to a fraction of its initial value, due to the negative coefficient of resistance with the rise of temperature—a natural characteristic of electrolytes.

Commenting further on that persistent and inefficient device, the arrester of any type of low discharge rate, proof is herewith offered, in the following paragraph, that such an arrester has no value in discharging lightning.

Current of Traveling Wave: A traveling wave has an average current of two amperes per thousand volts of potential of the wave. For the argument following it is necessary to accept this numerical figure.

Proof that the approximate current in a traveling wave is two amperes per kilovolt of surge voltage follows.

The energy in a traveling wave is half electromagnetic and half electrostatic (see any standard work on this subject, for example such authorities as Bedell and Crehore, Steinmetz, Pupin, Berg).

Expressed in a formula

$1/2\, C\, V^2 = 1/2\, L\, I^2$ where the capacitance C and the inductance L of a single wire are taken for any chosen unit of length of the wave. V is the effective voltage and I is the effective current over the length of wire chosen as a unit. Or V and I may be used as the crest voltage and crest current. By simple transposition and cancellation the value of surge current I in terms of the surge voltage becomes

$I = V \sqrt{C/L} =$ approximately 2 amperes for No. 0, B & S. wire at an average height of 30 ft. (900 cm.) above the conducting surface of the earth.

The inductance L of a single wire with the surface charge on the earth is not a definite quantity, but its widest possible variation will not affect the final results greatly because this factor appears under a square root sign. The value of inductance L used was calculated on the basis that the electromagnetic field of a line wire extended to its image at a depth below the surface equal to the height of the wire above. The single wire inductance was then used. The actual inductance is more likely to be greater than less.

To illustrate how much effect the size of wire and its height may have on the surge current there were chosen two extreme cases. First, a large wire, one million circular mils, at an average height of 25 ft. (750 cm.) was used, and this increased the surge current of a single wire by only 18 per cent. Second, a small wire, No. 6 B & S, at a considerable average height, for the lowest wire 40 ft. was chosen. This lowered the surge current of a single wire to only about 90 per cent of that in the No. 0 wire at 30 ft. (900 cm.) height.

Significance of the Current in a traveling wave. If, then, a traveling wave on a transmission wire has an average current of 2 amperes per thousand volts (about 10 per cent more or less according to the dimensions, spacing, and height of wires), a lightning charge of 200,000 volts would have a current of 400 amperes in its traveling wave. This wave travels at 300,000 kilometers per second (184,000 miles a second), and an arrester which can draw off only 10 amperes from the 400 amperes, as this traveling wave rushes headlong into the insulation of the transformer, is not doing much to reduce the voltage of that wave. If by assumption the traveling wave has only 10 amperes of current its voltage is only about 5 kv. and is harmless to any transmission circuit.

The lightning arrester can take only a share of the current as the traveling wave reaches the point where the arrester is located. In other words, if the arrester is at any point on the line except at the ends the lightning current will divide into two parts—one part continuing along the line and the other part passing through the arrester to ground. The voltage of the traveling wave is not reduced even in proportion to the reduction of the current involved in the wave. This is because half the energy of the traveling wave is electrostatic and half electromagnetic.

In this argument is there anything subtle or vague or improbable? It requires only the acceptance of the figure of two amperes per kilovolt in the traveling wave and the well-known theory of the division of current at a bifurcation of the circuit. This same argument applies to any lightning arrester of any make which has a low rate of discharge. It puts the burden of proof for such American and European practise as high resistance and a jet of water used as a lightning arrester, on the engineers who advocate it.

Furthermore, all our laboratory experience shows that such a jet of water or any lightning arrester of low discharge rate has no appreciable value in discharging a traveling wave.

(3) If no series resistance is used the large arcs of short circuits which can be blown for 30 or 40 feet to other circuits call for large space of installation. Also there is the inevitable interruption of service to say nothing of other intrinsic dangers of short circuits. Still further, if separate grounds for the three phases are used for these horn gaps, the space between grounds becomes a menace to life. The arrester does not sustain the line voltage but throws it down to the ground. This menace increases with the potential and power of the circuit. As another objectionable feature, the earth contacts dry out under heavy discharge. The earth resistance may amount to any high value. There

are other objections to these short circuiting devices from a protective standpoint.

In going over these matters with an interested transmission engineer, he asked at this point the very pertinent question: How is it that a prominent engineer, whose judgment and veracity we both respect and who has no personal interest in the manufacture or sale of lightning arresters of the horn-gap type, could install horn-gap arresters of comparatively low discharge rate on his circuits and honestly report successful operation?

In answer, there might be several ways that this condition could come about. As an illustration, if the insulators on a transmission line have an arc-over voltage of the order of say 120 kv. and the power voltage is 60 kv., lightning could not induce on the line more than double the normal line voltage without spilling over an insulator and relieving itself locally at the point on the line nearest the stroke between cloud and ground. The traveling wave is only about 70 per cent of the arc-over voltage of the line insulator, due to the

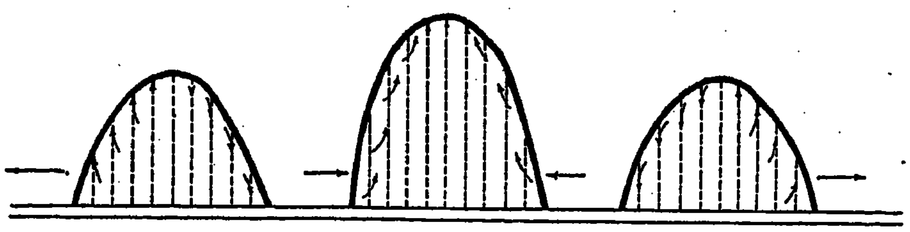

FIG. 1

Traveling wave to the left, one-half of the initial energy. Initial charge which is momentarily stationary. Traveling wave to the right, one-half of the initial energy.

lightning charge breaking into two parts which travel in opposite directions from the place of maximum induction (Fig. 1).

The insulation of the transformers is designed to withstand a test of double voltage for a minute. The only danger of this traveling wave lies either in a steep wave front which would damage the insulation between end turns, or in some remote possibility of an internal resonance in the transformer coils. The chances of damage are very slight. Then arises the question when such a condition of line insulation exists—why even go to the expense of the useless horn-gap arrester? An engineer may have inherited these conditions of low insulation on the line and may be making the very best engineering practise out of a bad situation, keeping very properly in mind the dividends to the stockholders. We venture to say, however, that this same engineer would not recommend low dielectric strength of insulators or a revival of the once tried practise of placing horn gaps at every insulator. The best practise today is in the direction of the highest reasonable factor of safety in the spark potential of the insulators.

Another way in which the user of a horn gap arrester of low discharge rate could escape without loss of insulation of the transformer is by using a horn gap without resistance, in parallel with the resistance type. In this case the dielectric strength of the insulators may be very high and the voltage of the traveling wave may be at a damagingly high value, and yet damage to the insulation of the transformer may not be evidenced. However, it is not a solution of the problem, because the primary object of a transmission system is to sell and deliver power. The power service is interrupted by the short circuit of the horn gap.

The Effect on Practise of the Demands of Continuity of Service. The foregoing statement of service brings us immediately to a difference in arrester practise between engineers of different systems in which they can all be right. At one extreme there is the demand of service so slightly emphasized as to make it permissible to disconnect the power from the line during lightning storms. If visual observation and storm detectors could be relied on there would be little need of lightning arresters under a condition of this kind. Any one might take a chance without being criticised.

At the other extreme is the requirement of service illustrated by the Edison companies where one interruption in ten years is considered a calamity. In between are all grades of requirements brought about by the supply of power to such industries as paper mills, mining pumps, weaving mills, and manufacturers of any material which requires a continuous movement of the machines from the beginning to the end of the piece being manufactured.

There is another factor relative to the installation of an arrester of low discharge rate which has not been sufficiently emphasized, namely that no matter what type of arrester is installed the expense of installation is always considerable. If the expense of the installation is to be undertaken, why not add a little more and get an effective discharge rate?

A large concern whose business is enhanced by perfect service of its main apparatus in the form of generators, transformers, motors, lamps, etc. cannot argue the case for a cheap ineffective lightning arrester and build up a business in this line based on incomplete and immaturely considered experiences.

The foregoing argument does not take into account the sincerity of research engineers who have collected and analyzed voluminous data for many years and have concluded that it is an economic waste to the art of transmission to invest in arresters of low discharge rate as now installed. To any one company the futile expense may not be damaging but the aggregate loss for the country over is very considerable. The idea of giving a new arrester a trial indicates an admirable progressive spirit. But to do this without considering the intrinsic factors or the characteristics of the arresters entails unnecessary waste. It is one of the objects of this discussion to present reasons for present practise and thereby give the dissenter an opportunity to present his side in open forum. The dissenter also owes it to the art to set us right, if we are wrong, and thereby effect a still greater saving in investment.

The Practise of Using No Lightning Arresters. We now pass on to another extreme of practise, namely, the system which operates without any lightning arrester. There is only one such overhead system of importance that I know of. What penalty it is paying for this practise is not yet fully determined. What financial losses are entailed? What kind of service is given? A review of the evolution of this condition may be valuable in preventing some other system from attempting the same practise without having the same conditions. The transformers on this system were rewound with extra-high insulation at a very considerable expense. This is the first and most important item. Aluminum lightning arresters were used in the earlier days, the neutral was non-grounded, and the practise of keeping the power on the circuit regardless of the conditions did, in one case I know of, hold a persistent arcing ground for ten hours. Naturally an aluminum lightning arrester was destroyed and the remarkable feature was it lasted the ten hours. At that time the engineer argued that he was willing to sacrifice the arrester to maintain the service, but he lost both the arrester and the service. Under this practise one arrester after another disappeared and there is no desire on the part of a manufacturer to sell more arresters. There are certain lines of argument that one may follow regarding this installation. (1) It may be contended that the lightning is not of sufficient voltage to cause any damage; or (2) it may be considered a better investment to put the lightning arrester money into spare transformers; or (3) it may be considered good practise to so highly insulate a transformer as to give it a high degree of immunity from lightning.

Considering these three possible arguments in the order given above, first, that the lightning may not be of sufficient voltage to damage the insulation—if the lines are highly insulated—one can only say, Alas! Tests made in the laboratory on coils representing end turns of a transformer have demonstrated the ease with which a spark may be formed between adjacent turns puncturing the insulation. To note this tendency on transmission lines the simplest method is to place a spark gap in parallel with a choke coil of comparatively few turns. During lightning storms frequent sparks will take place. Another situation where this effect is shown is the frequency of puncture of current transformers by traveling waves. Many such experiences have led to the conclusion that traveling waves, especially of steep wave front, will cause punctures between turns of the end coils of transformers—certainly they do in extreme cases of high voltage. This would require the best protection obtainable. To be sure, a single puncture of this kind does not, in general, cause short circuit, but the successive sparks may be cumulative in their effects, punctures being made at different points until the conditions are right for holding the arc. Small transformers and very large ones are more likely to fail than intermediate sizes due to the distribution between layers or between turns. More technical data on this subject are needed and are being collected.

Second, the spare transformer method of caring for dangerous lightning strokes needs comment. It is not necessarily a poor engineering proposition. On the contrary there are conditions which make it acceptable. As an example of an installation of a step-down transformer, if the requirements of continuity of service are rigid, if the transformers are of low kilowatt capacity and of high voltage, it is difficult to figure economy in an investment in a lightning arrester. Arresters have a way of mounting in cost as the required voltage of the circuit is higher, regardless of the kilowatt capacity of the transformer. We have given this matter attention for several years without being able to evolve a satisfactory arrester. Such an arrester must have the characteristics of low cost, high discharge rate, independence of attention, and practical indestructibility.

Admitting then there is now no acceptable standard practise for application of lightning arresters for high-voltage transformers of low kilowatt capacity, let us turn attention to those of higher capacity such as are installed in power stations and principal step-down stations. Will the service demands permit an interruption while a spare transformer is shifted from one station to another? Shall a spare transformer be ordered for each station? Shall it be single- or three-phase? If a lightning storm should damage two single-phase transformers out of the four available, would the loss of revenue, to say nothing of the prestige, far exceed the interest and depreciation on one set of arresters at this point—or even several sets of arresters included in a proportional charge? Is it worth the price to risk a possible cumulative damage to the insulation of generators and transformers by occasional heavy discharges without arrester protection? Where the answer is yes, the case is settled. Every transmission engineer must find a balance between the risk of no protection and the cost of failure without protection. The primary question for self-interrogation in any particular installation is: What will it cost in loss of revenue, in time, in repairs, and in prestige to have a failure of one, two or of all three phases? Lightning storms average up if the effects of enough of them are taken into account. The chances of a stroke near a station are not very great. In lightning-infected countries one must in general by pure chance expect, some time, a progressive thunder storm which, instead of crossing the lines at an angle, runs longitudinally with it, with practically every stroke effective in producing a high-voltage surge on the lines or in the station. One can go several years with hearty self-congratulation instead of lightning protection and finally meet a longitudinally traveling Waterloo.

It has been and still can be properly argued that

many or even the majority of discharges of lightning arresters are unnecessary as the charges are harmless. This is true where the gaps of the arresters are set at a spark voltage only slightly above line voltage. But such an argument does not decrease the intensity of the minority of discharges, nor does it prove that arresters are not necessary for protection for the lesser number of heavy strokes or that it is good judgment to do without arresters entirely.

To summarize some of the points: Arresters may be dispensed with (a) if there are no lightning storms and no surges on the lines; (b) if the insulation of the power apparatus has a higher factor of safety than the line insulators (leaving a chance of damage by a stroke near the station); (c) if there is available a good detector of lightning as it approaches the lines and the circuit breakers are opened before the storm breaks anywhere over the aerial line; (d) if the transformers are of such low kilowatt capacity that the relative cost of the arrester is above the economical dictates of risk and replacement of damaged transformer Loss of service to the customer and the interruption of the main power service by accidental failure of a small power transformer must at present be carried on the debit side of the book value of this customer's payments. At present the lack of acceptable solution of this problem is interfering with the installation of small-power transformers on high-voltage circuits. This is a condition the manufacturer of transformers regrets as much as the power company and is as eager to correct; (e) on underground systems with grounded neutral, arresters may be used sparingly.

Third. As to using thicker insulation instead of lightning arresters—thicker insulation on the transformer turns of the coils engenders more difficulties in extracting the heat from I^2R losses and lessens the kilowatt capacity of the transformer. Since it seems impossible to put on enough insulation to prevent all lightning troubles it has become standard practise to use a reasonable amount of insulation and employ a lightning arrester. The arrester seems necessary anyhow for occasional extreme voltages.

Taking up one of Mr. Hunt's questions relative to the installation of lightning arresters on a circuit consisting of six feeders leading out from a bus—he has received the answers that, at one extreme of practise a lightning arrester should be placed on each one of the six outgoing feeders; at the other extreme, either one lightning arrester on the bus is recommended or none at all if the feeders are cables. If the feeders are important, the lightning frequent, the service demands rigid, the six arresters are desirable. Even greater protection may be necessary. If, on the other hand, the demands of protection are not great, then one or two arresters on the busbars would be sufficient. Two arresters are recommended when it is important to have one as a spare. One arrester of high discharge rate reduces the risk to a small value. However, if this practise of using one arrester is followed there are two important things that must be done at the same time: First, the current transformers must be shunted by bypass gaps; second, since the arrester is on the generator side of the automatic circuit breakers the circuit should be protected against accidental short circuit by suitable fuses on the arrester.

Engineering judgment must be used and all the factors of protection taken into account in order to decide how many lightning arresters to install on these six feeders and how to place them. I shall now take another hypothetical case, not unknown in practise, in which even the installation of six arresters does not give good protection. Suppose the line insulators have an unusually high factor of safety against lightning potential. This is good practise. Money could scarcely be better invested in a transmission line. However, it influences the practise to be followed in lightning arresters. The higher insulation of the line prevents the local relief of induced lightning strokes and therefore carries into the station unusually high lightning voltages. The choice of high factor of safety in the insulators leaves the standard circuit breaker, for example, and the current transformer, for another example, relatively poorly insulated. It is an easy matter for the transmission engineers to select a current transformer of higher voltage than usually demanded. But it is not a matter that can be so easily taken care of in the circuit breaker. The circuit breaker is a combination of a porcelain bushing, steel parts, and metal mechanism which has been standardized and is expensive and presumably already in use in this hypothetical instance. The porcelain bushings cannot be either changed or increased in dielectric strength. To place a single lightning arrester on the bus without any protection on the feeders would be tantamount to inviting the lightning to jump over the bushings of that very important protective device, the circuit breaker, and thereby invite a calamity of serious nature. Such a condition of high insulation on the line and low insulation in the breaker demands not only a lightning arrester on each feeder but also a considerable inductance in the form of choke coils between the line and circuit breaker. It also demands for the best conditions of protection that a lightning arrester be placed on the bus of the station in order to discharge the quantity of electricity which gets through the choke coils of the feeders during the brief period that most of the lightning charge is finding its way to ground through the lightning arrester. A choke coil cannot choke back the traveling wave without absorbing some of the charge. Such an absorbed charge cannot, without reflection of the wave, return to the lightning arresters on the feeders any more than a bullet can return to a rifle barrel after it has passed the muzzle without rebounding from the target. The analogy is complete. Here, then, is described the condition where if the engineer were laying out an

installation in the first place he could have the choice of higher voltage circuit breakers and practically few lightning arresters or lower voltage circuit breakers and a full complement of protective apparatus. Like any other engineering proposition, all the parts must be designed to work together.

The casual critic who holds the weakness of lightning arresters reponsible for the interruption of service during lightning storms is misled by the name of this device, to wit, "lightning arresters", and is in utter confusion regarding their function. A lightning arrester is designed to protect end coil insulation from puncture and any other exterior insulation at the point where the arrester is installed. If it protects the service it is only a secondary matter due to its protection of the insulation. The most prolific cause of interruption of service on overhead lines is arc-overs of insulators by lightning at points distant from arresters. The lightning arrester has no function to prevent such an occurrence. The best protector for accidental arc-overs of insulators is the arc suppressor—a device not yet sufficiently perfected to be used in standard practise.

Prophecies. Closing this part of the subject,—this paper is not intended to give completely even the principles of protection, to say nothing of the theory and practise. It strikes a few high spots raised by the investigating committee. There must be the admission of lack of perfection in the art of protection. This admission is somewhat offset by renewed activities in researches and developments since the close of the war. It may be pertinent (although risky to the prophet) to say we can see the possible routes by which a high degree of perfection is to be attained. This statement is virtually saying that more than half the final spurt is run. Preventing interruption of service by arc-over of insulators will do away with the cause of the majority of interruptions on overhead circuits.

To clean up the final residue of failures and troubles will require the most hearty cooperation between the operating engineers and the laboratory specialists who spend their time studying the voltage phenomena and the characteristics of insulations—and will call for a power of analysis not yet in sight. For long-distance transmission the goal sought is the degree of continuity of service given by the Edison companies in the larger cities. It is possible and must be reached.

The Aluminum Arrester and Criticisms of Film Theories

One of the broad fundamentals dwelt upon in the foregoing pages is the need in an arrester of a high discharge rate, a rate comparable with the currents in lightning surges. It is not necessary to master the fine details of theories of films to determine if an arrester has this quality. Place a single cell of two cones for a unit period of one to four cycles on a 600-volt a-c. circuit of sufficient power to maintain the voltage. Does the current rise to several hundred amperes? Therein is the answer without any theory. An oscillograph gives full data on what takes place. It will give the answer, "No", to the question, "Does the arrester short-circuit the voltage?" The ballistic throw of a large ammeter, not too much damped to respond to a sixtieth of a second, will give an indication of large current flow.

Inspection and Repair of Aluminum Arresters. The question of overhauling the aluminum arresters is by far the most serious criticism that has been made of arresters. The whole subject of inspection and repair is under reconsideration. The following investigations show that the power factor of the aluminum cells, either as individual cells or as a whole stack, may be a desirable method of inspecting the condition of an arrester before deciding to disassemble the parts. The use of power factor is new and, furthermore, it is well-known that the effects given by aluminum cells, such as variations in current, wattage loss, and power factor, are factors of wide variation, depending upon the quality of the aluminum, the nature and temperature of the electrolyte, the wave form, and the like. Some cells have shown deterioration by the presence of an abnormally high charging current. (Unfortunately deterioration is not always accompanied by higher charging current.) Cells have also shown deterioration by the value of the watts loss. So far as the recent investigations have gone the power factor method seems to be the most generally reliable indication of the condition of the cells. Deductions drawn from the measurements of power factor are comparatively new and, while the figures given are actual test data, it will require a wide experience to determine on dependable instructions for making the inspection. With these words of caution against the interpretation of these favorable data as final, some excellent results of these investigations will be briefly reviewed.

The Adirondack Power Company had two 33-kv. arresters handy and of promising interest. Reliable information was received that they had not been overhauled since installation, thirteen years ago. The first point of interest was the conclusion that either the arresters must be in deplorable condition or else there was some good way of avoiding frequent overhauling. We were in search of deteriorated aluminum cones and would have been pleased to have found this condition. The operating engineer may be more pleased by the fact that the aluminum surfaces were not corroded or eaten at the contact line of oil and electrolyte. Of course, thirteen years of daily charging had partially exhausted the electrolyte. Although new electrolyte was needed the discharge rate of each cell on 600 volts was several hundred amperes, showing that the arrester still gave good protection. It was still in good operating condition. The oil was somewhat modified by the oxygen and hydrogen freed by electrolytic action, but was not in a condition risky for operation.

The second point of prime importance was the fact that the charging currents of the several phases of the arrester as read by ammeter were near normal. On the west arrester the currents were slightly below normal. On the east arrester they were only 9 per cent to 27 per cent above the recommended normal value. Wave shape, quality of aluminum, and quantity of electrolyte will make this much difference. Since other tests were made which showed the arrester needed overhauling, the results indicate the unreliability of depending on current readings alone to determine the best time to overhaul. The spark at the beginning and end of charging was snappy and normal. Here, then, was an arrester giving safe and satisfactory operation, but which had reached a point of exhaustion of electrolyte, marking the period most desirable to overhaul.

A new method of simple electrical test was adopted, which shows this deteriorated condition of the cells so strongly that it is more than 300 per cent greater than with new cells. The method consists in measuring the wattage and voltage in addition to the charging current and calculating the power factor. For example, one stack of cones on the east arrester was removed for other studies. A stack of new cones replaced it. The power factor of this new stack was 14 per cent. The three remaining stacks had power factors of 42 per cent, 46 per cent and 47 per cent. (three times normal).

The west arrester with charging currents less than normal had power factors higher and lower than the east arrester, 50 per cent, 44 per cent, 43 per cent and 27 per cent respectively for the four legs. Since no inspection of these cells has been made, other than indicated by these measurements, the physical condition of the cells of the west arrester is not yet known.

Twenty-one cells of the stack taken from a tank of the east arrester were given individually a detailed study. Such measurements were made as: (1) Initial current rush at 250 volts impressed, (2) normal charging current, (3) watts loss, (4) discharge rate at 600 volts impressed, (5) rate of dissolution, (6) power factor, (7) thickness of film, (8) restoration of normal film, (9) resistance of electrolyte, (10) quantity of electrolyte per cell, (11) concentration of electrolyte, (12) insolubility, if any, of precipitate, (13) exhaustion of electrolyte, (14) physical appearance of films and degree of corrosion of the aluminum surfaces, (15) sludge at surface of electrolyte, (16) sludge deposited on the free surface of the cones, (17) also sludge in the body of the oil, and (18) electrolyte in bottom of tank and (19) electrolyte in the oil.

Too much attention to the many details at the present moment will tend to obscure a few important results. In general the individual cells varied in their conditions. Most of them had low charging current. Three of them had currents three times normal. Three showed considerable dissolution of film and required special attention to reform them.

All of them showed relatively high power factor. The highest was 88 per cent. The lowest was 36 per cent. Several ran in the sixty-percentages. Most of them were in the forty-percentages, around the average value for the stack.

Attention was given to the typical groups of cells to determine if they could be brought back to the normal condition of new cells without disassembling. It was done simply and quickly. Electrical treatment (momentary high current rush) was given to the films and the old electrolyte was replaced by new. The power factors returned to the value for new cells. After thirteen years of continuous operation these particular cells were made as good as new without treatment with alkali or acid and without factory formation of film.

As depreciation goes on all apparatus, this record is satisfactory. So far as any one can see the aluminum is good for several decades more. It is desirable to renew the electrolyte more often than once in thirteen years, but apparently no harm has come from this long period of use. Why can not this record be extended to all installations of arresters? We can see no reason to the contrary at present. The materials in the arrester (aluminum, electrolyte and oil) seem to be the same as the average of all other arresters. The only apparent difference from standard practise is in the method of charging the cells each day. When this matter has received thorough investigation and repeated confirmation has cleared away all doubts, it will be time to make definite and final recommendations.

Before this longevity can be brought about there are many arresters in service to be overhauled. There are conditions where films are to be removed as the easiest way of removing impurities on the surface and in the cavities of the aluminum produced by the action of the modified oil. To send aluminum cones back to the factory with the expenses of express, factory labor and chemicals, and loss of time, is a serious factor and an endeavor is being made to develop methods which will avoid much of it in the future. The developments and early installations were made with aluminum formed without elaborate dipping tanks, water cooling and automatic regulation. In the routine standardization of factory processes the early art of formation was forgotten. These methods will be revived and improved so that a properly trained man may be able to reform films without loss of time at the place of installation.

To determine what approximate conditions were involved, single cells were experimented upon. The films were removed and the surfaces of the aluminum thoroughly cleaned, involving about a minute of time. After the cones were washed, the major part of the new film was put on, by the most rapid method known, in about a minute. The temperature of the electrolyte rose about 30 deg. cent. The finish was then applied by the normal charging method. Several minutes of application were used.

With suitable chemicals, machines and equipment

this work may be done in the field of operation. The standard electrolyte contains a germicide and two organic chemicals which make it less suitable and more expensive for forming films than "forming" electrolyte which does not contain them. The electrolyte used in forming is more or less exhausted in the process which involves considerable electrochemical energy. This exhausted electrolyte, therefore, must be replaced by fresh electrolyte after the new films are formed.

This is not the time or place to give the detailed instruction for the proposed methods of inspecting and overhauling. If it is found desirable after further experimentation, it is planned to give instruction elsewhere—in the *G. E. Review* and in pamphlet form.

The new power factor method of inspection of the condition of an aluminum arrester may be put into the hands of any one familiar with the handling of indicating instruments around a high-tension three-phase system. The methods of renovating the films at the place of installation is simple enough to anyone accustomed to manufacturing and laboratory work. There are a few things to be scrupulously avoided. There are corrosive chemicals to be used. Furthermore, an equipment is necessary to do the work economically. There should be two trained men, such things as standard electrolyte, forming electrolyte, acid, motor-generator, standard cells for comparison, exchange racks, "forming" racks, suitable meters (ammeter, voltmeter, wattmeter), potential transformer of variable voltage, jin poles, block and tackle, rapid filter, graduates, suitable glass and rubber tubing, motor-operated contactor and so on.

There will not be enough work on any one transmission system to keep an outfit busy and to retain experts properly trained to carry on the work rapidly with accuracy and judgment. The long intervals between overhaulings allow memory to play tricks in the performance of the method. Changing personnel and positions are other factors which deprive the operator of trained men. If it could be brought about, the most economical results would be obtained by having experts with their outfit go from one system to another devoting their time to this particular work. Will a number of transmission companies share the initial expense of apparatus? With the conditions compatible with success the greatest pains will be taken by the manufacturer to give experts instruction and experience, to help them train their judgment, and to inform them on the proper instruments, apparatus, and methods to employ.

To summarize the possibilities relative to overhauling aluminum arresters, the promises are: More accurate and definite methods of inspection of the arrester will soon be made available. Unnecessary overhauling may be decreased. Longer periods between overhaulings may possibly be brought about by slight changes in methods of charging. Longer life of the arrester may also be attained. The actual cost of overhauling will be decreased. The cost per annum will be greatly decreased. Deteriorated plates may be reformed at the place of installation.

Discussion*

Joseph Slepian: Mr. Creighton has explained very clearly the necessity for a high discharge rate in lightning arresters, if any real protection to electrical apparatus is to be obtained. If this high discharge rate path is also open to normal dynamic voltage, then, as Mr. Creighton points out, the large drafts of dynamic power which must be handled by the arrester makes it too large and costly to be practical. A clear case is thus made out for the valve type of arrester.

The electrolytic arrester is the most widely used valve type and has proven its great value in service. It depends for its action on rather obscure chemical phenomena taking place in thin films on electrodes in water solutions. It has disadvantages inherent with a water electrolyte, requires frequent attention, and sometimes trouble is experienced due to its sensitiveness to chemical impurities.

The recently introduced oxide film arrester also depends for its action on the chemical and electrical properties of a thin film. This film is dry, which is an advantage but like any other solid insulation, it may be somewhat slow in its breakdown under excess potentials.

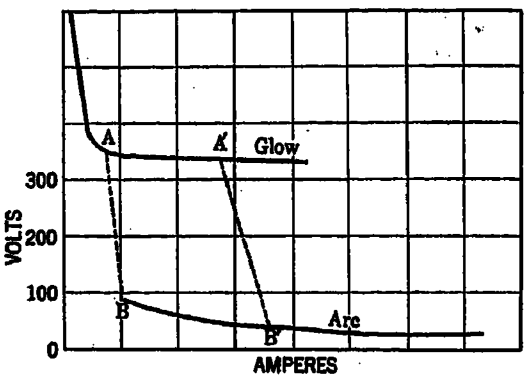

Fig. 1—Arc and Glow Discharge

For some time past, the company with which I am associated has been working on the problem of attaining the ideal valve type arrester, from the other end. That is, instead of starting with the chemical arrester, and trying to remove its disadvantages, we start with the simple spark-gap type of arrester and try to impart to it the valve characteristic. These efforts have been successful, and, as the results are now approaching commercial form, I believe it is of sufficient interest to briefly describe the principles utilized.

To have a valve characteristic, a gap must pass current when and only when the applied voltage exceeds a definite critical value. To be of practical use for lightning arrester purposes, this critical voltage should be of the order of at least several hundred volts. Now it is known that only low-current discharges n air require such high voltages to be maintained, hence an investigation of the volt-ampere relations in low-current discharges is suggested.

Fig. 1 shows the results obtained in such an investigation. For large currents, the ordinary arc characteristic BB' is obtained, with voltages from 20 to nearly 100. The arc issues from a brilliant incandescent cathode spot. As the current is reduced, a point is reached, B in the figure, where the rate of evolution of heat is insufficient to maintain the cathode hot spot, and the voltage and current suddenly jump to values lying on another curve AA'. This is the volt-ampere curve of glow discharge. By water cooling the electrodes, it is possible to carry the curve

*Includes discussion on "Questionnaire on Lightning Arrester Practice," by F. L. Hunt. (From the 1921 Annual Report of the Protective Devices Committe See A. I. E. E. Transactions, Vol. XL. 1921, p. 837.

AA' beyond the point A, say to A', before the developing of a cathode hot spot, and the sudden dropping into the arc characteristic at B'.

In the arc there is an incandescent cathode spot with resultant vaporization of the electrode. If this hot cathode spot is prevented from forming, the discharge takes the glow form, and, with most electrodes, requires not less than 350 volts to be maintained. It is evident that a spark between cold electrodes must always start as a glow, and only after a spot on the cathode becomes sufficiently heated, does an arc form.

The curves in Fig. 1 show that it is not practical to try to get much more than 350 volts consumed in the discharge, and they also show that, if the cathode is kept cool, considerable current density may be passed still maintaining this voltage. The use of electrodes of high specific resistance offers a means for keeping the cathode surface cool for the lengths of time involved in surges on power systems. For if the resistance in series with any point is high, it is clear that the current flowing from any spot on the surface is limited, and so, too, is the heat involved. The energy in the discharge is not turned loose mostly at a small spot on the cathode, but is distributed all over the face of the electrode. Thus, no spot heats excessively, and the discharge remains in the glow form.

Having ensured that the discharge will require 350 volts for its maintenance, we must, if the desired valve characteristic is to be obtained, provide that the discharge shall also start at

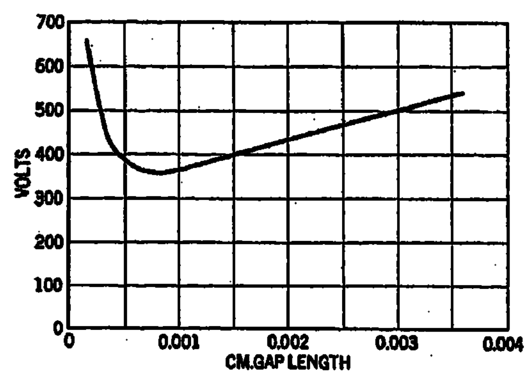

Fig. 2—Sparking Potentials for Small Air Gaps

about 350 volts. At first sight, this seems a requirement impossible of practical attainment, because of the exceedingly minute gap necessary. But here again the high specific resistance in the electrode material comes to our aid.

Fig. 2 shows the relation between the spark-over potentials and gap lengths for plane electrodes, and very short gap lengths.

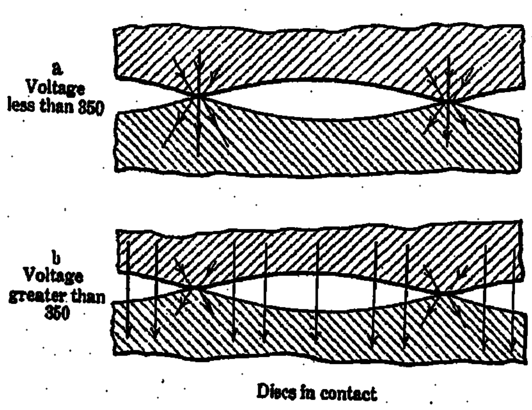

Fig. 3

It shows that the sparking potential reaches a minimum of a little over 350 volts for a gap length a little less than 0.001 centimeter, and that for smaller gap lengths, the sparking potential increases again. This may appear surprising to most of us, but it is well established by experiment.

Now suppose two disks of high-resistance material are laid one upon the other. (Fig. 3). With ordinary workmanship, the disks will make actual contact at only three or four points. Elsewhere, they will be separated by small air gaps, which may run up to three or four mils at their widest. Somewhere between the two extremes of the actual contacts, and the separation of several mils, will occur the separation of about 0.001 centimeter having the breakdown potential of about 350 volts.

When voltages less than 350 volts are applied to the disks, the current will pass only at the points of actual contact, and because of their constricted nature these current paths will be of exceedingly high resistance. Thus, very little total current will pass. (Fig. 3A). When, however, more than 350 volts is applied, the air gaps breakdown, and current is passed over the whole face of the disks. (Fig 3B). Thus, a very low over-all resistance is presented. The resistance in the electrode material forces the current to distribute itself uniformly. Hence there is no local heating, and the discharge remains in the glow form. When the voltage falls to less than 350, the discharge stops, and the current again falls to the very small value passed by the actual contacts.

To recapitulate, by the use of high-resistance electrodes, it becomes practical to use gaps so small that little more than 350 volts is required to break them down. Also the discharge which follows the breakdown is prevented by the resistance from concentrating at any point but must distribute itself over the whole face of the electrodes so that no local hot spot can form, with a resultant arc. Hence the discharge remains in the glow form, requiring over 350 volts to be maintained.

We have here then, an arrester of the valve type which has nothing whatsoever chemical in its principle of operation. It is as simple in its construction as the usual spark-gap arrester, and, in characteristics, parallels the electrolytic arrester. I believe that optimism as to the future of this device is quite justifiable.

Mr. Creighton suggests that the power factor of aluminum electrolytic arresters may be a reliable criterion of the extent of their deterioration. For several years I have been engaged in an extensive study of the power factor of aluminum cells, partly for whatever useful information might result for lightning arrester practise, and partly for the purpose of developing an electrolytic condenser for general power purposes. My experience makes me very doubtful if reliable conclusions can be drawn from the power factor as to the suitability, of a cell for lightning arrester purposes.

The electrical and chemical phenomena going on in the film on aluminum electrodes in an electrolyte are exceedingly complex, and apparently it is possible with different electrolytes to find any combination of the following properties in individual cells: 1. High power factor or low power factor. 2. Rapid dissolution or slow dissolution of film on open circuit. 3. Rapid corrosion or slow corrosion. 4. High charging current or low charging current. 5. Rapid formation of precipitates or slow formation of precipitates.

It is only the last four properties I mentioned which are significant for lightning arrester purposes, but the first is the one on which Mr. Creighton puts a lot of stress.

Actually it is possible to get any combination of all these properties in different electrolytes.

The only uniformity which I have noticed is that all cells which start with low power factor increase their power factor with time. This increase in power factor may or not may be accompanied by any considerable deterioration in respect to the properties (2), (3), (4) or (5). The only conclusion which can be drawn from high power factor is that of age, and little can be said about the properties which are more important for lightning arrester purposes.

As an example, in one electrolyte which I tried, the initial power-factor was 2½ per cent. The cell was connected permanently to the line and let run 24 hours a day. Here was a service thousands of times more severe than that which lightning arresters undergo. Nevertheless, the rise in power factor was very slow. The rise was inappreciable for the first two months, and after a year was only about 10 per cent. Judging by the power factor, here was an ideal lightning arrester electrolyte, but in respect to film dissolution, on open circuit it was quite inferior to the electrolytes now on the market.

Again, another electrolyte ran at about 6 per cent power factor,

but the corrosion was so bad that the run was terminated in a few weeks. Still another electrolyte, although it gave low power factor, kept shedding precipitates of aluminum hydroxide until the cell was almost packed solid with them.

With respect to reestablishing the low power factor by electrolyte renewal, and electrode treatment, I also found matters very complex. A series of experiments indicated very clearly that the rise in power factor was due in large part to a change taking place in the film on the aluminum itself. By re-treating the aluminum in fresh electrolyte it was possible to return to the low power factor, but unless every trace of the old film had been removed, the power factor in the re-treated cell would rise again much more rapidly than it had done in the old cell. For example, if the power factor in the old cell had risen 10 per cent in a year, after re-treating the power factor would rise 10 per cent in a month or two.

I maintain therefore that great caution should be used in drawing conclusions from power factor measurements as to the suitability of aluminum cells for lightning arresters. Many tests over periods of many years will be necessary before confidence can be established in a power-factor criterion.

D. W. Roper: The great difficulty in making a few installations of a new type of arrester is in drawing correct conclusions from the results. Having attempted some investigations of lightning arresters myself and concluded that after a few years it was impossible to draw any accurate conclusions from an installation of 700 arresters, it does not appeal to me when the experience with one or two installations is used as a basis of some general conclusions on high-voltage arresters. However, if we can induce a number of engineers to cooperate in the same investigation on lightning arresters and to use the lightning arrester committee as a clearing house for *all* their information, and not selected portions of it, then we should be able, in a comparatively brief time to get some accurate conclusions.

Quite a large number of types of arresters are mentioned in one of the papers. Not all of them are mentioned. One letter tells about the horn-gap water-barrel combination successfully performing its functions. I wonder if it ever successfully performed the function of a lightning arrester.

The Standards Rules of the A. I. E. E. contain a definition of an arrester, and that is as far as the rules go, but the definition includes the requirement that it must limit the voltage across the apparatus at the time of lightning discharge. Some types of arresters accomplish that result very efficiently. The arresters which have a very large amount of resistance in series apparently do not, and in this connection, I think that some attention should be drawn to a description of the lightning generator, as it was called, in the article in the *General Electric Review* for November and December. This appeared to the speaker one of the most interesting devices brought forward in recent years for the testing of lightning arresters, and the results as given in these two papers are the results which can be used in comparing directly different types of lightning arresters. That is, the tests give a measurement of the maximum potential across the terminals of the arrester at the moment of discharge, which is exactly what is wanted, and the results obtained from that lightning machine appear to check very closely with the results of experience with the different types of arresters in service.

Referring again to the letter regarding the performing of the functions of the lightning arresters, there are quite a few types of apparatus which are called lightning arresters, and which are on the market, and some of which find a ready sale. Some of them will make a funny noise when there is a lightning discharge, and some will make quite an interesting sputtering arc, and you could make them so that they would ring a bell or operate an automatic counter, but they do not comply with the function of a lightning arrester, that is, they do not limit the voltage across the arrester at the time of discharge. I suggest that the Institute might properly take some steps to protect the smaller companies who have occasion to use lightning arresters from the assaults of the glib salesman who sells these interesting, sputtering things called arresters, and which actually serve no useful purpose except to the salesman. The Institute might properly devise a performance specification for lightning arresters, and perhaps have a classification of types which would indicate the relative value of the various types of arresters, and then such a rule, with the backing of the American Institute of Electrical Engineers, would serve, you might say, as a blue sky law to prevent the sale of these lightning announcers to people who want lightning arresters.

J. L. R. Hayden: The deterioration of the aluminum arrester apparently is due to the current passing through it. This pits the cones and changes oil and electrolyte. It causes increase of current passing through. This still further increases the deterioration.

The total current in the aluminum arrester consists of a capacity current and an emergency current. The former does not pass through but merely into the arrester, and is harmless. It is the energy current which does the harm. The energy current normally is very small, compared with the capacity current, so that the total current is mainly made up of the capacity current. Therefore the energy current may considerably increase, without showing an appreciable increase of the total current. The total current may even decrease due to some loss of electrolyte which reduced the active plate surface. It requires a very great increase of energy current to show as an increase of the total current. It would therefore be reasonable to expect that the deterioration could be detected earlier, if the energy current could be measured alone. This is done by wattmeter measurement. Possibly direct-current measurements might do the same, as with direct current there is no capacity current.

The limitations of such method seems to me, that individual cells cannot well be measured, but only the whole stack of cells. The deterioration may be uneven. Only a few cells may have deteriorated, most are still good. Then the power factor of the whole stack would still be low and normal, but the arrester would be unsafe, as the few deteriorated cells heat and arc and thereby destroy the other cells.

As this method gives the average result of the whole stack, it can be useful only if the deterioration is fairly uniform through the whole stack. How far this is the case requires further investigation.

In the *OF* arrester, such measurement of deterioration by the energy current is more feasible, as in the *OF* arrester the capacity current is small, and most of the current is energy current. It therefore is our practise in life testing of *OF* arresters, to regularly measure the current and judge the deterioration from it. Individual cells can be measured. If in the cell the current is abnormally high, then the voltage on the cell is low, if it is in series with other cells. If the energy current is abnormally low—which also is objectionable in the *OF* arrrester,—then the voltage is high. Individual cells of the *OF* arrester therefore are tested by observing whether the voltage across the cell is within the proper limits. This is done in the standard method of service testing of *OF* arresters by the use of a neon tube connected across individual cells.

W. A. Lougee: An arrester to protect must have a sufficiently high current discharge rate, that is, its internal resistance must be low. Lightning arresters are one of the very few types of electrical apparatus which can not be tested and be thoroughly understood by the purchaser, and it is on account of this unfortunate situation that many incorrect ideas are obtained, and that many inefficient lightning arresters are in use.

I would like to take up a few points mentioned in the letters quoted in Mr. Hunt's paper. The oxide film arrester is spoken of as dependent on obscure phenomena and involving the action of films of very minute dimensions; also as a hair trigger device and based on fine haired theories and obscure chemical reactions.

The best answer to all this is to state briefly the arrester's action and behavior when connected to the lightning generator that Mr. Roper mentioned.

With this apparatus, we have been able to obtain a greater discharge through an arrester than the arrester will be subjected to in actual service, outside of a direct stroke. A piece of a tree branch placed in the circuit of this lightning generator will be splintered and torn to pieces. Now if an oxide film arrester is substituted for this tree branch, and, in addition the normal voltage of the arrester be also applied directly to the terminals from a circuit of large power capacity, the high power impulse discharge is successfully taken care of. That is, not only does the impulse go through the arrester without damage to either the dynamic circuit or the arrester, but the recovery or reseal action of the arrester prevents any dynamic power following through the arrester. It is evident to withstand such punishment, the arrester must be staunch and not a hair trigger device.

Another writer mentions the fact that only one of sixteen oxide film arresters discharged. Obviously, this is absurd unless one sits by the arrester and watches it continuously as the arrester itself gives no external indication of discharges.

Lightning arresters are not hot-house plants. They are given a more severe testing in the factory than the majority of electrical apparatus and they will stand a lot of abuse.

Reference was made to the possible high time-lag of the oxide film arrester due to the fact that it consists of solid insulation. The film is solid, but at the same time it is somewhat porous. An oxide film arrester on the circuit without a series gap will pass several milli-amperes of current, and it is on this account that it has not a high time-lag.

L. R. Lee: The writer is interested in lightning arresters from the standpoint of the construction and operating engineer, and in going over this matter of arrester with users, he has found that there is, as mentioned in this paper, some lack of confidence in the use of the lightning arrester. Papers like this should help in restoring some of this lost confidence as they give the user a better insight into the functions of the arrester, the way it performs and some simple tests by which he can convince himself of the value of the arrester as a device to limit the damage that may be caused by high voltage. I think that the account given about the arrester which went some thirteen years without being opened is interesting but I doubt the advisability of giving publicity to such examples. I would much rather hear about arresters that have been systematically repaired twice a year by opening the arrester and giving thorough inspection, and how this was accomplished at small cost and little inconvenience. I believe some of the lack of confidence has been due to lack of proper maintenance.

I do not believe the construction and the operating engineer are in a position to offer any valuable suggestions as to the way arresters should be built, it is their function to see that they are properly installed and maintained. It is up to the manufacturer to collect all possible data from the operating and construction engineers as to troubles or difficulties which they may have encountered in the use of arresters and make all possible use of such data in making progress in the design of this equipment. I doubt whether there could be too much emphasis placed by the manufacturer upon the proper care of the arrester and the proper way of installing it.

It is not only important that the manufacturer point out on the wiring diagram the location for the arrester but he should also advise with the construction engineer as to the physical arrangement of the connections for the arrester, and in planning for the installation of the arrester thought should be given to any trouble which may occur from the use of the arrester and also to the accessibility and convenient arrangement that may facilitate inspection and repair.

I realize that the manufacturer has been loath to lay down too rigid rules for the maintenance of this equipment, and I realize his good intentions of working out ways of testing the equipment so that it may not be necessary to disassemble it, but it seems to me quite natural to expect confusion on the part of the operating engineer when he is told about tests which may indicate to him the condition of his arrester and at the same time told that these tests may not work and that the arrester should be overhauled in any case. I believe it would be better to spend any effort along this line towards making it easier and cheaper to open the arrester and give it thorough inspection and such repair as may be necessary.

The writer has been much pleased to note the progress being made in the oxide film type of arrester as it seems that this arrester working on a similar theory to that of the electrolytic, is a device much simpler and easier repaired and altogether seems to have many advantages.

Condenser Discharges Through a General Gas Circuit

BY CHARLES P. STEINMETZ
Fellow, A. I. E. E.
Chief Consulting Engineer, General Electric Company, Schenectady, N. Y.

Review of the Subject.—*Any change in the electrical conditions of a circuit, whether internal, such as a change of load, starting and switching operations, short circuits, or external, such as due to lightning, involves a readjustment of the stored electromagnetic and electrostatic energy of the circuit, that is a so-called transient. Such transient is of the general character of a condenser discharge through an inductive circuit. The phenomenon of the condenser discharge through an inductive circuit therefore is of the greatest importance to the engineer, as the foremost cause of high-voltage and high-frequency troubles in electric circuits.*

With the development of radio communication—whether wireless or wired—the condenser discharge through an inductive circuit has assumed a great additional importance since, with the exception of a few of the highest power transoceanic stations, which use power-driven high-frequency alternators, the source of power in all radio communication is the condenser discharge through the inductive circuit, whether as a damped wave or as an undamped wave. In undamped wave radio communication, the condenser discharge circuit is coupled with a source of electric power—a battery—in such a manner, that, without interfering with the character of the oscillation, sufficient energy is fed into the circuit to maintain the oscillation, similarly as in the clock, the pendulum is coupled with a source of mechanical power—weight or spring—so as to maintain its oscillation undamped.

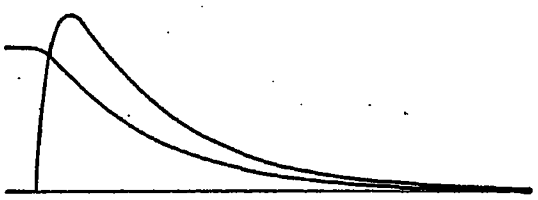

FIG. A

The condenser discharge through an inductive circuit is thus one of the most important phenomena with which the electrical engineer has to deal.

The classical equations of the condenser discharge through an inductive circuit were given a very long time ago, and are contained in all text books.

According to them, if the ohmic resistance r of the circuit is greater than a certain critical value $r_0 = 2\sqrt{\dfrac{L}{C}}$, *the discharge is unidirectional and non-oscillatory, that is, the voltage and current gradually die out without ever reversing in direction, and vanish, theoretically, after an infinite time, as illustrated in Fig. a for the case* $r = 1.5\, r_0$.

If the ohmic resistance r is less than the critical value r_0, *the discharge is oscillatory, that is, voltage and current perform a series of oscillations of gradually decreasing amplitude, but constant frequency, each half wave being less than the preceding one by a constant percentage, until finally, after a theoretically infinite number of half waves, the current and voltage become zero, as illustrated in Figs. b and c. Fig. b shows a rapid damping, due to the resistance of the circuit being not much less than the critical resistance,* $r = 0.5\, r_0$; *and Fig. c shows the slow damping that is, the more sustained oscillation, appearing in a low-resistance circuit,* $r = 0.1\, r_0$. *The half waves of current and of voltage are not sine waves, but are the product of a sine wave and an exponential, due to damping effect of the resistance, therefore the first part of each half wave is greater than the last part, and the maximum is not in the middle, but before the middle, as is best seen in Fig. b*

These classical equations of the condenser discharge however apply only when the resistance of the circuit is constant, or practically so, that is, when all the energy dissipation occurs in a metallic or electrolytic resistance; that is, a resistance consuming a voltage proportional to the current, and in which therefore the voltage drop in the resistance becomes zero for zero current. These classical equations however do not apply even approximately, when the resistance of the circuit is not constant but varies with the current, as is the case in a gas circuit, such as a spark gap, vacuum tube,

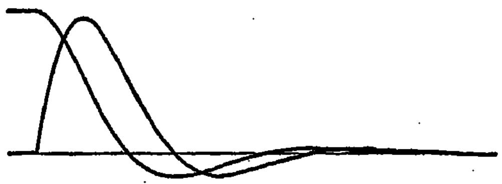

FIG. B

etc., as has been pointed out before. It is rarely that the condenser discharge through an inductive circuit does not include, at least, as a part of its energy-dissipating resistance, a gas circuit.

The usual method of producing a condenser discharge through an inductive circuit is gradually to charge a condenser from a source of electric power, until the condenser voltage has risen sufficiently high to jump a spark gap (the rotary gap, or quenched gap of the damped wave wireless for instance) and thereby discharge through the inductive circuit. In lightning disturbances of electric systems, and in high-voltage high-frequency disturbances, due to internal causes, an arc or spark discharge almost always is in circuit. The discharge of the lightning arrester which protects electric circuits, generally, occurs over a spark gap. In the production of undamped waves for radio communication, a vacuum tube is in circuit. The path of the lightning discharge in the clouds, or between clouds and ground, is entirely within the air, and the voltages and currents induced in transmission lines by the lightning flash naturally follow the voltage and current wave shape of the lightning flash, which is not that of the classical equations. A condenser discharge containing no gas path, like that of the bound charge of an overhead ground wire, set free by a cloud discharge, is rare

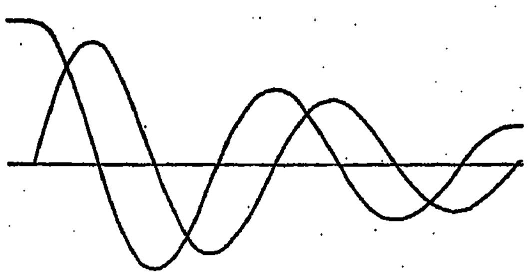

FIG. C

Obviously the larger the part of the total energy dissipation of the condenser discharge which occurs in a gas path, the more the discharge equations differ from the classical equations, so that, while the latter may give a fair approximation when the gas path constitutes only a small part of the energy dissipation, when it represents all or a large part of it, the classical equations become unsatisfactory. In view of the high industrial importance of the condenser discharge through an inductive circuit, and the relatively small amount of work done on the general equations of a condenser discharge through a non-ohmic resistance, a further study of it appears appropriate.

Presented at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

When dealing with a non-ohmic resistance, that is, a resistance varying with the current, it usually is preferable to drop the term "resistance", and deal with the relation between the current i and the voltage E. Thus, the general differential equations of the problem are derived from the classical equations by adding a term E, which is the potential drop across the gas path, or, in general the non-ohmic resistance. This voltage E is a function of the current i, and often also of the time t—where there is a lag of the effective resistance, that is an asymmetry between rising and decreasing current. As i also is a function of the time, E is a function of the time, and can be expressed by a Fourier series (multiplied by an exponential). This gives a general differential equation, which is integrated by the product of exponential function and Fourier series, and the constants of the integral equation—the integration constants and the indeterminate coefficients of the Fourier series—then follow from the terminal conditions, that is, the values of current and condenser voltage at time zero, and the relation between E and i in the gas path, that is, the volt ampere characteristic of the gas path, as shown in the mathematical part of the paper.

The general characteristics of the current flow through a gas circuit—arc, spark, vacuum tube, etc.,—is that the effective resistance" is not constant, but varies with the current, decreases with increases of current and becomes infinite for zero current. Or, considering the relation between current and potential drop, that is, the volt-ampere characteristics of the gas path—as more satisfactory in such circuits—the current is not proportional to the voltage, but no current (except a negligible ionic current) flow until a finite voltage E_1—the ionization voltage or disruptive voltage of the gas path—is reached. Then the current begins, and with increase of current, the potential drop across the gas path either remains approximately constant (as shown in oscillograms 1 and 2, low vacuum tube), that is, the effective resistance decreases inverse proportional to the current, or the potential drop decreases with increase of current (as shown in oscillograms 3, high vacuum tube), that is, the effective resistance decreases more than inversely proportional to the current. With decrease of current, the potential drop then increases again, to the final value E_2 at zero current (E_2 usually being smaller than E_1). At the reversal of the current, the potential drop across the gas circuit thus suddenly changes, from E_2 to $-E_1$, that is, shows a discontinuous or abrupt change by $E_1 + E_2$, as shown by the oscillograms.

There can be no instantaneous voltage change at the condenser, since such would mean an instantaneous change of condenser charge, and thus an infinite current. The change of potential drop across the gas path, at zero current, thus must be neutralized by an equal but opposite instantaneous change of the inductance voltage, and as the inductance voltage is proportional to the rate of change of the current, the rate of change of current, that is, the slope of the current wave, must abruptly change at the current reversal. Wherever therefore a gas path is in circuit the slope of the current wave abruptly changes at zero current, as shown in the oscillograms and frequently observed before, though its meaning has not always been realized. The voltage and current waves however must remain continuous.

As it is not possible to integrate over a discontinuity, the integral equations of the condenser discharge through a circuit containing a gas path can apply only for one half wave of current. It therefore is not possible to get a set of equations to represent the complete discharge, but for every half wave of current of the discharge, a new set of equations applies, as shown in the numerical examples. In general the equations of discharge current and voltage are of the same form throughout, but have different cons'ants for every half wave. The constants for the first half wave are derived from the initial terminal conditions, that is, the values of current and condenser voltage at the beginning of the discharge. The constants of the second half wave are derived from the final values at the end of the first half wave as initial values of the second half wave, and so on.

As the frequency is one of the constants derived from the terminal conditions, the different terminal conditions of the successive half waves may give different values of frequency for the different half waves of the same discharge. This is the case, and the frequency that is, the durat on of the successive half waves is not the same, but the frequency decreases. In other words, the duration of the successive half waves, or the wave length, increases, especially towards the end of the discharge, as is quite noticeable in the oscillograms. This increase of wave length may be quite considerable, as much as 25 to 30 per cent for the last half wave in some of the instances given in the paper. This feature may have some bearing in damped radio telegraphy, by limiting the sharpness of the possible tuning.

With a gas path in the circuit requiring a finite voltage E_1 for the current to start, it follows that if the initial condenser voltage e_0 is greater than E_1, the discharge takes place; if e_0 is less han E_1 no discharge occurs. The classical condenser discharge equations always give a discharge, whatever may be the value of the condenser voltage e_0.

From this it also follows that the condenser discharg through a gas circuit can have only a finite number of half waves, and not an infinite number of progressively increasing values, as given by the classical equations. At every successive half wave of discharge, the condenser voltage e is less than that of the preceding half wave, due to the energy dissipation in the circuit, and therefore, at a finite number of half waves, the condenser voltage e must drop below the voltage E_1, required to initiate the current through the gas path, and then the discharge abruptly stops leaving a finite voltage e, and therefore charge, in the condenser. This may be in the same or in opposite direction to the initial charge e_0, as seen on the oscillograms and the numerical examples calculated in the paper. Thus the condenser discharge through a gas circuit consists of a finite number of half waves, after which it abruptly stops, and it does not completely discharge the condenser, but leaves a "residual" voltage and charge on the condenser. The number of half waves is less the greater the energy dissipation and the more rapid therefore the decrease of the condenser voltage, so that at high energy dissipation, only a single half wave of current may occur, as shown in some of the examples. In this case, the discharge is unidirectional, but differs from the non-oscillatory discharge of the classical equations in that the current abruptly goes down to zero and a voltage is left on the condenser, while in the classical equations the current and voltage gradually fade out.

The simplest case is a condenser discharge through an inductive circuit of negligible ohmic resistance, but containing a gas circuit in which the counter e. m. f. is constant. The gas path then acts as a constant counter e. m. f. If the initial condenser voltage is e_0, the discharge current is that of the resultant voltage ($e_0 - E$) through an inductive circuit of negligible resistance, and is thus a sine wave. At the end of the first half wave the resultant voltage has reversed, being $-(e_0 - E)$, and with E as the counter e. m .f. of the gas path, this leaves $-(e_0 - E) + E$, or $-(e_0 - 2E)$ at the condenser. The second half wave of discharge is again a sine wave, but starting with the condenser voltage $-(e_0 - 2E)$, lower by $2E$, than the condenser voltage with which the first half wave started. Thus the resultant voltage is $-(e_0 - 2E) - E = -(e_0 - 3E)$, since during the second half wave $-E$ is the counter e. m. f. of the gas path. In this case, there is not attenuation or decay during the half wave, but the half waves are sine waves, and all the decay due to the energy dissipation in the gas path occurs discontinuously at the current reversal by the successive half waves of current and voltage being lower by a constant value.—the value due to $2E$, the voltage discontinuity at the current reversal.

It is interesting to note therefore, that no matter how high the energy dissipation in the gas path, that is, the effective resistance of the gas circuit, it has no effect whatever on making the discharge non-oscillatory, but the discharge through a gas path is always oscillatory, no matter how high the energy dissipation. Thus the lightning flash must always be oscillatory, though, if the energy dissipation is very rapid—as in the faint terminal streamers of a branch discharge— the oscillation may consist of one half wave only, as in Figs. 2(I) and 3(I) of the paper.

Such a condenser discharge through a gas circuit having a constant counter e. m. f., E, thus becomes non-oscillatory only, if in addition to the gas path, there is an ohmic resistance r in circuit greater than the critical resistance r_0 of the classical equations. Discharge waves of this character are given in Fig. 1 (III) of the paper for the case of negligible ohmic resistance, and in Fig. 1 (II) if the discharge circuit contains ohmic resistance besides the gas path.

Consider a gas circuit like that in oscillogram 3, in which the potential drop across the gas circuit decreases with increase of current, and therefore is a maximum E_1 at zero current, and a minimum E_m at high current. Then at the beginning of each half wave, the current starts at the rate of a sine wave discharge of the condenser voltage e_0 with a counter e. m. f. E_1, but with increasing current, the counter e. m. f. decreases, the more the greater the difference between E_m and E_1, and the resultant voltage $(e - E)$ thereby increases. That is the current increases at a greater rate than it would in a sine wave—the reverse of that in the classical equations— so that the first part of the current half wave is lower than the last part, and the current maximum is beyond the middle of the half wave, as shown in the oscillograms and numerical examples. That is, each half wave has the character of a cumulative oscillation, and the exponent of the exponential term is positive. (Such discharge waves are impossible with the classical equations.) Therefore, in the case of a gas path with double peaked potential drop, an attenuation occurs at the current reversal lowering the height of the following half wave below that of the preceding half wave; but in the following half wave a cumulative effect occurs and again increases the height of the half wave, Necessarily, the cumulative effect, being due to the difference $E_1 - E_m$, is less than the attenuation, which is due to E_1, so that the result is a decay of the discharge as obvious, but at a rate less than corresponds to E_1.

Or, in other words, at the current reversal, an attenuation or wave decay occurs, greater than that corresponding to the energy dissipation in the circuit, and during the following half wave, a cumulative effect occurs, returning the energy and reducing the attenuation to that corresponding to the energy dissipation. The effect is then of the character of a discharge through a circuit having a constant counter e. m. f., E_1, and a negative resistance. It is interesting to note, that in such a circuit an ohmic resistance r can be inserted, equal and even greater than the critical resistance r_0 of the classical equations, and the discharge nevertheless remains oscillatory. It becomes non-oscillatory only when the ohmic resistance, inserted in series to the gas path, is greater than the sum of the critical resistance r_0 and the apparent negative resistance of the gas path.

Numerical examples of such a discharge are given in Figs. 2 (III) and 3 (III) of the paper, for the case of negligible ohmic resistance, and in Figs. 2(I) and (II) for the case of the circuit containing ohmic, that is, constant, resistance in addition to the gas path.

The maximum value, which the negative resistance of the gas path can reach is equal to the critical resistance r_0.

The general method of integration described in the foregoing, applies not only to symmetrical circuits, that is, gas circuits in which the potential drop for rising current is the same as for decreasing current, but also for unsymmetrical gas circuits, or circuits in which the potential drop at decreasing current is different, almost always less, than for increasing current. Examples of both types of discharge are given in the paper, Figs. 1 and 2 being symmetrical, and Figs. 3 and 4 unsymmetrical discharges. As the integration takes place step by step for each half wave, the method applies equally to so-called unidirectional gas circuits, that is, gas circuits having a potential drop which for current flow in one direction is different, often very many times greater, than for current flow in the opposite direction, such as the circuit of a vacuum tube with one incandescent and one cold electrode, etc., such as so-called rectifing circuits. Examples of such are given in Fig. 7.

To conclude then; the condenser discharge through an inductive circuit of negligible ohmic resistance, but containing a gas circuit, is always oscillatory.

The oscillation consists of a finite number of half waves, the less, the greater the energy dissipation in the gas path.

The oscillation stops abruptly, leaving a finite voltage and charge in the condenser, which may be in the same or in the opposite direction to the initial voltage.

The frequency of the successive half waves is not constant, but decreases, that is, the wave length decreases, in the successive half waves. If the potential drop across the gas circuit is constant the discharge consists of pure sine half waves. In a circuit of negligible ohmic resistance, the successive half waves decrease by a constant difference.

In such a circuit, the discharge becomes non-oscillatory only if in addition to the gas path, it contains an ohmic resistance greater than the critical resistance of the classical equations.

If the potential drop across the gas circuit decreases with increasing current, the discharge waves are cumulative, that is, the current increases during each half wave, and the decay of the wave is produced by the amplitude of the successive half waves decreasing at the current reversal, but the exponent of the exponential term is positive.

Such a circuit acts like a combination of a constant counter e. m. f. and a negative resistance.

The discharge through such a circuit becomes non-oscillatory only if, in addition to the gas circuit, it contains an ohmic resistance greater then the sum of the critical resistance of the classical equations plus the negative resistance of the gas circuit.

The condenser discharge through an inductive circuit containing in addition to an ohmic resistance a gas path, is intermediate between the discharge through a pure gas path and the classical condenser discharge equations, but always retains the characteristics of the discharge through a gas path, of a finite number of half waves, a residual charge on the condenser, a decrease of the frequency and a change and often reversal of the attenuation constant.

THE usual equations of the condenser discharge through an inductive circuit, as given in the text-books, give an oscillation of progressively decreasing amplitude, if the circuit resistance is less, and an impulse or unidirectional discharge, if the circuit resistance is more than twice the surge impedance. They apply only for the case in which the resistance of the circuit is constant, that is, independent of the current, and therefore do not apply to the very common case in which the discharge circuit includes a spark gap or largely consists of a gas path (as is the case with the lightning flash). Experience shows that the phenomenon is essentially different; for instance, the condenser does not completely discharge, but a residual charge remains, which may be in the same, or in opposite direction to the initial charge.

A study of these more general discharge equations thus is of interest, and is given in the following in a somewhat different form from previous publications.

Let an electric circuit contain a constant capacity C, a constant inductance L, a constant ohmic resistance r, and an effective resistance r', the voltage E of which varies with the current in any desired manner:

$$E = i\, r' = f\,(i)$$

such as that of an arc, spark or vacuum discharge (lightning).

Characteristic of such gas or vacuum discharges is, that the voltage E does not vanish for zero current, but reaches a finite value at $i = 0$, that is, the "effective resistance" r' becomes infinite at zero current. Usually, the voltage E is a maximum for zero current, and decreases with increasing current.[1]

Some approximate empirical equations which have been proposed for such discharges, are:

Gas discharge $E = r' i = \dfrac{a}{1 + b i}$;

where a = disruptive strength of residual ionization of discharge path.

Arc $E = r' i = e_0 + \dfrac{a (l + \delta)}{\sqrt{i}}$

where e_0 = terminal drop, l = length of arc, and δ = terminal effect on arc stream.

Geissler Tube $E = r' i$ = const. (approximation, at fairly high gas pressures especially)

In all these cases, where the voltage E does not disappear, but reaches a finite value E_0 at zero current, it must as counter e. m. f. of energy dissipation in the discharge path, abruptly change at the current reversal, from $+ E_1$ to $- E_0$, that is, the counter e. m. f. E contains a discontinuity at $i = 0$.

In a circuit containing inductance and capacity, neither current nor voltage can change abruptly, that is, instantly, but both must be continuous, since a discontinuity of current would give an infinite e. m. f. of self-induction, a discontinuity of voltage an infinite capacity current. Thus the discontinuity of the counter e. m. f. of the discharge path must be compensated by an equal and opposite discontinuity of the counter e. m. f. of self-induction, that is by a discontinuity in the slope of the current wave.[2]

Due to the discontinuity of the slope of the current wave at the current reversal, the integration cannot be carried over the current reversal, but a different set of integral equations applies to each half wave of current. The integral equations of the successive half waves usually have the same form, but differ from each other by their integration constants derived from the terminal conditions: The initial terminal conditions of each half wave being the final terminal conditions of the preceding half wave.

1. In some conductors, with increasing current, the voltage E reaches a minimum, and then increases again with further increase of current. (pyro-electric conductors.)

2. Such discontinuities of the slope of the current wave are shown by the oscillograph in circuits containing such conductors, as those of rectifiers, circuit breakers, etc. For some such oscillograms, see "Transient Phenomena," II Section, in the chapter on arc rectification. Also see the following oscillograms, Figs. 8 to 10.

General Case

The differential equations of the discharge of a condenser of constant capacity C and initial voltage e_0, through a constant inductance L, a constant resistance r, and a circuit of counter e. m. f. $E = f(i)$, (lightning flash, Leyden jar discharge), are then given by:

Voltage at condenser terminals

$$e = L \frac{d i}{d t} + r i + E \tag{1}$$

Current in discharge circuit

$$i = C \frac{d e}{d t} \tag{2}$$

with the terminal conditions

$$t = 0; \quad i = 0; \quad e = e_0 \tag{3}$$

Differentiating (1) and substituting (2), therein, gives

$$L \frac{d^2 i}{d t^2} + r \frac{d i}{d t} + i/C + \frac{d E}{d t} = 0 \tag{4}$$

As i is a function of t, $E = f(i)$ may be expressed as a function of time

$$E = f(i) = f'(t)$$

and in the interval between two successive zero values of i, $f(i)$ can thus be expressed by a Fourier series of t.

Instead of expressing $f(i)$, without loss of generality, the function

$$F(t) = \epsilon^{ct} (B_0 - f(i)) \tag{5}$$

can be expressed in a Fourier series, where c is still an arbitrary constant, and B_0 chosen so that $f(i)$ has no constant term.

This gives

$$E = f(i) = B_0 - \epsilon^{-ct} F(t)$$
$$= B_0 - \epsilon^{-ct} \Sigma \{B_k \sin k q t + B_k' \cos k q t\} \tag{6}$$

where c is an exponential decrement, and q the wave length constant, that is, $q t = \pi$ gives the interval between two successive zero values of current. c and q appear as integration constants.

[Equation (5) excludes the case of the impulsive discharge, in which the current reaches zero only after infinite time, as occurs for $f(i) = 0$; $r \gtrless 2 \sqrt{L/C}$. This case is of no importance here.]

In view of equation (6), (4) is integrated by

$$i = \epsilon^{-ct} \Sigma \{ A_k \sin k q t + A_k' \operatorname{cost} k q t \} \tag{7}$$

As the integration is carried over one half wave only, we can, without loss of generality, assume the trigonometrical part of the second half wave of (8) and (7) as symmetrical with that of the first half wave, that is, (7) and (8) to contain only the odd harmonics: $k = 2 i + 1$

Substituting (6) and (7) into (1) and (4) gives

$$e = B_0 + \epsilon^{-ct} \Sigma \{ [A_k (r - c L) - k q L A_k' - B_k] \sin k q t + [k q L A_k + A_k' (r - c L) - B_k'] \cos k q t\} \tag{8}$$

$$\epsilon^{-ct} \Sigma \{ [A_k (1/C - c r - L [k^2 q^2 - c^2])$$

$$- k\,q\,A_k'\,(r - 2\,c\,L) + (c\,B_k + k\,q\,B_k')]\sin k\,q\,t$$
$$+ [k\,q\,A_k\,(r - 2\,c\,L) + A_k'\,(1/C - c\,r$$
$$- L\,[k^2\,q^2 - c^2]\,) - (k\,q\,B_k - c\,B_k')\,]\cos k\,q\,t\} = 0 \qquad (9)$$

$t = 0$ gives the terminal conditions; $i = 0$; $e = e_0$; thus, substituting into (7) and (8)

$$\Sigma\,A_k' = 0 \qquad (10)$$

$$e_0 - B_0 = \Sigma\,\{k\,q\,L\,A_k + A_k'\,(r - c\,L) - B_k'\}$$

and by (10)

$$e_0 - B_0 = \Sigma\,\{k\,q\,L\,A_k - B_k'\} \qquad (11)$$

As equation (9) must be an identity, its individual coefficients must vanish. This gives the $2\,n$ equations [where n = number of harmonics of the series in (6) and (7)]

$$\left.\begin{array}{l} A_k\,(1/C - c\,r - L\,[k^2\,q^2 - c^2]\,) \\ - k\,q\,A_k'\,(r - 2\,c\,L) + c\,B_k + k\,q\,B_k' = 0 \\ k\,q\,A_k\,(r - 2\,c\,L) + A_k'\,(1/C - c\,r \\ \quad - L\,[k^2\,q^2 - c^2]\,) - k\,q\,B_k + c\,B_k' = 0 \end{array}\right\} \qquad (12)$$

If the relation between the current i and the potential drop E across the gas circuit, is given by an equation

$$E = f\,(i) \qquad (13)$$

then, substituting for E and for i the equations (6) and (7) into (13), gives an identity in $\sin k\,q\,t$, $\cos k\,q\,t$ and the constant term, and their individual coefficients must vanish. This gives $(2\,n + 1)$ further equations.

If the relation between E and i is given empirically, by curve or table, $(2\,n + 1)$ corresponding values may be chosen and so give the second set of $(2\,n + 1)$ terminal equations.

The $2\,n$ equations (12), the $(2\,n + 1)$ equations derived from (13), and the two equations (10) and (11) give a total of $(4\,n + 3)$ equations, for the determination of the $4\,n + 3)$ integration constants A_k, A_k', B_k, B_k', B_0, c and g.

A. Constant Resistance

If the resistance of the discharge circuit is constant, $= r$, that is, $E = 0$; B_0, B_k, and B_k' vanish, and by (12), all the A_k and A_k' also vanish, that is, there is no discharge, unless in one of the A_k, A_k' the individual coefficients in (13) vanish, and this A_k and A_k' thus becomes indefinite.

Assume this to be the case for $k = 1$. This assumption leaves the conditions general, as by choosing another value of k, the k merely enters as a factor into the q.

We have then, for $k = 1$, by equation (12)

$$1/C - c\,r - L\,(q^2 - c^2) = 0$$
$$r - 2\,L = 0$$

thus

$$\left.\begin{array}{l} c = \dfrac{r}{2\,L} \\ q = \sqrt{\dfrac{1}{L\,C} - \dfrac{r^2}{4\,L^2}} \end{array}\right\} \qquad (14)$$

by (10), $A' = 0$, and by (11)

$$A = \frac{e_0}{q\,L}$$

thus

$$\left.\begin{array}{l} i = \dfrac{e_0}{q\,L}\,\epsilon^{-\frac{r}{2L}t}\,\sin q\,t \\ e = e_0\,\epsilon^{-\frac{r}{2L}t}\left\{\cos q\,t + \dfrac{r}{2\,q\,L}\sin q\,t\right\} \end{array}\right\} \qquad (15)$$

These are the well-known equations of the condenser discharge through a circuit of constant resistance, inductance and capacity.

The ratio of the values of two successive half waves is constant

$$i_2/i_1 = \epsilon^{-\frac{r\pi}{2qL}} \qquad (16)$$

that is, the discharge decreases in constant geometrical proportion.

An instance is plotted as curve I of Fig. 1, for the constants

$C = 10^{-6}$; $L = 10^{-2}$; $r = 50$; $e_0 = 20{,}000$, giving the equations:

Discharge Current

$$i = 207\,\epsilon^{-2500\,t}\sin 9685\,t$$

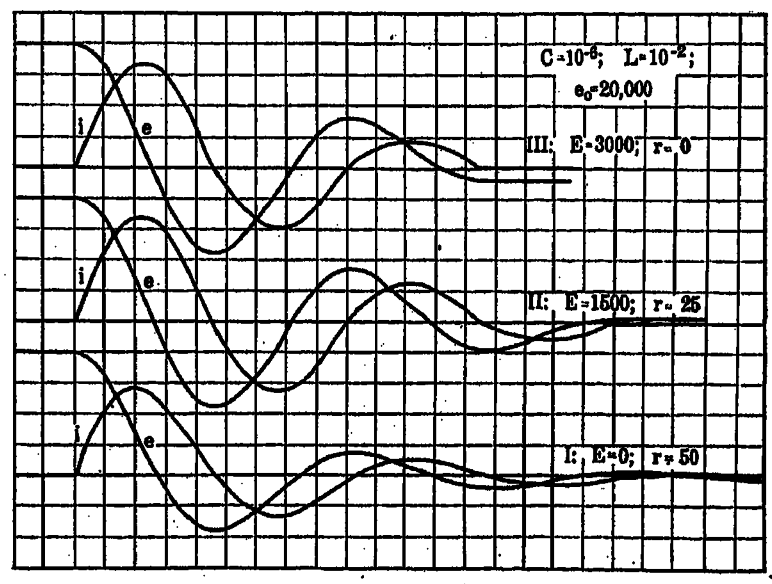

Fig. 1

Condenser Voltage

$$e = 20{,}000\,\epsilon^{-2500t}\,\{\cos 9685\,t + 0.258\sin 9685\,t\,\}$$

B. Constant Voltage Drop in Gas Circuit

$$E = \text{constant} = E_0$$

This gives $B_0 = E_0$; $B_k = 0 = B_k'$

Thus by the same reasoning, equation (12) gives

$$c = \frac{r}{2\,L}$$

$$q = \sqrt{\frac{1}{L\,C} - \frac{r^2}{4\,L^2}}$$

By (10); $A = 0$

and by (11) $A = \dfrac{e_0 - E_0}{q\,L}$

Thus

$$\left.\begin{aligned} i &= \frac{e_0 - E_0}{q\,L}\,\epsilon^{-\frac{r}{2L}t}\sin q\,t \\ e &= E_0 + (e_0 - E_0)\,\epsilon^{-\frac{r}{2L}t}\{\cos q\,t \\ &\qquad + \frac{r}{2\,q\,L}\sin q\,t\} \end{aligned}\right\} \quad (17)$$

An instance is plotted as curve II, Fig. 1, for the constants

$C = 10^{-6}$; $L = 10^{-2}$; $r = 25$; $E = 1500$; $e_0 = 20{,}000$ giving the equations

$$\begin{aligned}
i_1 &= 186.4\,\epsilon^{-1250t}\sin 9920\,t \\
i_2 &= -\,123\,\epsilon^{-1250t}\sin 9920\,t \\
i_3 &= +\,70.6\,\epsilon^{-1250t}\sin 9920\,t \\
i_4 &= -\,27.7\,\epsilon^{-1250t}\sin 9920\,t \\
i_5 &= 0 \\
e_1 &= 1500 + 18{,}500\,\epsilon^{-1250t}\{\cos 9920\,t + .126\sin 9920\,t\} \\
e_2 &= -\,1500 - 12{,}200\,\epsilon^{-1250t}\{\cos 9920\,t + .126\sin 9920\,t\} \\
e_3 &= +\,1500 + 7000\,\epsilon^{-1250t}\{\cos 9920\,t + .126\sin 9920\,t\} \\
e_4 &= -\,1500 - 2750\,\epsilon^{-1250t}\{\cos 9920\,t + .126\sin 9920\,t\} \\
e_5 &= +\,760 = \text{const.}
\end{aligned}$$

In the special case that the ohmic resistance is negligible, $r = 0$, and all the energy dissipation occurs in a gas circuit of constant potential drop $E = E_0$, we have,

$$\left.\begin{aligned} c &= 0 \\ q &= \sqrt{\frac{1}{L\,C}} \end{aligned}\right\}$$

thus

$$\left.\begin{aligned} i &= (e_0 - E_0)\,z_0 \sin q\,t \\ e &= E_0 + (e_0 - E_0)\cos q\,t \end{aligned}\right\} \quad (18)$$

where

$z_0 = \sqrt{L/C}$ = surge impedance, or natural impedance of the circuit

In this case, at the end of the first half wave, we have,

$$e = e_1 = -\,(e_0 - 2\,E_0)$$

and the second half wave is given by

$$\left.\begin{aligned} i_2 &= -\,(e_0 - 3\,E_0)\,z_0 \sin q\,t \\ e_2 &= -\,E_0 - (e_0 - 3\,E_0)\cos q\,t \end{aligned}\right\} \quad (19)$$

In this case, the difference between the maximum values of two successive half waves is constant:

$$\begin{aligned} e_1 - e_2 &= 2\,E_0 \\ i_1 - i_2 &= 2\,z_0\,E_0 \end{aligned} \quad (20)$$

that is, the discharge decreases in constant *arithmetical* porportion.

An instance is plotted as curve III of Fig. 1, for the constants:

$C = 10^{-6}$; $L = 10^{-2}$; $r = 0$; $E = 3000$; $e_0 = 20{,}000$, giving the equations:

$$\begin{aligned}
i_1 &= 170\sin 10{,}000\,t \\
i_2 &= -\,110\sin 10{,}000\,t \\
i_3 &= +\,50\sin 10{,}000\,t \\
i_4 &= 0 \\
e_1 &= 3000 + 17{,}000\cos 10{,}000\,t \\
e_2 &= -\,3000 - 11{,}000\cos 10{,}000\,t \\
e_3 &= +\,3000 + 5000\cos 10{,}000\,t \\
e_4 &= -\,2000 = \text{const.}
\end{aligned}$$

If $e_0 = 2\,p\,E_0 \pm e_0'$ (21)

where p is the largest integer by which $2\,E_0$ divides into e_0, and leaves e_0' numerically (irrespective of the sign) less than E_0, that is, $e_0'^2 \leqq E_0^2$, p is the number of successive half waves of the discharge, and $\pm e'_0$ is the residual charge, remaining in the condenser, after the discharge stopped. That is, in this case, the condenser discharge does not consist of a (theoretically) infinite number of gradually decreasing half waves, which completely discharge it, but the discharge stops after a finite number of half waves, and does not completely discharge the condenser, but leaves a residual charge (as well-known in the discharges of condensers, such as Leyden jars, through a spark). This residual charge may be in the same direction or in the reverse direction of the initial charge e_0.

Thus in this case, the total discharge, $\int i\,d\,t = \theta$, is not constant and equal to the charge of the condenser: $\theta_0 = e_0\,C$, but may be more or less.

If $E_0 = > e_0/3$, only one half wave of discharge occurs, and the discharge thus is unidirectional, showing a similarity to the impulsive discharge. It differs therefrom by terminating sharply at a definite time, while the impulsive discharge tapers into infinity.

In the general case B, essentially the same conditions pertain; a finite number of half waves, and a residual charge remaining in the condenser. The decrement is neither geometrical (logarithmic) nor arithmetical.

C. Sine Wave Discharge

It is of special interest to investigate the conditions under which the successive half waves of discharge current and voltage are pure sines (except as regards to the exponential factor, and the discontinuity of the current slope), that is free of higher harmonics.

Then the trigonometric series ends with $k = 1$, and it is

$$i = A\,\epsilon^{-ct}\sin q\,t \quad (22)$$

$$E = B_0 - \epsilon^{-ct}\{B_1 \sin q\,t - B_1' \cos q\,t\} \quad (23)$$

$$e = B_0 + \epsilon^{-ct}\{[A\,(r - c\,L) - B_1]\sin q\,t + [A\,q\,L + B_1']\cos q\,t\} \quad (24)$$

[For convenience, the sign B_1' has been chosen negative, so as to make B_1' positive for the usual form of the gas discharge.]

$2\,n + 1 = 3$ constants can then be chosen arbitrarily, that is, by experiment, etc., in the relation between i and E.

As such the following are preferably chosen:

The potential drop across the gas circuit at zero current at the beginning of the discharge: $E = E_0$ for $t = 0, i = 0$.

The potential drop across the gas circuit at zero current at the end of the discharge: $E = E_1$ for $q\,t = \pi, i = 0$.

The potential drop across the gas circuit for (approximately) maximum current, at the middle of the discharge: $E = E_m$ for $q\,t = \pi/2, i = i_m$.

In general, $E_m \leqq E_1 \leqq E_0$

This gives the equations, by substituting into (23)

$$\left.\begin{aligned} E_0 &= B_0 + B'_1 \\ E_1 &= B_0 - \delta^2 B_1' \\ E_m &= B_0 - \delta\, B_1 \\ \text{where } \delta &= \epsilon^{-c\pi/2q} \end{aligned}\right\} \qquad (25)$$

thus

$$\left.\begin{aligned} B_0 &= \frac{\delta^2 E_0 + E_1}{1 + \delta^2} \\ B_1 &= \frac{B_0 - E_m}{\delta} = \frac{\delta^2 E_0 + E_1 - (1 + \delta^2) E_m}{\delta\,(1 + \delta^2)} \\ B_1' &= \frac{E_0 - E_1}{1 + \delta^2} \end{aligned}\right\} \qquad (26)$$

from equation (11) follows,

$$e_0 - B_0 = q\,L\,A + B_1'$$

$$\left.\begin{aligned} \text{thus} \qquad A &= \frac{e_0 - B_0 - B_1'}{q\,L} = \frac{B}{q\,L} \\ \text{where} \qquad B &= e_0 - E_0 \end{aligned}\right\} \qquad (27)$$

the equations (12) give,

$$\left.\begin{aligned} A\,[L\,(c^2 - q^2) - r\,c + 1/C] + [c\,B_1 - q\,B_1'] &= 0 \\ A\,q\,[r - 2\,c\,L] - [q\,B_1 + c\,B_1'] &= 0 \end{aligned}\right\}$$

and denoting,

$$\left.\begin{aligned} \frac{r}{L} &= a \\ \frac{1}{L\,C} &= k^2 \end{aligned}\right\} \qquad (28)$$

and substituting (27) for A, we have,

$$\left.\begin{aligned} B\,(c^2 - q^2 - c\,a + k^2) + q\,(c\,B_1 - q\,B_1' &= 0 \\ B\,(a - 2\,c) - (q\,B_1 + c\,B_1') &= 0 \end{aligned}\right\} \qquad (29)$$

From these two equations (29) follow the values of c and q, and thereby all the constants in i and e are evaluated.

As c and q enter into B_1 and B_1', through δ, equations (29) are best evaluated by approximation. That is, from (29) it follows that,

$$q = \frac{a\,B\,B_1}{B_1^2 + (2\,B + B_1')^2} + \sqrt{\frac{k^2\,B\,(2\,B + B_1')^2}{(B + B_1')\,[B_1^2 + (2\,B + B_1')^2]} + \left(\frac{a\,B\,B_1}{B_1^2 + (2\,B + B_1')^2}\right)^2 - \frac{a^2\,B^2}{B_1^2 + (2\,B + B_1')^2}} \qquad (30)$$

$$c = \frac{a\,B - q\,B_1}{2\,B + B_1'} \qquad (31)$$

Assuming first $q = k$ and $c = 0$, gives a first approximation of B_1 and B_1', and with these values of B and B_1', by equations (30) and (31) a first approximation of q and c is calculated, and this used in the same manner to get a second approximation of B_1 and B_1', and of q and c, and so on, until the approximation is sufficiently close, and this is usually obtained very rapidly.

Impulsive Discharge

Here q becomes imaginary, and the discharge thereby ceases to be oscillatory and becomes impulsive, when the term under the square root in (30) becomes negative. This is the case for

$$a^2 > k^2 \frac{B_1^2 + (2\,B + B_1')^2}{B\,(B + B_1')} \qquad (32)$$

or

$$r > 2\,z_0 \sqrt{1 + \frac{B_1^2 + B_1'^2}{4\,B\,(B + B_1')}} \qquad (33)$$

for $B_1 = 0$, $B_1' = 0$, this gives the usual equation: $r > 2\,z_0$.

In general, in a gas circuit B, B_1 and B_1' are positive, and thus the energy dissipation that occurs in the gas circuit does not lower the values of the ohmic resistance r, at which the discharge ceases to be oscillatory, but on the contrary, the presence of a gas circuit causes the discharge to remain oscillatory for values of the ohmic resistance r, greater than those at which otherwise the discharge would become impulsive.

Symmetrical Gas Discharge

If the discharge through the gas circuit is symmetrical, that is, the potential drop across the gas circuit, E, has the same value for decreasing as for increasing current i, or in other words, the discharge through the gas circuit has no time lag, then we have,

$$E_1 = E_0;\; B_1' = 0;\; B_0 = E_0;\; B_1 = \frac{E_0 - E_m}{\delta},$$

and

$$q = k \sqrt{\left\{ \frac{1}{1 + \left(\frac{B_1}{2\,B}\right)^2} - \frac{a^2}{4\,k^2} \frac{1}{\left[1 + \left(\frac{B_1}{2\,B}\right)^2\right]^2} + \frac{a}{2} \frac{\frac{B_1}{2\,B}}{1 + \left(\frac{B_1}{2\,B}\right)^2} \right\}} \qquad (34)$$

$$c = \frac{a}{2} - q \frac{B_1}{2\,B} = \frac{a}{2} \frac{1}{1 + \left(\frac{B_1}{2\,B}\right)^2} - k \frac{B_1}{2\,B} \sqrt{\frac{1}{1 + \left(\frac{B_1}{2\,B}\right)^2} - \frac{a^2}{4\,k^2} \frac{1}{\left[1 + \left(\frac{B_1}{2\,B}\right)^2\right]^2}} \qquad (35)$$

$$\left.\begin{aligned} i &= \frac{e_0 - E_0}{q\,L}\,\epsilon^{-ct}\sin q\,t \\ E &= E_0 - (E_0 - E_m)\,\epsilon^{-ct + c\pi/2q}\sin q\,t \\ e &= E_0 + \epsilon^{-ct}\left\{ (e_0 - E_0)\cos q\,L \right. \\ &\left. + \left[\frac{r\,(e_0 - E_0)}{2\,q\,L} - \frac{E_0 - E_m}{2\,\delta}\right]\sin q\,L \right\}. \end{aligned}\right\} \quad (36)$$

Discharge with Negligible Ohmic Resistance

If the ohmic resistance of the discharge circuit is negligible, $r = 0$, that is, all the energy dissipation occurs in the gas circuit (as is probably usually the case with a lightning discharge, etc.), we have,

$$a = 0$$

$$\frac{c}{q} = \frac{-B_1}{2B + B_1}$$

$$q = k\,(2B + B_1')\sqrt{\frac{B}{(B + B_1')\,[B_1^2 + (2\,B + B_1')^2]}} \quad (37)$$

$$c = -\,k\,B_1\sqrt{\frac{B}{(B + B_1')\,[B_1^2 + (2\,B + B_1')^2]}} \quad (38)$$

that is, the exponent of the exponential term is positive, and the oscillation cumulative, thus increasing during the half wave—to drop however again discontinuously at the end of the half wave—to a value less than the preceding half wave, giving the decay of discharge, by the discontinuous voltage change at the current reversal, from $+E_1$ to $-E_0$.

In the condenser discharge through a constant ohmic resistance r, the exponent of the exponential term is,

$$c = \frac{r_0}{2\,L}$$

where r_0 = ohmic resistance.

Substituting in (38),

$$c = \frac{r_0}{2\,L}, \qquad k = \frac{1}{\sqrt{L\,C}}, \quad \text{gives,}$$

$$r_0 = -\frac{2}{\sqrt{L\,C}}\,B_1\sqrt{\frac{B}{(B + B_1')\,[B_1^2 + (2\,B + B_1')^2]}} \quad (39)$$

The gas discharge acts like an effective negative resistance of value r_0.

Symmetrical Gas Discharge of Negligible Ohmic Resistance

If the gas discharge is symmetrical, that is, in a symmetrical gas discharge of negligible ohmic resistance we have,

$r = 0$; $a = 0$, and $E_1 = E_0$, $B_1' = 0$; $B_0 = E_0$;

$$B_1 = \frac{E_0 - E_m}{\delta},$$

and,

$$q = \frac{k}{\sqrt{1 + \left(\frac{B_1}{2\,B}\right)^2}} = \frac{1}{\sqrt{L\,C\left(1 + \frac{E_0 - E_m}{2\,\delta\,(e_0 - E_0)}\right)^2}} \quad (40)$$

$$c = -\frac{k\,\frac{B_1}{2\,B}}{\sqrt{1 + \left(\frac{B_1}{2\,B}\right)^2}} = -\frac{E_0 - E_m}{2\,\delta\,(e_0 - E_0)}\,q \quad (41)$$

In this case, q is always real. Such a condenser discharge through a circuit of negligible ohmic resistance, but containing a symmetrical gas path, is always oscillatory, never impulsive, that is, unidirectional, though the oscillation may comprise one half wave only.

Decrement and Frequency

As a gas circuit acts like an effective negative resistance, it follows that in the circuit of a condenser discharged through a gas circuit a considerable ohmic resistance r_1 may exist, and the decrement of the circuit still be zero: $c = 0$.

The conditions of such a circuit of zero logarithmic decrement are,

$$c = 0; \quad \delta = 1.$$

$B = e_0 - E_0$; $B_0 = 1/2\,(E_0 + E_1)$; $B_1 = 1/2\,(E_0 + E_1 - 2\,E_m)$; $B_1' = 1/2\,(E_0 - E_1)$:

From (31) it follows that

$$q = a\,\frac{B}{B_1}$$

and, substituting this into (30), gives,

$$a = k\,\frac{B_1}{\sqrt{B\,(B + B_1')}}$$

$$q = \frac{k}{\sqrt{1 + \frac{B_1'}{B}}},$$

thus

$$r_1 = z_0\,\frac{E_0 + E_1 - 2\,E_m}{\sqrt{2\,(e_0 - E_0)\,(2\,e_0 - E_0 - E_1)}} \quad (42)$$

$$q = \frac{q_0}{\sqrt{1 + \frac{E_0 - E_1}{2\,(e_0 - E_1)}}} \quad (43)$$

where

$$z_0 = \sqrt{L/C}$$

$$q_0 = \frac{1}{\sqrt{L\,C}}$$

Thus, if in a condenser discharge circuit containing a gas path, the ohmic resistance $= r_1$ (42), the exponential decrement is zero, and the half waves of discharge are perfect sines. If the ohmic resistance r of the circuit is greater than r_1, $r > r_1$, the logarithmic decrement is positive, that is, the wave decays. If the

ohmic resistance r of the circuit is less than r_1, $r > r_1$, the logarithmic decrement is negative, that is cumulative, and the wave increases—to decrease however discontinuously at the end of the half wave by the change of the potential drop across the gas path, at the current reversal, from E_1 to $-E_0$.

For a symmetrical gas discharge we have, $E_1 = E_0$; $B_1' = 0$, thus,

$$r_1 = z_0 \frac{E_0 - E_m}{e_0 - E_0} \tag{44}$$

$$q = q_0 = \frac{1}{\sqrt{LC}} \tag{45}$$

It is interesting to note that, when the logarithmic decrement of the discharge oscillation disappears, due to the effective negative resistance of the gas path compensating for the constant ohmic resistance of the circuit, the frequency of the discharge—as given by $q = 2\pi f$—only then becomes equal to that of the circuit without energy dissipation, when the discharge is symmetrical. If however the gas circuit is not symmetrical, but the potential difference for rising current is greater than for decreasing current, in other words, if a time lag exists in the gas path, then the frequency of the oscillation is lowered by the asymmetrical nature of the gas path (43).

As the decrement c and the frequency constant q depend not only on the constants of the circuit and the gas path, but also on the initial condenser voltage e_0, it follows, that for the successive half waves of such a discharge, the decrement c and the frequency constant q are different. The value of c changes from positive to negative and increases negatively, that is, the damping effect of the successive half waves decreases, is replaced by a cumulative effect, and the latter indefinitely increases, until the discharge stops. The frequency in the successive half waves of discharge decreases, that is, the wave length increases, especially towards the end of the discharge, as seen from the illustration given below, and their equations, and the appended oscillograms.

Maximum Increment

In a condenser discharge through a gas circuit, the exponent of the decrement ϵ^{-ct} may be positive, $\epsilon^{+c_1 t}$, that is, the discharge is cumulative. The question arises under which conditions this cumulative effect is a maximum, that is, when c is a maximum negative value.

Equation (31) shows that this is the case for $a = 0$, that is, when $r = 0$, or there is no ohmic resistance, as was to be expected.

In this case we have,

$$c = -q \frac{B_1}{2B + B_1'}$$

thus, c is a maximum for $B_1' = 0$, or $E_1 = E_0$, a symmetrical discharge.

The maximum cumulative effect should occur with the symmetrical gas discharge of negligible ohmic resistance.

We have, then from (41)

$$c = -k \frac{\frac{B_1}{2B}}{\sqrt{1 + \left(\frac{B_1}{2B}\right)^2}}$$

$$= -\frac{\frac{E_0 - E_m}{2\delta(e_0 - E_0)}}{\sqrt{1 + \left(\frac{E_0 - E_m}{2\delta(e_0 - E_0)}\right)^2}} \tag{46}$$

which increases with increasing E_0 and decreasing E_m.

That is, the cumulative exponential decrement due to a gas path is the larger, the larger the potential drop across the gas path at zero current, and the smaller is the potential drop at maximum current, and approaches the final value for $E_m = 0$ and $E_0 = e_0$, of $c = -q_0$, or $r_0 = -z_0$.

That is, the effective negative resistance of the gas path approaches, as a maximum, the value of the surge impedance $z_0 = \sqrt{L/C}$ of the circuit.

Impulsive Discharge

The question arises, whether, and under what conditions the condenser discharge through a gas circuit may cease to be oscillatory, and becomes impulsive or unidirectional.

If, as is usually the case in a gas circuit, $e_0 > E_0 > E_1 > E_m$, B, B_1 and B_1' are positive, and by equation (33) the ohmic resistance r is given, which must be exceeded by the circuit, to become non-oscillatory, and this ohmic resistance is greater than in the absence of a gas path.

The further question arises, whether any condition of a gas circuit can be conceived, in which the discharge becomes impulsive by the energy dissipation in the gas circuit, irrespective of the ohmic resistance of the rest of the circuit. That is, whether a condenser discharge through a gas circuit of negligible constant ohmic resistance, but high energy dissipation in the gas path—such as a lightning flash—can ever be non-oscillatory.

If the ohmic resistance of the circuit is negligible, $r = 0$, and we have from (37),

$$q = \frac{k(2B + B_1')}{\sqrt{B_1^2 + (2B + B_1')^2}} \sqrt{\frac{B}{B + B_1'}}$$

$$c = -q \frac{B_1}{2B + B_1'}$$

q then can only become imaginary, that is, the discharge non-oscillatory, if

$$\frac{B}{B + B_1'}$$

becomes negative.

If $B_1' = 0$ in a symmetrical gas circuit, this is not possible, but

$$\sqrt{\frac{B}{B + B_1'}} = 1,$$

and, as stated after equation (**41**), such a discharge through a symmetrical gas circuit always is oscillatory, no matter how high the energy dissipation in the gas circuit, unless it is made non-oscillatory by constant series resistance (**33**).

The only condition, under which such a condenser discharge through a gas circuit of negligible ohmic resistance ceases to be oscillatory occurs when B_1' is negative and $- B_1' > B$, that is, by (**26**) and (**27**):

$$\frac{E_1 - E_0}{1 + 2\,\delta} > e_0 - E_0$$

Since $$E_1 > e_0 + \delta^2 (e_0 - E_0)$$

and as $E_0 < e_0$, otherwise the discharge would not start, it would mean a gas path in which the potential drop at the beginning of the discharge starts, for zero current, with a value E_0 less than the condenser voltage e_0, then decreases to E_m, and then increases to a value E_1, higher than the initial condenser voltage. In this case the discharge would obviously cease. It might be possible to experimentally create such conditions, by a slow vacuum discharge, producing a gas pressure and thereby increasing its potential drop, but in general, such would not occur. Unless a constant ohmic resistance of sufficiently high value is in series, a discharge through a gas circuit, such as a lightning flash, always must be oscillatory, no matter how great the energy dissipation, though the oscillation may contain one half wave only.

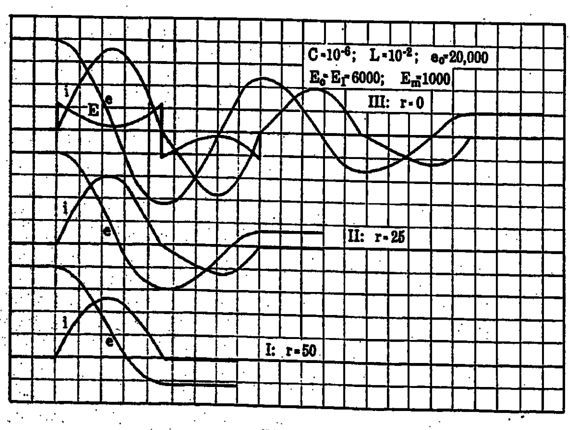

Fig. 2

Numerical Examples

As illustrations the following examples are given of some numerical values in Figs. 2 to 4, of the successive half waves of discharge, for the constants,

$$C = 10^{-6}; \quad L = 10^{-2}; \quad e_0 = 20{,}000$$

and in Fig. 2 for a symmetrical gas circuit varying from 6000 volts at zero current, to 1000 volts in the middle of the current wave, and back to 6000 volts at zero current, and for the three values of constant ohmic resistance.

Curve I. $r = 50$ ohms.

$i_1 = 146\, \epsilon^{-600t} \sin 9600\, t$

$i_2 = 0$

$e_1 = 6000 + \epsilon^{-600t} \{900 \sin 9600\, t + 14{,}000 \cos 9600\, t\}$

$e_2 = - 5500 = \text{const.}$

$E_1 = 6000 - 5520\, \epsilon^{-600t} \sin 9600\, t$

$E_2 = 0$

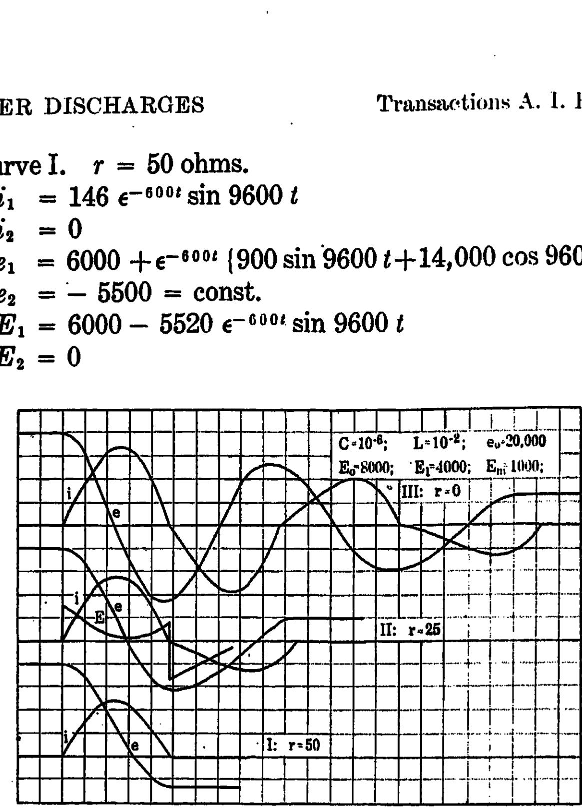

Fig. 3

Curve II. $r = 25$ ohms.

$i_1 = 140\, \epsilon^{+435t} \sin 10{,}000\, t$

$i_2 = - 39.3\, \epsilon^{+2780t} \sin 9900\, t$

$i_3 = 0$

$e_1 = 6000 + \epsilon^{+435t} \{ - 570 \sin 10{,}000\, t + 14{,}000 \cos 10{,}000\, t \}$

$e_2 = - 6000 - \epsilon^{2780t} \{ - 1140 \sin 9900\, t + 3900 \cos 9900\, t\}$

$e_3 = + 3450 = \text{const.}$

$E_1 = 6000 - 4680\, \epsilon^{+435t} \sin 10{,}000\, t$

$E_2 = - 6000 + 3220\, \epsilon^{+2780t} \sin 9900\, t$

$E_g = 0$

Curve III. $r = 0$.

$i_1 = 142\, \epsilon^{+1420t} \sin 9900\, t$

$i_2 = - 102\, \epsilon^{+1830t} \sin 9830\, t$

$i_3 = + 62\, \epsilon^{+2600t} \sin 9650\, t$

$i_4 = - 23\, \epsilon^{+4800t} \sin 8750\, t$

$i_5 = 0$

$e_1 = 6000 + \epsilon^{+1420t} \{ - 2000 \sin 9900\, t + 14{,}000 \cos 9900\, t \}$

$e_2 = - 6000 - \epsilon^{+1830t} \{ - 1870 \sin 9830\, t + 10{,}000 \cos 9830\, t \}$

$e_3 = + 6000 + \epsilon^{2600t} \{- 1660 \sin 9650\, t + 6000 \cos 9650\, t \}$

$e_4 = - 6000 - \epsilon^{+4800t} \{- 1120 \sin 8750\, t + 2000 \cos 8750\, t\}$

$e_5 = + 5200 = \text{const.}$

$E_1 = 6000 - 4000\, \epsilon^{+1420t} \sin 9900\, t$

$E_2 = - 6000 + 3740\, \epsilon^{+1830t} \sin 9830\, t$

$E_3 = + 6000 - 3270\, \epsilon^{+2600t} \sin 9650\, t$

$E_4 = - 6000 + 2220\, \epsilon^{+4800t} \sin 8750\, t$

$E_5 = 0$

For the same values $C = 10^{-6}$; $L = 10^{-2}$ and $e_0 = 20{,}000$, Fig. 3 gives the discharge waves through an unsymmetrical gas circuit, varying from 8000 volts at zero current, to 1000 volts in the middle of the

current wave, and then back to 4000 volts at zero current, and for the three values of constant ohmic resistance.

Curve I. $r = 50$ ohms.

$$i_1 = 131\, \epsilon^{-450t} \sin 9180\, t$$
$$i_2 = 0$$
$$e_1 = 5840 + \epsilon^{-450t} \{720 \sin 9180\, t + 14{,}160 \cos 9180\, t\}$$
$$e_2 = 6330 = \text{constant}$$
$$E_1 = 5840 - \epsilon^{-450t} \{5250 \sin 9180\, t - 2160 \cos 9180\, t\}$$
$$E_2 = 0$$

Curve II. $r = 25$ ohms.

$$i_1 = 129\, \epsilon^{+545t} \sin 9300\, t$$
$$i_2 = -\, 29.3\, \epsilon^{+3450t} \sin 7900\, t$$
$$i_3 = 0$$
$$e_1 = 6180 + \epsilon^{+545t} \{-\, 830 \sin 9300\, t + 13820 \cos 9300\, t\}$$
$$e_2 = -\, 7200 - \epsilon^{+3450t} \{-\, 1340 \sin 7900\, t + 3120 \cos 7900\, t\}$$
$$e_3 = +\, 5100 = \text{const.}$$
$$E_1 = 6180 - \epsilon^{+545t} \{4740 \sin 9300\, t - 1820 \cos 9300\, t\}$$
$$E_2 = -\, 7200 + \epsilon^{+3450t} \{3080 \sin 7900\, t - 790 \cos 7900\, t\}$$

Curve III. $r = 0$.

$$i_1 = 129\, \epsilon^{+1550t} \sin 9310\, t$$
$$i_2 = -\, 90.5\, \epsilon^{+2060} \sin 9070\, t$$
$$i_3 = +\, 55\, \epsilon^{+2880t} \sin 8500\, t$$
$$i_4 = -\, 20.5\, \epsilon^{+4500t} \sin 7320\, t$$
$$i_5 = 0$$
$$e_1 = 6500 + \epsilon^{+1550t} \{-\, 5250 \sin 9310\, t + 13{,}500 \cos 9310\, t\}$$
$$e_2 = -\, 6700 - \epsilon^{+2060t} \{-\, 5860 \sin 9070\, t + 9500 \cos 9070\, t\}$$
$$e_3 = +\, 7000 + \epsilon^{+2880t} \{-\, 5110 \sin 8500\, t + 5700 \cos 8500\, t\}$$
$$e_4 = -\, 7500 - \epsilon^{+4500t} \{-\, 3300 \sin 7320\, t + 2000 \cos 7320\, t\}$$
$$e_5 = +\, 6300 = \text{const.}$$
$$E_1 = 6500 - \epsilon^{+1550t} \{4250 \sin 9310\, t - 1490 \cos 9310\, t\}$$
$$E_2 = -\, 6700 + \epsilon^{+2060t} \{4000 \sin 9070\, t - 1310 \cos 9070\, t\}$$
$$E_3 = +\, 7000 - \epsilon^{+2880t} \{3530 \sin 8500\, t - 1030 \cos 8500\, t\}$$
$$E_4 = -\, 7500 + \epsilon^{+4500t} \{2300 \sin 7320\, t - 500 \cos 7320\, t\}$$
$$E_5 = 0.$$

As seen, the number of half waves of the discharge under these conditions of a high open-circuit voltage of the gas path, varies from one at the constant resistance of 50 ohms, to four with no ohmic resistance in circuit.

Fig. 4 shows the discharge curves, for the same constants $C = 10^{-6}$; $L = 10^{-2}$; $e_0 = 20{,}000$, for a low ohmic resistance, $r = 10$, and through an unsymmetrical gas path of lower voltage; from $E_0 = 3000$ volts at zero current, down to $E_m = 500$ volts for larger currents, and up again to $E_1 = 1000$ volts for zero current.

We have,

$$i_1 = 175\, \epsilon^{-67t} \sin 9720\, t$$
$$i_2 = -\, 131\, \epsilon^{+66t} \sin 9650\, t$$
$$i_3 = +\, 93.5\, \epsilon^{+278t} \sin 9510\, t$$
$$i_4 = -\, 61.6\, \epsilon^{+626t} \sin 9270\, t$$
$$i_5 = +\, 34.9\, \epsilon^{+1315t} \sin 8840\, t$$
$$i_6 = -\, 12.1\, \epsilon^{+3250t} \sin 7450\, t$$
$$i_7 = 0$$
$$e_1 = 1990 + \epsilon^{-67t} \{120 \sin 9720\, t + 18{,}010 \cos 9720\, t\}$$
$$e_2 = -\, 2010 - \epsilon^{+66t} \{-\, 90 \sin 9650\, t + 13{,}610 \cos 9650\, t\}$$
$$e_3 = +\, 2050 + \epsilon^{+278t} \{-\, 285 \sin 9510\, t + 9840 \cos 9510\, t\}$$
$$e_4 = -\, 2110 - \epsilon^{+626t} \{-\, 450 \sin 9270\, t + 6620 \cos 9270\, t\}$$

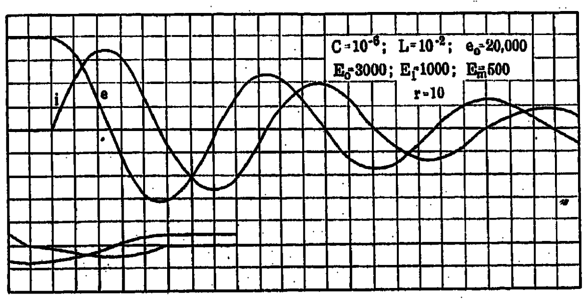

Fig. 4

$$e_5 = +\, 2230 + \epsilon^{+1315t} \{-\, 570 \sin 8840\, t + 3850 \cos 8840\, t\}$$
$$e_6 = -\, 2600 - \epsilon^{+3250t} \{-\, 570 \sin 7450\, t + 1300 \cos 7450\, t\}$$
$$e_7 = +\, 2500 = \text{const.}$$
$$E_1 = 1990 - \epsilon^{-67t} \{1510 \sin 9720\, t - 1010 \cos 9720\, t\}$$
$$E_2 = -\, 2010 + \epsilon^{+66t} \{1490 \sin 9650\, t - 990 \cos 9650\, t\}$$
$$E_3 = +\, 2050 - \epsilon^{+278t} \{1480 \sin 9510\, t - 950 \cos 9510\, t\}$$
$$E_4 = -\, 2110 + \epsilon^{+626t} \{1450 \sin 9270\, t - 895 \cos 9270\, t\}$$
$$E_5 = +\, 2230 - \epsilon^{+1315t} \{1380 \sin 8840\, t - 775 \cos 8840\, t\}$$
$$E_6 = -\, 2600 + \epsilon^{+3250t} \{1080 \sin 7450\, t - 410 \cos 7450\, t\}$$
$$E_7 = 0.$$

It is interesting to note that in the successive half waves of discharge through a gas circuit, especially an unsymmetrical one, under these conditions the frequency decreases, that is, the wave length increases, by over 30 per cent between the last and the first half wave.

The exponential decrement steadily decreases, and thus changes from a decrement in the first half wave, to an increment of increasing amplitude in the successive half waves. If the ohmic resistance is small, the first half wave shows an increment.

D. Non-Sinoidal Discharge

As a further illustration there is shown, in Fig. 5, the first half wave of a discharge carried out to the third harmonic, through a symmetrical gas path and a constant ohmic resistance of such value as to make the decrement vanish, that is, to give $c = 0$; for the constants: $C = 10^{-6}$; $L = 10^{-2}$; $e_0 = 20,000$, and for the voltages of the gas path given as

E_0 = 6000 volts at zero current, at the beginning and the end of the half wave,

E_m = 1000 volts in the middle of the half wave, and

E = 2000 volts at 30 degrees after the beginning and before the end of the half wave.

The values E_0, E_m and E_2 substituted into equation (**6**) give five expressions for the determination of the five constants, $B_0, B_1, B_1', B_3, B_3'$. The four equations (**12**) express the values A_1, A_1', A_3, A_3' in the values of B, and, substituted into equations (**10**) and (**11**), give two equations for the determination of q and r, by approximation.

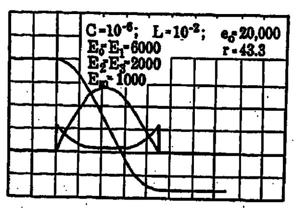

Fig. 5

This gives the value of constant ohmic resistance as $r = 43.3$ ohms, and the discharge equations,

$$i = A_1 \sin q\,t + A_1' \cos q\,t + A_3 \sin 3\,q\,t + A_3' \cos 3\,q\,t = 139 \sin 9946\,t + 3.6 \cos 9946\,t + .2 \sin 29{,}838\,t - 3.6 \cos 29{,}838\,t$$

$$e = B_0 \Sigma \{ (r\,A_k - k\,q\,L\,A_k' - B_k) \sin k\,q\,t + (k\,q\,L\,A_k + r\,A_k') \cos k\,q\,t \} = 6000 - 330 \sin 9946\,t + 14{,}100 \cos 9946\,t + 80 \sin 29{,}838\,t - 100 \cos 29{,}838\,t$$

$$E = B_0 - B_1 \sin q\,t - B_3 \sin 3\,q\,t = 6000 - 6000 \sin 9946\,t - 1000 \sin 29{,}838\,t.$$

Volt-Ampere Characteristics

Fig. 6 gives the volt-ampere characteristics (of the first half wave) of the preceding figures, that is, the potential drop of the gas circuit E, as ordinate, with the current as abscissas (in a fraction of its maximum value).

Line $C\,D$ (2) gives the E to i relation of the symmetrical gas circuit of Fig. 2.

Curve E-D-F (3) gives the unsymmetrical circuit of figure 3, with $E\,D$ for increasing, $D\,F$ for decreasing current.

Curve C (5) D gives the E to i characteristic of the discharge. Fig. 5, containing the third harmonic.

For comparison, $A\,B$ (r) is the volt-ampere characteristic of a constant ohmic resistance, and $C\,B$ (1) that of a gas path of constant voltage.

E. Asymmetrical or Unidirectional Conductor

The volt-ampere characteristics of gaseous conductors very often depend on the direction of the current flow, that is, the potential drop across the conductor, and its variations with the current are entirely different for the current flowing in one direction, from that of the current flowing in the reverse direction,—often very much lower. Such for instance is the case in the

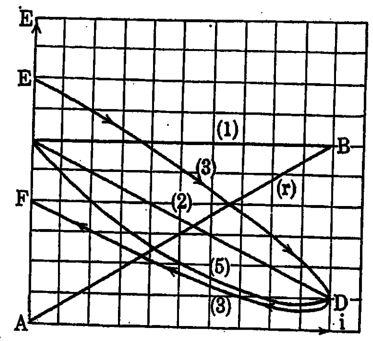

Fig. 6

vacuum tube with one hot and one cold electrode, or a vacuum tube with one cold carbon electrode and one ionized mercury electrode. In this case the potential drop across the tube is very low and approximately constant if the incandescent or ionized electrode is negative, and the potential drop may be very high, especially at zero current in the beginning of the discharge, if the cold electrode is negative.

Since the equations of the condenser discharge through a gas circuit have to be calculated for every half wave separately, the calculation of the condenser discharge through such a unidirectional or "rectifying"

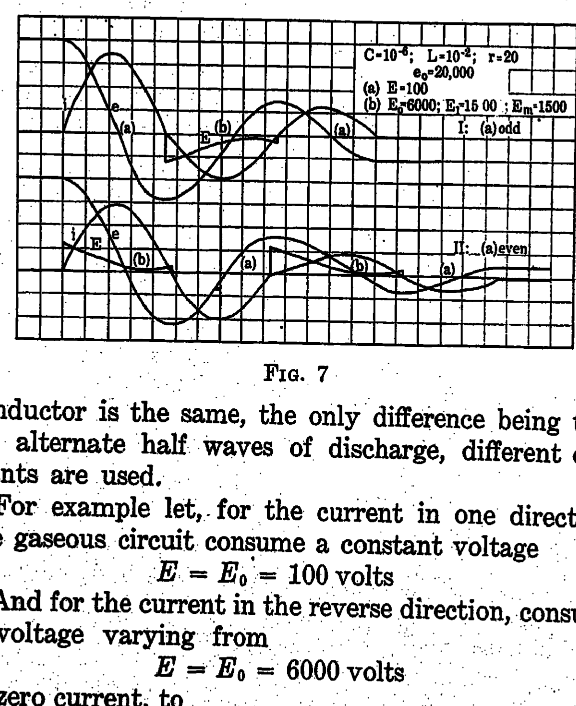

Fig. 7

conductor is the same, the only difference being that for alternate half waves of discharge, different constants are used.

For example let, for the current in one direction, the gaseous circuit consume a constant voltage

$$E = E_0 = 100 \text{ volts} \qquad \textbf{(a)}$$

And for the current in the reverse direction, consume a voltage varying from

$$E = E_0 = 6000 \text{ volts} \qquad \textbf{(b)}$$

at zero current, to

$$E = E_m = 1500 \text{ volts} \qquad \textbf{(b)}$$

in the middle of the discharge, and reaching again

$$E = E_1 = 1500 \text{ volts} \qquad \textbf{(b)}$$

for zero current at the end of the discharge.

Then the even half waves of the discharge are calculated with the one, and the odd half waves with the other set of constants, (a) or (h), as shown in Sections B or C.

Fig. 7 shows the two discharge curves, for

$$e_0 = 20{,}000; \quad C = 10^{-6}; \quad L = 10^{-2}; \quad r = 20$$

and, in Curve I for the first half wave being in the direction of the conduction of the gas path, (a), while in Curve II the first half wave of the current is in such direction that the gas circuit offers a high opposing voltage (b).

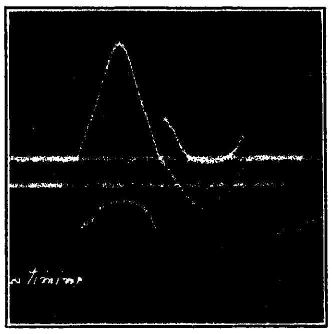

Fig. 8

The equations of the discharge then are:

Curve I. High Conductivity during Odd Half Waves.

$$i_1 = 200\,\epsilon^{-1000t} \sin 9950\,t$$
$$i_2 = -\,93.8\,\epsilon^{+185t} \sin 8900\,t$$
$$i_3 = +\,73\,\epsilon^{-1000t} \sin 9950\,t$$
$$i_4 = 0$$
$$e_1 = 100 + \epsilon^{-1000t}\{2000 \sin 9950\,t + 19{,}900 \cos 9950\,t\}$$
$$e_2 = -\,3830 - \epsilon^{+185t}\{-\,225 \sin 8900\,t + 10{,}470 \cos 8900\,t\}$$

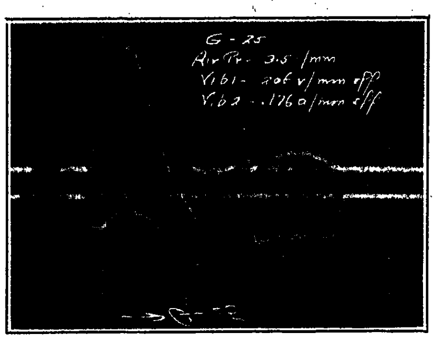

Fig. 9

$$e_3 = +\,100 + \epsilon^{-1000t}\{730 \sin 9950\,t + 7270 \cos 9950\,t\}$$
$$e_4 = -\,5160 = \text{const.}$$
$$E_1 = 100$$
$$E_2 = -\,3830 + \epsilon^{+185t}\{2260 \sin 8900\,t - 2180 \cos 8900\,t\}$$
$$E_3 = +\,100.$$
$$E_4 = 0.$$

Curve II. High Conductivity during Even Half Waves.

$$i_1 = 151\,\epsilon^{-237t} \sin 9270\,t$$
$$i_2 = -\,114\,\epsilon^{-1000t} \sin 9950\,t$$
$$i_3 = +\,28\,\epsilon^{+2060t} \sin 7530\,t$$
$$i_4 = -\,33.6\,\epsilon^{-1000t} \sin 9950\,t$$
$$i_5 = 0$$
$$e_1 = 3660 + \epsilon^{-237t}\{425 \sin 9270\,t - 16{,}340 \cos 9270\,t\}$$
$$e_2 = -\,100 - \epsilon^{-1000t}\{1140 \sin 9950\,t + 11{,}350 \cos 9950\,t\}$$
$$e_3 = +\,4650 + \epsilon^{+2060t}\{-\,935 \sin 7530\,t + 3450 \cos 7530\,t\}$$
$$e_4 = -\,100 - \epsilon^{-1000t}\{335 \sin 9950\,t + 3340 \cos 9950\,t\}$$
$$e_5 = +\,2300 = \text{const.}$$
$$E_1 = 3660 - \epsilon^{-237t}\{2240 \sin 9270\,t - 16{,}340 \cos 9270\,t\}$$
$$E_2 = -\,100$$
$$E_3 = 4650 - \epsilon^{+2060t}\{2070 \sin 7530\,t - 1350 \cos 7530\,t\}$$
$$E_4 = -\,100$$
$$E_5 = 0.$$

It is interesting to note, that not only the amplitudes and the decrements of the odd and of the even half waves are different, but also the frequency or duration of the half waves.

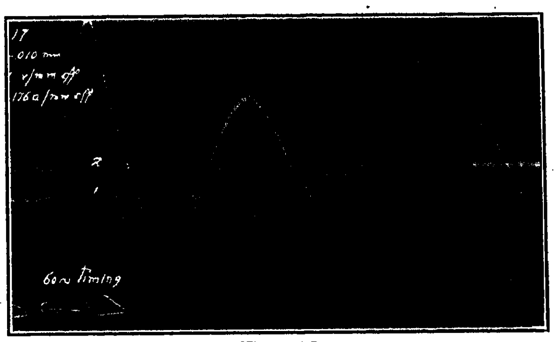

Fig. 10

As the calculated curves given in the preceding section show a number of characteristics different from the usual oscillating discharge curves, a series of oscillograms was taken of such an inductive condenser discharge through a gas circuit. Three of these oscillograms are given in Figs. 8, 9 and 10.

The gas circuit consisted of a vacuum tube of 1 1/2 in. diameter and 36 in. length, with tungsten electrodes.

The inductance was measured as $L = 7.4$ h., the capacity 1.7 μf; the ohmic resistance of the circuit $r = 34.5$ ohms, and the initial voltage of the condenser discharge was $e_0 = 10{,}000$ volts.

These oscillograms very decidedly show the characteristics calculated in Figs. 2 and 4:

A discontinuity in the slope of the discharge current at the reversal.

The wave shape of the current, characteristic of a cumulative discharge, that is, decreasing more abruptly than increasing (the reverse of the usual damped discharge.)

The gradual increase of the wave length, that is, decrease of q.

These three characteristics becoming more pronounced towards the end of the oscillation.

The residual charge left in the condenser—in this case gradually leaking out through the oscillograph shunt.

The oscillograms give the discharge current, the voltage across the vacuum tubes, and a 60-cycle timing wave.

In Fig. 8, the air pressure in the vacuum tube was 5 mm. of mercury. The oscillation consisted of two half waves, of maximum currents $i = 6.25$ and 2.85 amperes, and wave length constants $q = 176$ and 164. The second half wave of voltage gives $E_0 = 4150$; $E_1 = 3080$; $E_m = 1530$.

In Fig. 9, the air pressure was 3.5 mm. of mercury. Three half waves occurred, with maximum currents $i = 6.7$; 3.17; $.88$ amperes, and wave length constants $q = 228$; 218; 203. The second wave gave $E_0 = 2830$; $E_1 = 2430$; $E_m = 1480$.

In Fig. 10, the air pressure was 0.01 mm. of mercury, and the voltage curves therefore are of materially different appearance. Five half waves occurred of the maximum currents $i = 8.2$; 5.42; 3.75; 2.53; 1.58 amperes, and the wave length constants $q = 250$; 242; 230; 215; 199. The second half wave gave $E_0 = 3030$; $E_1 = 2470$; $E_m = 530$.

Discussion

V. Karapetoff: I shall first consider the specific cases treated by the author, and then the general case, which he puts first.

The first two cases, A and B, correspondong to $E = 0$ and $E =$ constant; they do not require any special or new method of integration of the fundamental eq. (4), since the troublesome term, $d\,E/d\,t$, vanishes. Hence, these cases lead to familiar decremental sinusoidal expressions. The fact that in the second case the discharge stops after a finite number of alternations is very interesting, and it follows directly from the nature of the circuit.

In the case C the shape of the current wave is assumed *a priori*, so that no integration of the fundamental equation is necessary. This case seems somewhat arbitrary, in that a physical quantity, E, instead of being taken in the beginning as a certain function of i, according to experimental facts, is deduced theoretically from an assumed law of variation of current. Of course, the shape of the current in the oscillograms (Figs. 8 to 10) shows the reasonableness of such an assumption, but the mathematical results for q and c are so complicated as to minimize the importance of this case.

In the remainder of the paper the author also seems to treat cases in which eq. (4) is not integrated in its general form, and no use is made of the empirical relationships between E and i, quoted at the very beginning of the paper. On the contrary, these relationships are deduced theoretically (Fig. 6).

While such a treatment may be valuable as a first approach to the subject and while the theoretical curves have considerable similarity with the actual oscillograms, a somewhat different approach, more in accordance with the physical facts of the passage of electricity through gases, is also desirable. The very purpose of the "General Case" treated at the beginning of the paper should be to indicate the solution of the problem for a given empirical relationship between E and i, and yet the author does not seem to use this method at all in his special cases.

I therefore suggest the following alternative treatment of the general case: Since

$$d\,E/d\,t = (d\,E/d\,i)\,(d\,i/d\,t) \qquad \textbf{(a)}$$

eq. (4) may be written in the form

$$L\frac{d^2 i}{d\,t^2} + (r + d\,E/d\,i)\,d\,i/d\,t + i/c = 0 \qquad \textbf{(b)}$$

or

$$\frac{d^2 i}{dt^2} + \varphi(i)\,d\,i/d\,t + a\,i = 0 \qquad \textbf{(c)}$$

where $\varphi(i) = 1/L\,(r + d\,E/d\,i)$ **(d)**

and $a = 1/(L\,C)$ **(e)**

The quotient $d\,E/d\,i$ may be called the ionization slope of a gas. It is a negative quantity which characterizes the reduction in the resistance of the gas with the increase in current. For solid metals at a constant temperature this factor is a positive constant and represents the ordinary ohmic resistance. Thus, the expression in the parentheses of eq. (d) may be called the *generalized resistance* of the circuit, and is one of the data of the problem.

The advantages of eq. (c) over Dr. Steinmetz's eq. (4) are as follows: (1) Eq. (c) contains only one dependent variable, i, as a function of t. Eq. (4) has two dependent variables i and E. (2) In Eq. (c) the given gas is characterized by its permanent and general physical property, $d\,E/d\,i$; in eq. (4) it is characterized by a specific variable factor $d\,E/d\,t$, which applies only to a particular circuit. (3) Eq. (4) apparently requires a complicated solution with $(4\,n + 3)$ simultaneous equations for the determination of the integration constants. Eq. (c) can probably be solved by assuming a simple algebraic function for $\varphi(i)$, and using a method of approximations. In fact $\varphi(i)$ may be assumed to vary in steps, in which case for each step $\varphi(i)$ is a constant, and the usual solution, of the form of eq. (15), holds true. (4) Eq. (c) can be reduced to a differential equation of the first order by putting

$$d\,i/d\,t = p \qquad \textbf{(f)}$$

In this case $\dfrac{d^2 i}{d\,t^2} = d\,p/d\,t = (d\,p/d\,i)\,(d\,i/d\,t)$

or

$$\frac{d^2 i}{d\,t^2} = p\,(d\,p/d\,i) \qquad \textbf{(g)}$$

Eq. (c) becomes $p\;d\,p/d\,i + p\,\varphi(i) + a\,i = 0$ **(h)**

While I doubt if this equation can be integrated in the general form, certain plausible assumptions may possibly be made in regard to $\varphi(i)$ and p, to enable an approximate integration of this equation to be carried out, for practical purposes.

There are some minor statements in the paper which ought to be corrected. For example, the solution of a differential equation is called an integral equation; the latter term is used in modern mathematics in an entirely different sense. The quantities C and q are called "integration constants" which they are not, being functions of the given circuit constants. The equation (7) may be a particular solution only, and nothing is said of the complementary function, such as the solution of case A. Eq. (4) is supposed to have only two constants of integration, being an equation of the second order; the statement that it has $4\,n + 3$ such constants ought to be explained more in detail.

Charles P. Steinmetz: I was considerably interested in Professor Karapetoff's remarks, as I also tried to introduce the direct relation $d\,e/d\,i$ into the equations but found that the relations between e and i usually met in gaseous conduction—some of them being indicated in my paper—are such that the resulting differential equation cannot well be integrated. I therefore resorted to the method usual in such case, to represent the inconvenient relation by a Fourier series and use the first terms of this series. In other words, started from a special simple solution of the general equation and from this determined the conditions of the $e - i$ relation.

Speaking of the $2\,n + 3$ constants as "integration constants" is an obvious lapse; "indeterminate constants" was meant.

The dynamic characteristic of the general $e - i$ relation I have introduced by the asymmetry of the $e - i$ relation adopted. In the oscillograms given in the paper, the frequency is sufficiently high to give a strongly marked dynamic form of the characteristic—the frequency is seen by comparison with the 60-cycle timing wave shown in the oscillograms.

The Petersen Earth Coil

Review of the Subject.—*Accidental arcing grounds on transmission lines constitute the foremost problem to be solved in the transmission of electrical energy over great distances. There has come into use to a limited extent, arcing ground suppressors. This device consists in principle, of a switch in the station which is automatically closed in parallel with the accidental arc at any point out on the system. The parallel path through the switch shunts the current from the arc and thereby extinguishes the arc. This development is not yet completed.*

This paper gives the results of some experiments on an entirely different device for suppressing accidental grounds—a device that was first advocated by Prof. W. Petersen of Darmstadt, Germany. The essential part of this new apparatus is a suitable reactor c nnected between the neutral of the circuit and ground. This reactance is chosen of such a value as to neutralize the capacitance of the circuits when an accidental ground of one phase takes place. Under this accidental condition the reactor is electrically in parallel with the active capacitances and, by the well-known fundamental law, the only current that flows to the combination of the inductance and capacitance in parallel is the current necessary to supply the energy loss in the combination. The simplified equivalent conditions are shown in Fig. 4. This energy current can be made very small and it is this relatively small current that passes through the accidental arc to ground. If the ground is of the arcing type, the arc will, under favorable conditions be extinguished, as the energy flowing through the fault is only that necessary to supply the losses in the resonant circuit. If the losses are low, the energy flowing through the fault will be insufficient to support an arc and the voltage of the resonant system is gradually reduced to zero, while the voltage between the former faulty wire and ground gradually rises to normal value.

In a comparison of the various methods of grounding and their effects on the operation of a power system, the solid and the low-resistance grounds assume first and second place in the order of desirability. The distinction however, between these two is slight and choice will be determined by local conditions. Either the Petersen earth coil or the critical-resistance ground will assume third place in the order of desirability as the relative advantages and disadvantages of these two are about equal.

The advantages of the Petersen earth coil system are: first, the suppression of arcing grounds under favorable conditions; second, the reduction of insulator trouble; and third, small earth current when a fault occurs to ground.

The disadvantages are: first high potentials between line and ground due to series resonance; second, maintenance of a series of arcs under unfavorable conditions, that is, resonance and high loss, or large dissonance and either high or low loss; third, difficulty in obtaining selection of the faulty line by means of relay protection; fourth, reduced lightning protection due to the necessity of high settings on arresters; and fifth, increased system insulation due to the shifting of the neutral with abnormals or transients.

CONTENTS

THE use of an inductance coil connected between the neutral of a power system and ground is advocated in an article by Prof. W. Petersen of Darmstadt, Germany, in the *Electrotechnische Zeitschrift*, January 2nd and 9th, 1919. This inductance is resonated at the fundamental system frequency with the capacity reactance of the power system to ground. It is claimed that when one wire becomes grounded the current flowing through the fault is of insufficient value to support an arc.

Additional information relative to the operation and limiting features of the earth coil has resulted from investigations and tests made in this country and a comparison made between this and other methods of grounding.

I. Theory

The earth coil is applicable to single-phase and polyphase systems upon which a neutral may be established. For the sake of simplicity, however, the single-phase system will be considered first.

A single-phase transmission system is represented schematically in Fig. 1, involving a generator, G,

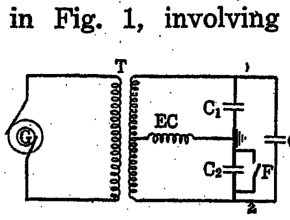

FIG. 1—APPLICATION OF AN EARTH COIL ($E\,C$) TO A SINGLE-PHASE CIRCUIT

Closing the switch F is equivalent to an accidental ground on wire 2 and actually short-circuits its capacitance.

a transformer, T, a capacity between wires 1 and 2, $C_{1\text{-}2}$, capacities between wire 1 and ground, and wire 2 and ground, C_1 and C_2 respectively, and an earth coil $E\,C$. A fault on wire 2 to ground short-circuits the condensers C_2 and the system may then be represented as shown in Fig. 2.

Presented at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

This diagram (Fig. 2) shows that the charging current for the line capacity $C_{1\text{-}2}$ flows through the wires 1 and 2 as heretofore, but the charging current for the capacity C_1 flows through the earth coil *E C*, fault, and wire 1. The exciting current for the earth coil *E C* flows through wire 2, fault, and earth coil *E C*, forming with the

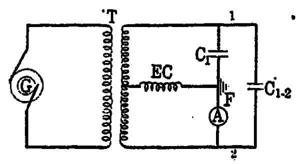

FIG. 2—SIMPLIFICATION OF FIG 1 WHEN WIRE 2 IS GROUNDED

The voltage on the capacitance between wires 1 and 2 remains constant but the voltage between wire 1 and ground has risen from half to full line-to-line voltage.

capacity C_1 a parallel resonant circuit adjusted for resonance at fundamental power frequency. In practise, the currents through the earth coil and the capacity

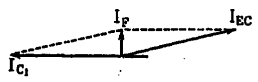

FIG. 3—CURRENT IN THE EARTH COIL (*E C*), CURRENT IN THE CAPACITANCE WIRE 1, AND THE RESULTANT CURRENT OF THE TWO (I_F)

C_1 to ground are quite large but the two currents being almost in opposition as shown in Fig. 3, the resultant current, which is the current through the fault, is

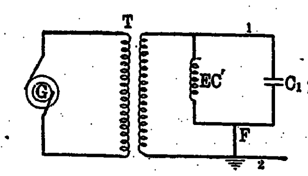

FIG. 4—SIMPLIFIED DIAGRAM OF FIG 2

comparatively small, and is determined by the values of energy losses in the resonant system.

The conditions of resonance of a reactor and condenser

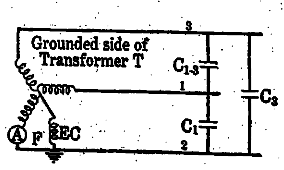

FIG. 5—APPLICATION OF THE EARTH COIL (*E C*) TO A THREE-PHASE CIRCUIT, WITH WIRE 2 GROUNDED

in parallel are shown more clearly in Fig. 4 in which the earth coil is replaced by an equivalent reactor, taking the same current and connected across the lines.

A three-phase star-connected system with earth coil is shown in Fig. 5. The operation of this system on the occurrence of a fault to ground is similar to the single phase system shown in Fig. 4 but in this case the earth coil is to be resonated with the sum of the currents through the capacities C_1 and C_3.

The earth coil may be tuned with the line capacities to ground under actual operating conditions by inserting an ammeter as shown in Fig. 2 and with one phase wire grounded adjusting the reactance of the coil for minimum current as shown in Fig. 6.

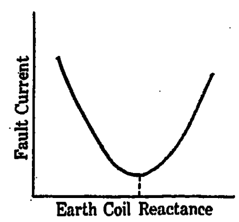

FIG. 6

The lowest part of the curve of current occurs at the value of reactance which gives resonance with the capacitance in parallel.

II. OPERATION

Effects of Resonance and Energy Loss. The most favorable conditions for the proper functioning of the earth coil, that is, the suppression for arcing grounds are perfect resonance and low energy losses in the resonant system. Under these conditions, the voltage across the fault, which is the difference between the supply voltage and the voltage of the resonant system, builds up gradually to the normal voltage to ground. When the current through the fault is interrupted, due to there being insufficient current to support an arc, the two voltages have magnitude and phase relations shown in Fig. 7. The voltage of the resonant system is then gradually reduced to zero by the dissipation of the energy losses and the voltage between the former faulty wire and the ground rises gradually to normal value.

The chief advantages of the Petersen earth coil system are due to the two characteristics, of small fault current,

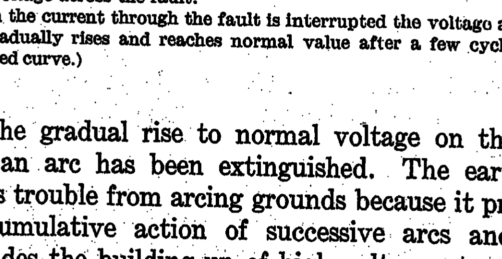

FIG. 7

1. Supply voltage.
2. Resonant voltage.
3. Voltage across the fault.

When the current through the fault is interrupted the voltage across the fault gradually rises and reaches normal value after a few cycles. (See the dotted curve.)

and the gradual rise to normal voltage on the lines after an arc has been extinguished. The earth coil avoids trouble from arcing grounds because it prevents the cumulative action of successive arcs and thus precludes the building up of high voltages, tending to cause serious disturbances.

With perfect resonance, but high loss, the operation

is as described above, except that the fault current is very much larger and may be of sufficient magnitude to maintain an arc, thus preventing a realization of the advantages of the earth coil.

Effects of Dissonance and Energy Loss. The effect of dissonance with either high or low loss is to cause the resonant system to have a natural frequency other than that of the supply, consequently the voltage across the fault may rise to a value slightly less than twice the star voltage in a period of a few cycles, as shown in Fig. 8. This voltage may be even larger than that which occasioned the fault and, as a result,

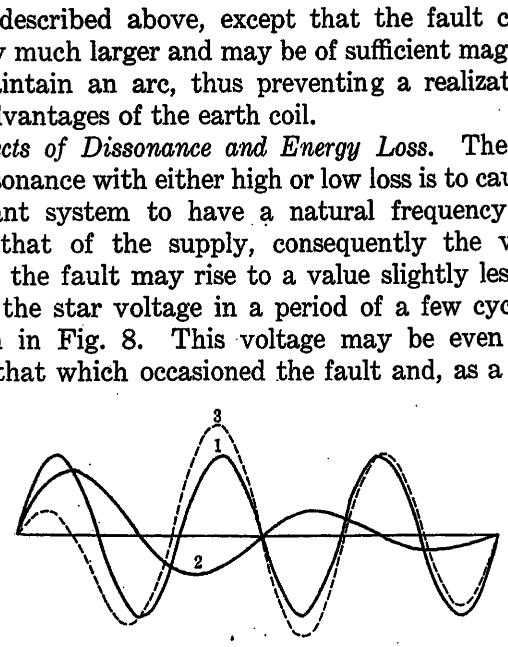

Fig 8—Condition of Dissonance

1. Supply voltage.
2. Resonant voltage.
3. Voltage across the fault.

The voltage across the fault (dotted wave) is shown as rising above normal voltage in the second cycle after the arc ceases in the fault.

a series of arcs may be maintained. System oscillations producing a succession of arcs may become cumulative in their effect and produce excessive voltages. The maintenance of such a succession of arcs, causes the transmission line as a whole to vibrate up and down in voltage and may lead to serious trouble.

Both dissonance and energy loss increases the current through the fault and on this account an arc may be maintained. If the arc is maintained the transmission wire or insulation will probably be damaged to such an extent as to put the line out of commission effectively.

Voltage Between Sound Wires and Ground. When the equivalent of a non-arcing ground occurs on one wire, the voltage between the sound wires and ground will rise from Y voltage to line voltage above ground. But when there is a "make and break" through the accidental arc the transient voltage may rise to slightly less than twice line voltage. This high voltage is the result of a redistribution of energy in the resonant system at the instant the fault occurs.

Laboratory experiments made on an artificial line indicated that when a fault occurs, the sound wires will under extreme conditions, rise to 250 per cent or more of normal voltage. With the set-up of apparatus shown in Fig. 9 the application of a fault at the switch y produces the high voltages measured by the spark gap at the sphere gap x. In this respect, the earth coil system operates similarly to a *free neutral system.*

Series Resonant System. The system may also be considered as a series resonant system as shown in Fig. 1 in which current flows through the earth coil, $E\ C$, divides equally in the transformer T, and flows through the two line wires and through their respective capacities C_1 and C_2 to ground. Any voltage induced in series with the series resonant system will produce a current limited only by the losses of the system. The voltage which may appear between the neutral of the system and ground is determined by the impedance of the earth coil and the current flowing through it.

Voltage may be induced in the series resonant circuit by some other transmission line, by lightning discharges, by mutual induction, by unsymmetrical impedance under load, unequal capacities from line to ground, or such abnormal conditions as a single-phase short circuit or an open circuit on one wire. The induced voltage may be only a small percentage of the star voltage, but if the resistance of the system is low, and if resonance occurs, the voltage between one wire and ground may be many times the star value.

For this reason then, if the earth coil is used, special attention should be given to the transmission system to have it well transposed and balanced.

Maintenance of Resonance. The condition necessary for the most successful operation of the Petersen earth coil, that is, resonance and low energy loss, is difficult to obtain and maintain on a network composed of a variable number of feeders operating in parallel. For such cases adjustable reactors are required. Either a main earth coil may be provided with taps, so that the inductance may be adjusted for each change in line capacity, or an individual earth coil may be associated with each feeder, these coils being cut in or out with the feeder. Such complication, requiring a grounded connection on every feeder, appears to be very undesirable, and such installations are contrary to usual American practise.

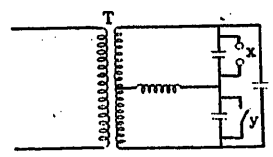

Fig. 9—Connections of an Artificial Line Tested in the Laboratory

When a fault was produced at the switch y the voltage across the sphere gap x rose to two and a half times the normal value.

Lightning Protection. The installation of the earth coil necessitates a change in lightning arrester settings for the transmission system. With the grounded neutral system, the lightning arresters are set so as not to discharge for star voltage under wet weather conditions. With the earth coil in service, the protection must either be reduced by setting the arrester higher than line voltage or cutting the arrester out of service when a transmission wire becomes grounded. Neither of these alternatives is desirable. On systems where lightning disturbances are infrequent, the operation of the earth coil, requiring an increase in the setting of the arrester, may not be very detrimental, but in

other regions the change in the lightning arrester setting would be very undesirable. If the earth coil were capable of satisfactory performance for various conditions, its operation would tend to relieve the arrester from interrupting the power arc which follows a lightning discharge.

The introduction of any impedance between the neutral point of a system and ground permits the *neutral to rise to a voltage above ground* during abnormal conditions. Hence the installation of the earth coil would impose greater voltage stresses on the transmission system under abnormal conditions, including lightning disturbances, than would be the case with a solidly grounded neutral.

Relay Protection. The installation of the earth coil in the neutral of a transmission network protected by any modern relay system prevents the automatic isolation of a grounded feeder due to the small differences in magnitudes and phase relations of the resultant currents flowing during the abnormal condition from those flowing under mormal conditions. Devices which give satisfactory indications showing the particular phase grounded are obtainable, but considerable difficulty will be experienced in determining immediately the particular feeder that is accidentally grounded.

An impracticable method of locating the faulty feeder is by an increase in current brought about either by the introduction of sufficient dissonance or by the increase of energy loss to such a value that the fault current will be of sufficient magnitude to operate the relays selectively. Under these two conditions the fault current may support an arc and the principal advantage of the earth coil installation will be lost.

As an alternative suggestion of a solution of the problem, it should be noted that the installation of a critical resistance at the neutral of a relatively small power system will also offer the same possibilities as a Petersen earth coil. The critical resistance at the neutral of a large system has the advantage of permitting sufficient value of current to obtain selective relay operation.

If the fault persists for an appreciable length of time, another method of overcoming the disadvantage of the earth coil is the installation of a relay in series with the earth coil which causes a switch in shunt with the earth coil to close and thereby solidly grounds the neutral of the system. When the earth coil is shunted by the switch, sufficient current for selective relay operation is permitted to flow. This is really a combination of two systems, initially an earth coil system, changing over to a solidly grounded neutral system and, therefore, it has some of the advantages and disadvantages of both. With this arrangement, it is evident that, if an insulator flashes over and the arc persists, the system just described would punish the insulator more than would be the case if a solidly grounded neutral were employed. On the other hand, if the earth coil system interrupts the arc following an insulator flashover, it is evident that the particular insulator would not be punished as much. However the insulators on the other phases would be subjected to higher voltages with the use of the earth coil than would be the case with solidly grounded neutral.

Effect on the Insulation of Systems. The Petersen earth coil system cannot be applied to transmission systems having transformers with graded insulation, due to the fact that when one line becomes grounded, the other lines rise to line potential above ground; nor to systems in which auto-transformers are used, due to the excessive voltages it would impress on low-voltage windings when a fault occurs in the high-tension side. Hence the adoption of the earth coil would materially increase the cost of the higher voltage transmission systems by preventing the possible economy arising from the use of graded insulation on transformers and the use of auto-transformers with a solidly grounded neutral.

The adoption of the earth coil system as compared to a grounded neutral system, would increase the voltage stresses which would be imposed upon transmission line insulators, on cable insulation, and on switching equipment. As a result, either the cost of line insulators and switching equipment would be increased or the factor of safety in insulation would be materially reduced.

III. Operating Tests

Tests were made upon a 26,400-volt, three-phase, 60-cycle network of five lines totalling 59.8 miles, to obtain information relative to the operation of the Petersen earth coil and to collect data indicating the suitability of such an installation for the suppression of arcing grounds.

The charging currents of the systems were measured with various combination of lines as follows:

Lines in Service	Amperes Charging Current
H-112, *V*-126, *L*-142, *G*-111, *B*-132 (All Lines)....	11.2
H-112, *V*-126, *L*-142, .. *B*-132.............	10.5
H-112, *V*-126, .. *G*-111, *B*-132.............	10.6
H-112, *V*-126, *L*-142, *G*-111, ...	5.9
.. *V*-126, *L*-142, *G*-111, *B*-132.............	10.0
H-112, .. *L*-142, *G*-111, *B*-132.............	10.0

The Earth Coil of Variable Inductance. Approximately a 1450-ohm reactance, rated at about 160 kv-a. was required for installation at the neutral of the system to resonate with the capacitance. This value was made up by connecting the high-tension side of a 300-kv-a. transformer (ratio of 13,200/2,400 volts) between the neutral of an 11,500-kv-a. transmission transformer (ratio of 13,200/26,400 volts) and ground. Two 100-kv-a. distribution transformers (ratio of 2400/240-480 volts) were connected to the low-tension side of the 300-kv-a. transformers, and on the low tension side of the two 100-kv-a. transformers a 250-ampere, 5 per cent feeder reactance (1.525 ohm)

was connected. Adjustment of the correct reactance value was obtained both by changing the ratio of transformation and by tapping off only such portion of the reactance coil as needed.

Tuning the Earth Coil and Dissonance. The earth coil was adjusted to resonate at 10.5 amperes, which is the charging current for the electrostatic capacity of four feeders of the network, consisting of the second

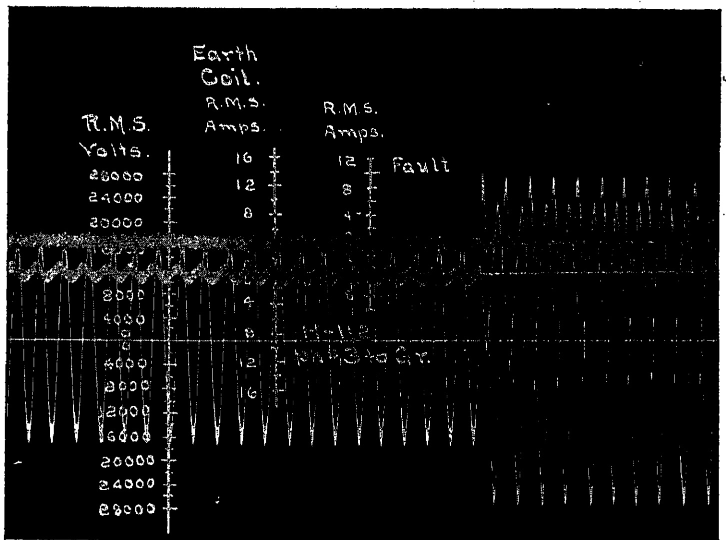

Fig. 10—Film 13

Reactance of the Earth coil is at resonant value. Phase No. 1 is grounded at the instant shown in the oscillogram of sudden change of currents and voltage. The three records are as follows: The upper record (right scale) measured the current in the fault. This current is shown as a wide zero line until the ground is made on phase 1 when the deflection suddenly rises to a peak value of about 7 amperes.

The middle record (middle scale) measure the current in the earth coil. This current has a peak value of nearly 1.5 amperes (the small thick lined wave) even under normal insulation of the three phases. This current is due to unbalanced conditions of the three phases. When phase 1 is grounded the current in the earth coil rises to a steady state value with an average peak of about 16 amperes.

The lower record (left scale) measures the voltage of a non-grounded phase; that is, phase 3 to ground. When phase 1 is grounded, phase 3 rises from y voltage to delta voltage.

group of lines in the table above, viz.: *H*-112, *V*-126, *L*-142, and *B*-132. Line *G*-111 was out of service. Leaving the earth coil reactance constant and reconnecting *G*-111 (charging current 11.2 amperes) a condition of +7 per cent dissonance[1] was established. Next, disconnecting *B*-132 a condition of − 44 per cent dissonance was established. In addition to providing convenient operating conditions, these combinations of feeders provided a wide range for tests. Incidentally the weather was hot and dry at the time the earth coil was tuned. There had been no rain for several days and therefore the line leakage was small.

The Petersen coil was adjusted for 60-cycle resonance under service conditions by measuring the current through a ground fault applied to No. 1 phase of Line *H*-112 and measuring the current through the coil. A number of progressive changes were made in order that the point of minimum current through the fault, indicating resonance, might be determined. The unneutralized or residual current under this condition was 2.7 amperes with 11.9 amperes through the earth coil.

The total energy loss in the system under dry weather conditions, determined by the decrement method, was about 30 kw. of which about 12 kw. occurred in the earth coil. The energy (not voltage) loss in the earth coil might be reduced somewhat for a permanent installation, by making up a specially wound coil, but the loss in the earth coil being the minor fact, the total loss could not be greatly reduced. The effect of wet weather conditions will be to increase the energy losses and this factor can not be controlled.

Tests—Grounding and Ungrounding One Phase. In addition to other tests, oscillograms were taken to show the ability of the earth coil to suppress arcing grounds and to obtain data on the operation of the coil during the transient state.

A fault was placed on phase No. 1 of feeder *H*-112 at the station end, with various combinations of trans-

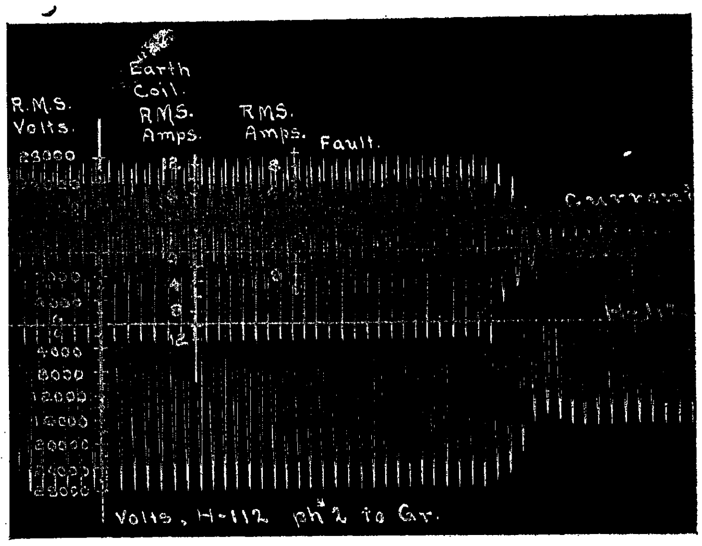

Fig. 11—Film 15

Reactance of earth coil is at resonant value. The ground on phase 1 is removed at the instant shown in the oscillogram of sudden change of currents and voltage. The three records are as follows:

The upper record (right scale) measures the current in the earth coil. When the switch representing the fault is opened, the current drops from the continuous value it previously had to zero (shown by the wide horizontal line of the upper record).

The middle record (middle scale) measures the current in the earth coil. When the switch representing the fault is opened the current in the earth coil does not drop immediately to zero value as in the case of the current in the fault. The current in the earth coil first rises a little and reduces gradually through three successive cycles to the small value of unbalanced current that is characteristic of the system.

The lower record (left scale) measures the voltage between ground and a non-grounded phase. After the ground is removed from phase 1 this voltage gradually through three cycles reduces to less than y value and recovers in two cycles to y value.

mission lines in service. Tests were made with resonance and with + 7 per cent and − 44 per cent dissonance. In each of these dissonance tests the shortening of the gap by closing a disconnecting switch caused a steady arc discharge as the blade approached the jaw of the switch. On opening the switch there was no evidence of an arc. These results indicated

1. In this article the use of ± a per cent dissonance indicates that the charging current was a per cent greater or less than that required for resonance.

that, for dry weather condition, considerable variation in the number of lines connected in service was permissible without destroying the effectiveness of the earth coil to suppress the arc.

The oscillograms, for example, film 13, indicated that there was a certain amount of dissymmetry in the three phases of the transmission system which caused current to flow in the circuit composed of the transmission lines and the capacity to ground, returning to the lines through the earth coil and the step-up transformers. The magnitude of this circulating current was determined by the change in magnitude of load current, but was, however, quite small—about one ampere.

The voltages of the different phases to earth changed almost instantly with the application or removal of the fault. This result was to be expected as the change of voltages takes place as rapidly as the line capacity charges or discharges.

At resonance, and during the steady state condition, the current through the fault (film 15) appeared quite peaked, having a maximum value of 4.5 amperes. The corresponding maximum value of current through the earth coil was 17 amperes. On closing the fault, the current built up through the earth coil in from 3 to 4 cycles. On opening the fault, the current through the fault dropped to zero immediately and the voltage between phase 3 and ground became stable in 4 to 5 cycles. There was a noticeable overcharge during the transient which occurred on opening the fault as shown by the voltage, phase 3 to ground, in films 15 and 16.

During the transient which occurred when the fault was closed with a condition of +7 per cent dissonance, the current through the fault reached a maximum value of 18 amperes, and the current through the earth coil, a maximum of 70 amperes. The transient lasted for about 4 cycles, during which the current through the fault reduced to a steady state maximum value of 4.5 amperes and that through the earth coil to a maximum value of 17 amperes.

On closing the fault with a condition of −44 per cent dissonance, the current through the fault reached a maximum value of about 45 amperes and through the earth coil a maximum of 100 amperes. After a transient lasting from 12 to 15 cycles, the current reduced to a steady state values of 7 amperes maximum through the fault and 16 amperes maximum through the earth coil.

These tests showed that for the steady state the current through the fault and the current through the earth coil approached the same steady value, and that the transient current on opening the fault lasted the same number of cycles. However, on making the fault, the character of the transient current depended upon the particular instant at which the switch was closed. During the transient conditions there appeared to be an even harmonic in the earth coil current. This effect of an even harmonic was probably due to the unidirectional flow of energy, to re-establish balanced conditions, which caused the transformer to become saturated. Hence during the transient condition the peaking of the current wave during one half of the cycle and the flattening of the wave during the other half of the cycle were to be expected from the particular conditions that existed for this test. In addition, a path for the return of negative current from a local street railway was provided by the fault, the current flowing through the fault, the transmission wire, the transformer, and the earth coil to ground. This flow

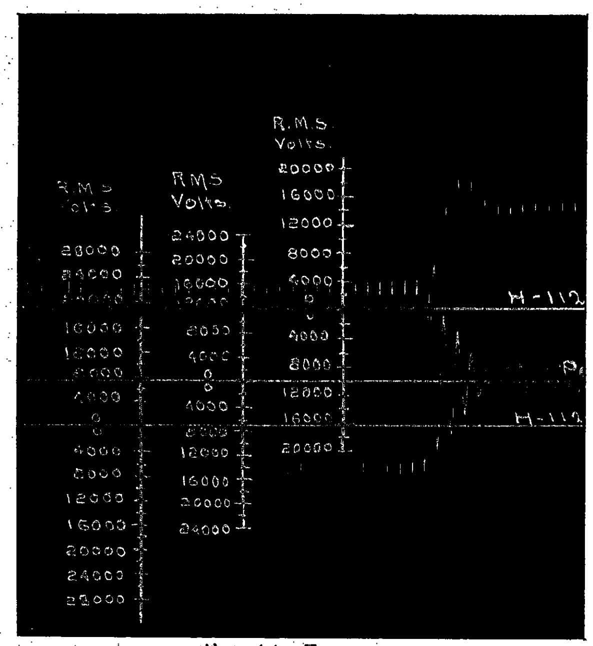

FIG. 12—FILM 16

Reactance of Earth coil adjusted to resonant value. As before, the ground on phase 1 is removed at the instant shown in the oscillogram of sudden change in the voltages. This oscillogram shows three voltages (no currents). The records are as follows:

The upper record (right scale) is the voltage of phase 1 to ground. This voltage is shown as a wide zero line until the switch representing the fault is opened when it rises in four successive cycles to a value slightly greater than its normal y value oscillates to less than normal and then returns to normal.

The middle record (middle scale) is the voltage across the earth coil, that is to say from neutral to ground. This voltage drops gradually in four successive cycles to the small constant value which is characteristic of the unbalanced system.

The lower record is too dim to reproduce. It is the voltage of the non-grounded phase 3 to ground. In four successive cycles it gradually reduced from delta value to y value.

of direct current would also tend to saturate the transformer and produce even harmonics.

Tests were also made to determine the possibility of maintaining a continuous series of arcs by moving the fault disconnecting switch back and forth within arcing distance. The test was made with +7 per cent dissonance, and with wet weather condition, the air being very moist and the transmission system having been thoroughly soaked by a heavy rain a few hours before the tests.

Under the above conditions a power arc was maintained. The arc was approximately two inches long and several inches broad, and was of a yellow color. The arc was noisy and appeared to the eye to be fluc-

tuating, that is, forming a continual series of arcs. The effect of the arc was to cause the blade and jaw of the disconnecting switch to become slightly pitted at various points.

An oscillogram of this arcing condition, film 25, value of voltage between neutral and ground was about 1.3 times normal.

There appeared to be a certain regularity as to the period at which the arc was interrupted. This average value was from 1.8 to 2 cycles. To explain this uni-

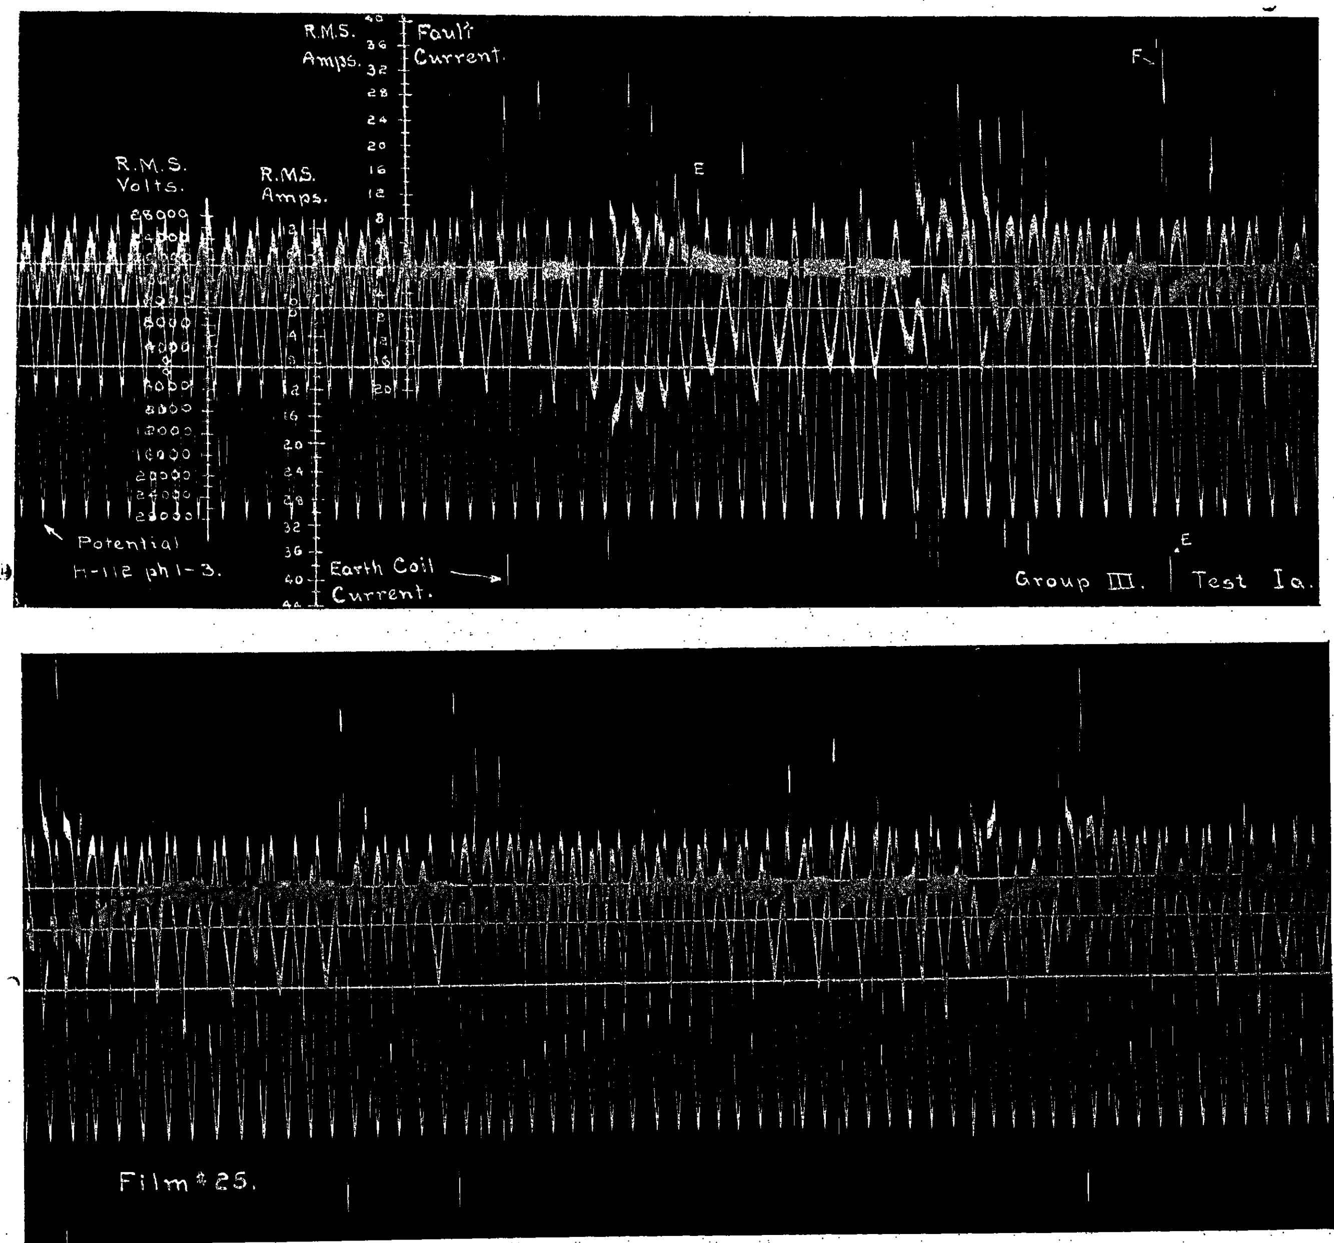

FIG. 13—FILM 25

Earth coil not tuned to exact resonance. Dissonance plus 7 per cent. After a severe rain storm an arcing ground was established on phase 1. Again the upper record is the current at the fault, the middle record is the current in the earth coil, and the lower record the voltage to ground of a non-grounded phase.

The oscillogram starts with the condition of metallic ground showing an alternating current wave to ground. This wave is ragged with harmonics (probably 3rd, 5th and 7th). When the switch representing the fault is opened to an arcing position both the current in the arc to ground and the current in the earth coil made many sudden large changes in value. There is great irregularity due to the various instants in the cycle that the arc is extinguished and again established. The current in the arcing ground shows now and then a gradual adjustment toward zero. This was described in the text.

The current in the earth coil shows dangerously high values which carry the deflecteous far off the edge of the film. The most severe current rushes are too dim on the photograph to reproduce (one of these large deflecteous is scratched in).

while rather difficult to follow, brought out a few points of interest. The maximum value of the current through the fault was from 80 to 100 amperes; the maximum value of the current through the earth coil was probably in excess of 70 amperes. The magnitude of the current through the earth coil indicated that the maximum formity of the re-establishment of the arc, the theory of beats caused by the fundamental frequency and the natural frequency of the oscillating system, has been put forth. On this basis the estimated dissonance was found to be from 6 to 7 per cent. When the fault was applied the two systems vibrated at the supply

frequency and the phase relation between these two systems was such as to cause negligible voltage across the disconnecting switch. When the fault was removed the two systems drifted apart causing the voltage across the disconnecting switch to reach a maximum value in about two cycles. The voltage caused by the oscillating system consisting of the earth coil and line capacities was gradually reduced to zero by the energy losses in this circuit. Hence, the most probable condition for the re-establishment of the arc occurred within a number of cycles corresponding to one half of the difference between the resonant frequency and the supply frequency. The resonant frequency obtained from the above considerations checked well with the increased line capacity.

These tests showed a peculiar wave shape of the residual and of earth-coil currents. This current of the earth coil was shown as a heavy wide line, which curved at a relatively slow rate to the zero value. Apparently this curve was due to the snapping out of the arc at an instant when energy was left in either of two forms, namely, a direct charge stored in the system or electromagnetic energy stored in the current transformer. This stored energy caused a current to flow until the energy was entirely converted into $I^2 R$ loss. Hence, it appeared that the earth coil did not dissipate direct charges entirely, and therefore, did not operate in a way to remove completely the cause of arcing grounds. Reference to film 25 shows that the maximum current through the earth coil, and therefore the maximum voltage between the neutral and ground was preceded by a series of arcs occurring at uniform intervals, indicating that the earth coil system under certain conditions permits system oscillations which are cumulative and produce voltages between neutral and ground which may reach excessive values.

In connection with film 25, it should be noted that with the exception of the weather, the conditions with only 7 per cent dissonance were favorable to the operation of the earth coil. There was no doubt but that the chances for obtaining an arcing ground would have been much greater if line *B*-132 had been cut out of service. The effect of the + 7 per cent dissonance was to increase the effective condenser capacity which probably was somewhat reduced in effect by leakage resistance. During the tests of the arcing condition, the lightning arresters were in service and discharged frequently.

IV. Comparison of Methods of Grounding Neutrals of Systems

Five methods of grounding the neutral are considered and an order of preference given for each from the view points of voltage stresses, current stresses, relay operation, continuity of service and cost. This arrangement is designed to give a clear conception of the status of the earth coil with respect to other methods of grounding and a comprehensive view of the relative advantages of the different methods.

It should be understood that a general comparison of this kind cannot be of a definite and precise character. There are many factors which must be considered and sharp distinctions cannot be made in the analysis. All that is attempted here is to give a general idea based upon a broad classification of the important items that require consideration.

For the purpose of this article, the five methods of grounding the neutral are defined as follows:

v. *Dead Ground.* The neutral connected directly to the grounded earth plate without the installation of reistance or reactance coils.

w. *Low Resistance Ground.* A ground connection to the neutral having a resistor of the order of two to four ohms permanently installed between the neutral and ground plate.

x. *Critical Resistance Ground.* A ground connection arranged as in the preceding paragraph *w*, but of the critical value of resistance necessary to damp out the natural oscillation of the system. In general, this will be a high resistance compared to two to four ohms.

y. *Petersen Earth Coil.* A ground connection to the neutral through a reactor, which takes the place of the resistor of the two previous paragraphs the reactor being tuned for resonance at fundamental system frequency with the capacity of the system to ground.

z. *Infinite Resistance from Neutral to Ground.* This is the ungrounded or free neutral system.

Effect on	Order of Preference				
	1	2	3	4	5
A—Voltage Stresses					
(a) At normal frequency....	v	w	x, y, z		
(b) Due to arcing grounds...	x, y	v, w	z		
(c) Due to lightning.........	v	w, x	y, z		
B—Current Stress.................	z	x, y	w	v	
C—Relay Operation...............	v	w	x, y, z		
D—Continuity of Service..........	v	w	x	y	z
E—Cost					
(a) Insulation of power system...............	v	w	x, y	z	
(b) Grounding devices......	z	v	x	w	y

A—Voltage Stresses.

(*a*) *At normal frequency* the dead ground limits the voltage stress which may occur to a constant maximum value of approximately 50 per cent of that which may occur in any other form of ground connection. With the low resistance ground, the voltage stress across transformers may be something less than line voltage.

(*b*) *Due to arcing grounds.* From a technical standpoint the critical resistance and the earth coil under the favorable conditions assumed in the table of comparison, seem to be the most desirable for the suppression of arcing grounds. Under unfavorable conditions the earth coil does not deserve first choice because of the possibility of producing excessive voltages due to the cumulative effects of a series of arcs. However, experience shows that most any system of grounding

is found to be sufficient to reduce the troubles arising from arcing grounds. From a practical operating point of view, many companies prefer to ground the neutral solidly or dead and isolate the feeder on which the ground occurs.

(c) *Due to lightning.* Three factors enter into the question of lightning protection. The installation of any impedance between the neutral of the system and ground tends to place additional voltage stresses on transformers and other apparatus. From this standpoint a dead grounded system is to be preferred and the earth coil and ungrounded system are the least to be desired. A second factor is the effect of the installation of a critical resistance which tends to damp out the natural oscillations. A third factor is the adjustment of lightning arresters. With the dead grounded system, the arrester may be adjusted approximately to star potential, whereas with the other methods, it is necessary to adjust for practically line potential.

B—Current Stresses.

The current stresses on apparatus due to currents flowing to ground through a fault are obviously zero with the ungrounded system and a maximum with the dead ground. With a grounding system permitting adequate relay protection, line to ground faults should not develop into line to line faults, hence the use of an impedance in the neutral would reduce the duty on breakers.

C—Relay Operation.

The reliability of relay operation is dependent upon the value and uniformity of the characteristics utilized to select the faulty lines. The dead ground is therefore to be preferred, as the variations in the resistance of the fault may limit the current flow to such values as to give incorrect relay operation if a resistance or other current limiting device is installed.

D—Continuity of Service.

In any power system the essentials necessary for the provision of continuous service are: first, the prevention or reduction of disturbances which may result in failure of apparatus, lines or equipment, and second, the isolation of apparatus, lines or equipment in the event of failure.

Since the means of prevention or reduction of disturbances on power systems has not developed to the extent that relay protection has been developed, a majority of the power companies prefer to rely on the latter method. The dead ground is, therefore, to be preferred which permits the utilization of full current values for selective relay operation. From a purely operating standpoint, however, some difficulty is experienced in holding synchronous machines in step after a fault has been cleared on a dead grounded system. Consequently a low resistance is generally installed in the neutral. The introduction of any impedance in the neutral connection tends to limit the distortion of the voltage triangle in case of a ground on one wire and thus to increase the probability of synchronous machines staying in step.

E—Cost.

(a) *Insulation.* Theoretically, there will be a difference in the cost of insulating a power system in favor of the dead ground. Advantage has not been taken of this fact, except for high-voltage systems; most power companies preferring to employ the additional factor of safety.

(b) *Grounding Devices.* Of course the ungrounded system is the cheapest in this respect and the dead ground without the installation of limiting devices is the next preference, the installation of the earth coil being most undesirable, particularly if it is necessary to employ reactors associated with each feeder.

V. CONCLUSIONS

The advantages of the Petersen earth coil system are: First, the elimination of arcing grounds under favorable conditions; second, the reduction of insulator trouble; and third, small earth current when a fault occurs to ground.

The disadvantages are: First, high potentials between line and ground due to series resonance; second, maintenance of a series of arcs under unfavorable conditions, that is, resonance and high loss, or large dissonance and either high or low loss; third, difficulty in obtaining selection of the faulty line by means of relay protection; fourth, reduced lightning protection due to the necessity of high settings on arresters; and fifth, increased system insulation due to the shifting of the neutral with abnormals or transients.

An analysis of the table giving an order of preference, results in the following arrangement of the different methods of grounding from the viewpoint of desirability: First, dead ground; second, low-resistance ground; and third, critical-resistance ground or the Petersen coil. The distinction however between dead ground and low-resistance ground is very slight and choice will be determined by local conditions. Either of these is generally preferable to the critical resistance or Petersen earth coil. An installation of an earth coil on a free neutral system would probably result in a reduction in interruptions to service. An installation of an earth coil on a dead grounded system would probably show no improvement in service and under most circumstances would introduce complications. In this connection, it is pointed out that reduction in interruptions are not significant, if made on the basis of a change from free neutral to earth coil, but merely prove that a grounded system is better than an ungrounded neutral system.

Numerous technical difficulties with the earth coil have been pointed out and it is interesting to find that some of these points, such as high potential due to series resonance, have given rise to serious interruptions in some European installations.

Discussion

W. W. Lewis: In the paper by Messrs. Conwell and Evans it is interesting to note that the only part which gives actual data, that is, Section 3, shows that the Pertersen coil functioned satisfactorily in the manner that it was intended to function, that is, as an arc suppressor. The conditions under which the arc was made were not those usually existing in practise. In the tests an arc was made between switch blades with a comparatively small separation, say a couple of inches or so. Under these conditions the residual current even though small may be enough to maintain an arc. In practise the arc is usually over an insulator with 10 or 12 in. arcing distance and considerable current is required to maintain such an arc even without the neutral reactor.

In the author's comparison of methods of grounding neutrals of systems (page 147) they give for continuity of service first order of performance to the grounded neutral system and fourth to the Petersen coil system. This seems to be a curious inversion of order. That system which is deliberately intended to cause a short circuit and an interruption in case of an arc-over is placed first, and that system which puts out the arc without interruption is placed next to last.

It seems to the speaker that the authors have not made a good comparison between the system with Petersen coil and the isolated and grounded neutral systems. The Petersen coil system really stands between the two. As far as voltage stresses are concerned it is an improvement over the isolated neutral system but not as good as the grounded neutral system. As far as current stresses are concerned it is an improvement over the grounded neutral system, and probably also over the isolated neutral sytem in which an arc-over usually results in a short circuit. It is applicable to moderate voltage systems in which the charging current is low, hence the ohmic reactance of the neutral coil high, so that the reactance of the transmission line itself has practically no effect on the neutral current. Under this condition it is comparatively easy to obtain a balance and the residual arc current may be kept at a minimum no matter at what point on the line the arc takes place. However, on high-voltage sytems or very long low-voltage systems, the charging current is large, hence the ohmic reactance of the neutral coil low. The reactance of the transmission line on the other hand is high so that it is difficult to maintain a balance for arcs at different points on the line and there may be enough residual current to maintain the arc. In no event, however, can the voltage strains be as severe as on an isolated neutral system. In view of these considerations the field of the reactor at the present time would seem to be limited to moderate voltage, moderate length systems.

Some tests were made by the speaker on a 100-mile, 44,000-volt power system in the South equipped with a neutral grounding reactor. The tests were made to approximate operating conditions as nearly as possible. The line was energized and from one conductor to ground was placed a circuit consisting of an oil circuit breaker an insulator or horn gap, a current transformer and ground. Across the insulator was placed a one-ampere fuse. The oil circuit breakers was closed allowing the current to flow to ground, blowing the fuse and causing an arc. The setting of the reactor could be changed by means of taps. All told about 50 arc-overs were made with different settings of the reactor, different lengths of line, pin-type and suspension-type insulators and horn gaps, with the line carrying load and with the line unloaded. In all these tests the coil acted satisfactorily as an arc suppressor even with, in the terms of the authors, as much as plus 60 per cent and minus 20 per cent dissonance. There was in the majority of cases a conspicuous absence of measurable overvoltages such as feared by the authors.

C. L. Fortescue: The theory of the Petersen earth coil is presented in the simplest form when considered in terms of symmetrical coordinates. Thus, for example, at the point at which ground occurs, the system has impressed on it: (1) The normal polyphase voltages which may be resolved into positive and negative phase sequence symmetrical components, and which since their sum at any instant is always zero, can produce no ground current, and, therefore, will have no effect on the choke coil connecting the neutral to ground.

(2) The zero phase sequence voltage tends to cause a flow of current through ground. These currents are of zero phase sequence, and have been termed by telephone engineers residual currents. Under the condition of ground, therefore, we shall have quite obviously a circuit to this zero phase sequence component consisting of the joint capacity of all the wires to ground and the Petersen coil in multiple.

Let us now consider the action of such a system when a ground takes place. Since the impedance of all the conductors in multiple is quite low, there will be an initial rush of charging current. During the period of adjustment, this charging current will set up high surge potentials in apparatus connected across the lines. After the steady condition is attained, the system consisting of the zero phase sequence line capacity and the Petersen coil will oscillate naturally at fundamental frequency.

We have at the instant of zero current, the point of contact at ground potential, and the system oscillating at its natural period, at a zero phase sequence potential equal to the voltage from line to neutral. Therefore there will be no potential between the point at which the ground initiated, and earth and the arc will not be re-established after the first cycle.

Through the dissipation of energy in the system the line will gradually resume its nominal zero phase sequence potential, which, if there be no dissymmetry in the system, will be zero.

So far the system appears to be ideal, but let us examine it still further:

(a) The ground current is not the contact current, but will be very large, especially in large cable systems, where the capacity of all the conductors to ground has a large value. The ground current is the capacity current when all the conductors are charged to a potential above ground equal to the Y voltage. The duration of this condition depends upon the closeness of the resonance, thus if there were no losses in the system during resonance, the time would be prolonged indefinitely. The interference or residual currents, are, therefore, not small and they extend through the system for its complete length.

(b) Unbalanced impedance in the lines, will cause under load conditions a zero phase sequence e. m. f. in the system to which the Petersen earth coil and the line capacity form a resonant system. If the losses are low, there will be nothing to prevent a high potential being induced in the system. If a short circuit takes place between lines in which there is dissymmetry, the potential to which the system may be raised is very high.

Breakdown of lines, of transformer, generators and motors will all produce high potential rises, and a fault, which, with a dead grounded neutral would be confined to a narrow scope, may be spread to other parts of the system.

(c) In a large interconnected system, we would have the undesirable condition that a ground on one feeder would raise the potential of the whole system. This might result in dangerous conditions for the users of power where their circuits are not grounded.

(d) The transient condition at the installation of the short circuit may cause severe surges in connected inductive apparatus.

(e) From the point of view of electrical apparatus in general, the system is undesirable. It is introducing an uneconomical system to take the place of a standard of power transmission and distribution, which has been established and is the result of a great deal of experience and careful thought.

It should be borne in mind that in the long run, the system

that is most favorable to the power producer and user will also work out best for the telephone system.

The dead grounded neutral system has become standard. This condition has not been reached by haphazard means, but it is the result of a long history of bitter experience with isolated systems.

The speaker was among the first to recognize the advantages of the dead grounded neutral, and has lived to see the opinions of transmission engineers come around to this point of view as the result of actual experience in the field. We must guard against permitting the alleged advantages, in a narrow field, of such a device as this one under discussion taking hold of our imaginations. If it has applications in a certain field, let us define this field as closely as necessary to prevent misapplications of it, which may lead to serious trouble in the future.

In considering the relations between the power and telephone interests, we should guard against concessions to the latter which will hold back the development of the power resources of this country. One of the essential requirements for furthering the rapid development of power is a stable system of transmission and distribution. This can be obtained only with a dead grounded neutral system. The general recognition of this system as the standard will lead to standardization in line materials, insulation, transformers, etc., so as to produce better performance at the least cost.

In considering the relative merits of the two cases in the controversy, we should keep in mind the ultimate investment, and the system which will make this the minimum will be best suited to our needs.

H. M. Trueblood: The authors speak of resonanting the earth coil with the sum of the currents through two of the line capacities to ground. One ordinarily thinks of resonance as a condition obtaining between two reactances, rather than between a reactance and a current. It would possibly lead to confusion, however, if the statement were taken to mean that the earth coil inductance is to be resonated with the sum of the capacities to ground of the two non-grounded phases. The earth coil inductance should be resonant with the sum of the *three* capacities to ground, that is, if with solidly grounded neutral, the three Y-connected legs of the transformer bank be energized with three equal fundamental frequency voltages, all in phase, the quadrature component of the neutral current should be equal in magnitude to the same component of the current taken by the reactor when energized by one of the same three voltages. This current component will, however, also be equal to the sum of the currents taken by *two* line capacities with the third phase grounded when the system with neutral isolated is energized three phase at the same star voltages as before, provided the voltages and capacities to ground are balanced. The reason is of course that in the latter case the reduction in total capacity to ground is exactly counter-balanced by the higher voltages to which the two capacities are subjected, combined with the effect due to their phase displacement (60 deg.). If the neutral is grounded through a correctly tuned reactor, instead of isolated, the quadrature components of current (referred to the star voltage of the grounded phase) through the line capacities and through the reactor annul each other at the fault, so that, as stated in the paper, the minimum reading of an ammeter carrying the fault current indicates correctness of tuning. An ammeter located as shown in Fig. 5 would carry a charging current for wire-to-wire capacity as well as the fault current.

This equality of the quadrature current taken by the reactor at star voltage to the sum of the currents taken by the capacity to ground of two phases, with the third grounded, is what constitutes the "parallel resonance" of the system. As is explained in the paper, it is this condition, which exists only when one phase is grounded, that operates to extinguish the arc to ground. The "series resonance" condition is equally fundamental to the operation of the reactor. As is perhaps not quite clearly explained in the paper, it is this condition which becomes operative to prevent the restriking of the arc, after the condition of parallel resonance has brought about extinction of the arc, and has thereby ceased to exist. It is because of this "series resonance" that the current taken by the total direct capacity to ground at star voltage is equal to the quadrature reactor current at the same voltage, as previously pointed out. The transition from the "parallel" to the "series" resonance condition takes place when the arc goes out, and is accompanied by no appreciable transient due to fundamental frequency, if extinction occurs when the fundamental frequency current passes through zero. At this instant, the fundamental frequency charges and currents in the system have the proper values for both types of oscillation, except perhaps for slight deviations due to system losses.

In their discussion of dissonance the authors might be understood as stating that the phase which had been grounded might within a few cycles be subjected to a voltage slightly less than twice the star value, with dissonance and with either high or low loss. Over-voltage due to dissonance will be more pronounced with low than with high loss. The resultant voltage shown in Fig. 8 can hardly be described as slightly less than twice normal. It would seem to be rather less than 1.4 normal, and would evidently be greater if the damping were smaller.

In referring to the trouble which may be produced by voltage vibration on a transmission line, the authors presumably do not mean that the effects would be worse than with isolated neutral under similar circumstances.

The experimental result showing that with a single-phase set-up a voltage to ground 250 per cent of normal, *i. e.*, 125 per cent of line voltage is obtained on the sound wire, checks quite well with some theoretical calculations I have made regarding this matter. It would be interesting to know whether similar tests with free neutral were made, and if so, what results were obtained. I have been unable to discover any theoretical reason for expecting greater over-voltage with the Petersen than with the free neutral system from transient effects rising from the redistribution of energy referred to in the paper. With the Petersen system, the principal transient term is nearly the same as with the free neutral system, and there is an additional non-oscillating term due to dissipation in the circuit consisting of coil and grounded transformer leg. This, however, is insignificant compared to the other, so far as the voltage from a sound phase to ground is concerned.

The authors state that with "a 'make and break' through the accidental arc, the transient voltage may rise to slightly less than twice line voltage." It is not quite clear just what is intended here, but if a single "make and break" is referred to it seems unlikely that the highest voltage of a sound phase to ground would exceed 125 to 150 per cent of line voltage.

An oscillating system responds with large effect only to impressed forces of approximately its natural period. It is therefore not easy to see why lightning is given as a possible source of resonant effect in the "series resonant" circuit. As to inductive effects due the action of currents belonging to the system itself, which I presume are what is referred to in mentioning "mutual induction," "unsymmetrical impedance under load" etc., I think these will be relatively small so long as the currents are confined to the line conductors and are not of excessive magnitudes, *i. e.*, are not short-circuit currents. When the currents are confined to line conductors the inductive effects of interest in this connection arise from differences in the mutual inductances between line wires, and the distribution of current among the latter is thus not a factor of great importance. In some cases I have calculated, the effect from balanced and symmetrical currents of about full-load magnitude is nearly the same as from a single-phase current of the same magnitude per wire. Neither was large. There is a further reason why the effects of such induction in the series resonant circuit is lessened. It is

that the induction does not take place directly in this circuit. The induced voltage is distributed linearly along the circuit. So is the capacity of the resonant circuit. The two are therefore not directly in series. If the system consists of a single line, the effect of this factor alone is to reduce the current in the resonant circuit by 50 per cent of what would be if the induction occurred directly in series. Furthermore, this current can be reduced to an insignificant amount by transpositions. The effects of short circuits cannot, of course, be entirely avoided by transpositions. In a single line system of considerable kv-a. capacity, it would seem that the neutral might be raised to a considerable fraction of star voltage above ground by a single-phase short circuit, under circumstances favorable to the production of such an effect. In a multi-line radial system or in an interconnected network, the effect of a single-phase short circuit would be much smaller.

Unbalance of line capacities probably produces the most important effect of any non-accidental sources of induction. To keep their effect small it is necessary that the ratio of the vector sum of the three admittances to ground to their arithmetical sum be small compared to the ratio of the resistance of the coil to its reactance. This should usually be obtainable with only a modest amount of transposing.

Induction from the voltages of neighboring power circuits would not be in the series circuit except in the rather rare case of a practically complete parallel to all lines of the system on which the coil is installed. It should therefore usually be of relatively small effect, except possibly when the neighboring system is in trouble.

It is difficult to verify the statement that "the induced voltage may be only a small percentage of the star voltage, but if the resistance of the system is small, and if resonance occurs, the voltage between one wire and ground may be many times the star value." Assume a ratio of 1/10 for the coil resistance to its reactance and assume also that the "small percentage" of the star voltage is not more than 10. The voltage thereby produced between wires and ground would be about one times star voltage. If it were exactly in phase with one of the line voltages to ground, the highest resultant line voltage to ground would be about twice star voltage. By reducing the coil resistance-reactance ratio and increasing the "small percentage", this might be brought up to 3 times star voltage, but it would be hard to get it higher. Seven to eight per cent of star voltage in the series resonant circuit would be a liberal estimate for the voltage due to capacity unbalance, even if the line is not transposed at all.

The authors describe an interesting series of tests and advance explanations of a number of effects that were observed. They have not, however, collected into a separate series of statements the conclusions which they draw from this experimental work, and it is difficult to decide just what inferences one is expected to make. The discussion of film 25 on page 147, and also in the fine print under Fig. 13, seems to indicate that the authors believe that excessive or dangerous voltages between neutral and ground must have occurred, because of the large instantaneous values of reactor current. On page 146, however, they state that "the magnitude of the current through the earth coil indicated that the maximum value of voltage between neutral and ground was about 1.3 times normal." If this means 1.3 times star voltage, it seems hardly larger than might be expected even without an arcing ground. I would like to ask whether the authors do not suppose that the excessive currents observed in the fault and in the earth coil, in the arcing test and also in some of the other tests, are due to saturation in the transformers which were used in the connection from neutral to ground. Apparently the 13.2 kv. transformer was worked at some 20 per cent above normal voltage, with one phase grounded, even under steady state conditions, and of course the exciting current would be considerably larger than normal with this excess above normal voltage. The figure given for reactor current in the test for adjustment of resonance appears to indicate some effect due to saturation.

It seems to me that the drawing of conclusions of general applicability from these tests is very considerably complicated by the presence of a factor so difficult to evaluate as over-saturation of iron. Some of the other peculiar effects shown in film 25 may be connected with it. Certainly it must be agreed that this film is rather difficult to follow. For instance, in the author's discussion of the non-oscillatory shape occasionally present in the trace of one of the currents on this film, they are apparently talking about the coil current, yet the oscillogram looks as though it were the fault current which has this characteristic.

On page 145 the authors speak of a "noticeable overcharge during the transient which occurred on opening the fault as shown by the voltage, phase 3 to ground, in films 15 and 16." The trace of this voltage is too dim to be seen on film 16 and is not present on film 15, unless the film is incorrectly labelled. Presumably the effect to which they refer is that which appears in the phase voltages on the two films, however. It is due, I believe, to inexactness of tuning. It may be seen that the frequency of the coil voltage in film 16 and the coil current in film 15 slows down as soon as the free oscillation begins. The ratio of the frequency of this oscillation to that of the fundamental appears to be about 8:9. If the tuning were exact, the reactor voltage in film 16 should be in the same or the opposite phase (depending on the polarity of vibrator connections) to the voltage on the phase from which the fault has been removed. The two appear to coincide at about the third maximum after the beginning of the free oscillation, and this apparently produces the overvoltage on phase one.

Livingston P. Ferris: I have given the Petersen earth coil some consideration from a different point of view from that of the authors and have had an opportunity to see several of the European installations. These I will describe very briefly and then outline some facts showing the effect of the device on induction in neighboring communication circuits.

Rome Municipal Line—22 miles—Twin Circuits. Two 30,000-volt, 3-phase 42-cycle, 7500-kv-a., star-connected generators are connected direct to line. The transformers at the Rome end are delta-delta. The system was first operated isolated. Trouble developed with the insulation of generators at times of line faults. A Petersen coil was installed in the Castelle Modamo Station in January 1920. A visit to this station was made in July 1920. The chief of the station was questioned at length and some test records were examined. He was convinced that the action of the Petersen coil had been beneficial. This is not a typical installation, but if its testimony can be believed, it is against the presence of excessive over-voltages as otherwise no benefit would have resulted. This installation is decribed by Lombardi in *L'Ellectrotechnica*, August and September, 1920.

Alta Italia-Line—65 Miles: 42-47 kv., 3 phase, 21,000-kv-a. Two star-connected auto transformers make slight changes in voltage between generating station and receiving station in Turin. A Petersen coil is installed between neutral of the star-delta receiving transformers and ground. It had been in service 1½ years at the time I interviewed Ing. Palestrino and saw the coil in October 1920. Previous to installation of coil, the neutral was isolated. Ing. Palestrino considered that the coil had been beneficial in reducing interruptions. A new coil of larger capacity was then under construction to replace the original. It was proposed to apply a Petersen coil to a 75-kv. circuit. The Alta Italia installation is described by Palestrion in *L'Ellectrotechnica* for July 5, 1920.

A number of other installations exist in Italy where the system is being given serious study by a committee of the I. E. A., headed by Prof. Lombardi who has published a number of articles on its theory and application. It will be of interest to

know that Petersen, according to Lombardi, does not advocate exact resonance, but rather that the coil should have 10 to 15 per cent less reactance than the line. This was mentioned in connection with a discussion of unsymmetrical capacities and I suggested to Lombardi that the difficulty arising from such dissymmetry could be easily overcome by transposing the circuit. To illustrate how practical this is, the following figures are presented, based on experiments on a 36-mile power circuit of vertical configuration (one of the most unbalanced types). Residual voltage, fundamental frequency, isolated neutral, untransposed line, 6.9 per cent of voltages between wires. After two transpositions were installed on poles nearest third points, the residual voltage was too small to measure, but certainly less than 0.6 per cent. The residual voltage in this case is a measure of the capacity unbalance.

Swiss installation: One of the most extensive and interesting applications of the Petersen system is in Switzerland. Here it is applied with a number of coils to a very high-voltage cable and transmission line network. The coils in this case have air cores whereas in all other cases they had iron cores. Here apparently the purpose is to reduce damage to cable at times of fault by limiting fault current to the relatively small loss current rather than full charging current to ground in case of isolated systems or short-circuit current in case of grounded system. Of course, with a cable one can scarcely expect a fault to heal like some flashovers on a line. A high-voltage cable network would be about the last place to apply a Petersen coil if there were danger of serious transient over-voltages. I refrain from speaking more specifically of this Swiss case as the engineers responsible have not yet published their views. I have reason to expect they will do so in the near future.

No information which I have been able to obtain on any European installation would warrant the rather vaguely stated final conclusion of the paper. It would seem proper that the authors should submit more specific evidence in its support.

Now as to the bearing of this device on inductive interference problems, a matter ignored by Petersen and all other Europeans

COMPARISON OF DIFFERENT METHODS OF GROUNDING THE NEUTRAL
From Standpoint of Residual Voltages and Currents

Method of grounding neutral	Under abnormal conditions ground on one phase		Under Normal Conditions				
			Fundamental		Harmonics not of triple series		Harmonics of triple series
	Residual voltage	Residual current	Residual voltage	Residual current	Residual voltage	Residual current	Residual voltage and current
1 Petersen Coil	$\sqrt{3}\,E$	Max. $\frac{E}{\sqrt{3}}\, l\,\omega\, C\,g$ at Coil Zero at other end of line.	May be large if capacities are unbalanced to ground. Can be made unimportant if line is transposed.	May be large if capacities are unbalanced to ground. Can be made unimportant if line is transposed.	Practically same as (2) 104%— 5th 100%—29th	Practically same as (2)	15%—3 rd 1/2%—27th
2 Infinite Impedance (Isolated) △ Y △ △	$\sqrt{3}\,E$	Max. $\frac{E}{\sqrt{3}}\, l'\,\omega\, C\,g$ at fault, between 50% and 100% of max. for (1). Zero at ends of line.	Larger than (3) or (4) but smaller than (1) $3\,E\,\frac{C\,r}{C\,g}$	Zero	Depends on unbalance of line capacities. Can be made small as desired by transpositions. Relative magnitude 100%.	Much smaller than (3) Zero at ends of line.	Zero
3 Zero Impedance (Solid Ground)	$\frac{E}{\sqrt{3}}$	Short circuit current, same everywhere between fault and neutral. Large compared with (1) or (2).	Zero except for dissymetry in transformer voltages.	Smaller than (1) when due to unbalanced capacities. With multiple grounds may be large.	Zero except for dissymetry in transformer voltages and slight effect of capacity unbalance.	Depends on unbalance of line capacities and dissymmetry in transformer voltages.	Depends on transformer design rating excitation and line constants. Relative magnitude 100%.
4 Moderate Resistance Rm Less than *Rc* generally larger than faulty phase impedance	$\sqrt{3}\,E$ Max. value for low impedance fault.	$\frac{E}{\sqrt{3}\,R\,m}$ Small compared with (3).	Much smaller than (1) (2) or (5).	Same as (3) or slightly smaller.	Approximates (3) Much smaller than (1), (2) or (5).	Approximates (3) Larger than (1), (2) or (5).	Smaller than (3) much larger than (1). More effective at higher frequencies.
5 Critical Resistance Rc	$\sqrt{3}\,E$	$\frac{E}{\sqrt{3}\,R\,c}$ Usually smaller than (4).	Larger than (3) or (4) but usually smaller than (1) or (2).	Smaller than (4).	Slightly larger than (3) or (4). Smaller than (2).	Lies between (3) and (2) depending on extent of system.	Smaller than (4). Larger than (1) at least at higher frequencies.

* —Vector sum of voltages to ground or vector sum of line currents.
E —Normal voltage from wire to wire.
$C\,g$—Total direct capacity to ground per mile of 3 wires in parallel.
l —Length of line in miles.
l' —Maximum length of line on one side of fault.
$C\,r$—Residual capacity = combination of 3 direct capacities in 120° relation.

and not mentioned by Messrs. Conwell and Evans. To appreciate this it is necessary to make comparisons with other systems of grounding or not grounding power circuits. To facilitate such, the foregoing table is presented. It compares the residual voltages and currents for different methods of grounding the neutral of a power circuit and for different conditions, normal and abnormal. As the balanced currents and voltages are inherently the same, irrespective of the condition of the neutral, they do not enter into our comparison of different systems. The possible inductive effects of corresponding factors of the several systems are, of course, directly proportional to the magnitudes of those factors in their respective systems.

From the above table, it will be noted that the Petersen system will, under conditions of a ground, produce inductive effects from voltage unbalances of the same order of magnitude as those produced by an isolated system, and that these are approximately three times as great as would be produced by a system with neutral solidly grounded. Electric induction from this cause will affect neighboring open-wire telephone lines, but will have no effect on underground telephone circuits, and relatively little effect on telephone circuits in aerial cables, if the sheath is grounded. The magnetic induction from the residual current will obviously be very much greater in the case of the grounded neutral system than in the case of a system grounded through the Petersen coil or isolated. The magnetic induction will furthermore affect underground as well as open-wire circuits. Theoretical studies and experience combine to indicate that the effects of induced voltages in case of a fault to ground, considering both electric and magnetic components, are more severe with the solidly grounded neutral than with the isolated system except perhaps in case of long exposures involving very high-voltage power circuits. This is largely because of the greater transfer of energy by magnetic induction with the grounded neutral. From a theoretical study of the Petersen coil, it would be expected that the effects under abnormal conditions would be quite similar to those produced by isolated systems, except that the tendency to prevent the formation of arcing grounds would constitute a considerable advantage for the Petersen system, as the results of an arcing ground are proportionately as undesirable from the standpoint of neighboring telephone circuits as from the standpoint of the power system.

Under normal load conditions, the principal effect of the Petersen coil is practically to suppress the inductive effect of such triple harmonics as may arise from the transformers in a grounded neutral system, thus making it approximate the isolated system as regards the absence of induction from triple-harmonic residuals. So far as harmonic residuals not of the triple series are concerned, these remain practically the same with the Petersen coil as with the isolated neutral, and are capable of reduction by the same method, namely power circuit transpositions.

Detailed comparisons of inductive effects from residuals under abnormal and normal conditions and including systems employing a resistance in the neutral connection, may be based on the table. It should be remembered that under normal load conditions, the inductive effects of the balanced components must also be considered. Under abnormal conditions, the inductive effects of the balanced components are generally masked by the much larger effect of the abnormal residuals.

Under abnormal conditions, the magnitude and phase of the residual current or unbalanced current to ground at all points in an isolated network or one grounded through a Petersen coil, may be very closely determined by considering all three phases in multiple and replacing the fault by a single-phase generator connected between the 3 multipled phases and ground, whose voltage is equal in magnitude but opposite in phase to the normal voltage of the grounded conductor and whose internal impedance is equal to that of the fault. If we are interested in the actual currents in the several phases, these may be obtained by combining the unbalanced currents with the normal load and charging currents. This method of analysis is very helpful on occasions and leads to quick results.

In discussing the effect of the Petersen coil on the selective action of relays, the authors point out a real difficulty but may we not hope that if the advantages of the Petersen coil are sufficient in other respects this difficulty may be overcome. The authors, themselves, suggests a means of avoiding this difficulty if not of overcoming it, by shunting the Petersen coil with an automatic switch which may either solidly ground the neutral or cut in any desired amount of resistance. The authors claim that such a combination system would punish an insulator more than would be the case if a solidly grounded neutral were employed. It is not apparent that there would be much difference or that it is of importance. I would suggest in this connection, that if instead of reverting to a solidly grounded neutral, a moderate resistance were cut in by the switch, not only the insulator in question would be spared from punishment but, also, neighboring communication circuits. For all those cases which the Petersen coil may clear without interruption, both the power circuit and neighboring communication circuits are the gainers. It remains to be determined by experience whether cases of the latter kind will be a sufficiently large proportion of the total to warrant the use of a combination system.

I wish to make it clear that I do not regard the Petersen coil as a panacea for all inductive difficulties but merely that it is of sufficient importance to warrant a comprehensive, and preferably cooperative, study from all points of view, to bring into light all the pertinent facts by which it must be judged. As yet, we have no experimental data bearing particularly upon inductive interference but, of course, data as to its effect on the power circuit give us a good guide as to what we may expect since the two are intimately related. Primarily and fundamentally, the device must satisfy power circuit requirements. If this is done, we should then, in particular cases where inductive interference is involved, give due weight to its advantages or disadvantages from this and other standpoints along with those of all other systems in arriving at a decision as to which should be used. I think this is a basis upon which we may all agree.

F. C. Hanker: Most of the comparisons made today have been made with the free neutral system. Such a basis of comparison seems rather surprising when one considers the actual practise in power systems, the growth and inter-connection of systems. A number of years ago it was felt that the size of a transmission system or the extent of a net work would be limited on account of the effect of arcing grounds, a phenomenon incident to the operation of a free neutral system. Since that time, the tendency has been more and more toward the grounded neutral system and for that reason I believe that the basis of comparison of power systems would be a grounded neutral system.

The Petersen coil has certain advantages if it could be worked in with existing power systems and if it did not in any way limit the expansion of power service. With respect to continuity of service, which is really the criterion of best service, which would be of advantage to the power company and customer, our experience has shown that the grounded neutral system has had a far better record than was the case in the days of the free neutral system. This means that we must recognize the possibility of arc ground disturbances when the characteristics of a free neutral system are approached. It also follows that we must devise and develop protective devices that will take care of such disturbances, and not put a handicap on power systems and limit their development. It has been stated a number of times that there are possibilities of protector breakdown and fire hazard and other difficulties as a result of magnetic induction. Experience has not always borne out these possibilities. When power systems are compared the basis should be on what promises to be the best service conditions to the customer, taking into account future growth and interconnection of systems.

The study of the earth coil indicates that the application is limited. High-voltage transmission lines or extensive cable systems are not favorable for the application of the earth coil because of the high charging currents involved. The earth coil is not suitable for application on systems where graded insulation or auto-transformers are employed, because the neutral point cannot be solidly grounded. Complicated networks are not favorable for the application of the earth coil due to the difficulty of securing isolation of faulty feeders. The most suitable conditions for the application of the earth coil are on moderate voltage systems of rather limited extent, particularly those where duplicate transmission lines do not exist. It appears, therefore, that the earth coil is not suitable for general application on power systems.

H. S. Warren (communicated after adjournment): The "Petersen earth coil," so-called, has an important effect from the inductive interference standpoint. One of the most difficult problems in inductive interference-prevention is that of avoiding the severe surges of high voltage induced in a telephone circuit when a fault develops on a paralleling power circuit. Such a situation will be clear from the following diagram. (Fig. 1).

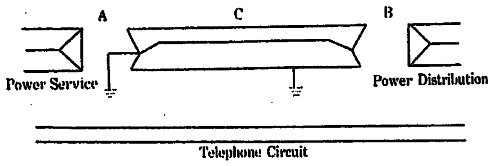

FIG. 1

The transformer at A supplying power to the transmission circuit is shown with the neutral of its high-tension winding solidly grounded. Under conditions as shown, with normal load and the circuit balanced, no current of fundamental frequency will flow through the neutral connection. When, however, the insulation fails, as at C, grounding one phase wire through the fault either solidly or through an intermittent arc, the voltage of that phase is suddenly short-circuited through the grounded phase wire, fault, and earth back to the neutral, thereby causing a large current through the loop consisting of the faulty phase and earth. By electromagnetic induction this large current through the grounded loops sets up a large voltage along the wires of the paralleling telephone circuit. These suddenly induced voltages produce various harmful effects, the most serious of which in recent experience is that of acoustic shock to telephone operators.

Now as to the bearing of the Petersen earth coil on this matter. If the Petersen coil were used in the neutral ground connection, the current at such times of fault, through the fault and the earth loop, would be relatively small and thereby the severe electromagnetically induced surges avoided. It should perhaps be added that the foregoing has in view more particularly transmission lines of lower voltage, as compared with the highest voltage lines now in operation.

If the resistance were inserted in the neutral ground connection the short-circuit current through the fault would be. of course, less than with a solidly grounded neutral. By making the resistance high enough the induced voltage can be made as small as desired. The method of high resistance in the neutral ground connection is therefore an alternative to the Petersen reactor as a possible solution of this inductive interference problem.

If the use of the Petersen earth coil proves feasible from the power standpoint, it will be of considerable benefit from the standpoint of telephone service where parallels exist. To a certain extent the interests of the two services are alike for if the Petersen coil were objectionable from the power standpoint by reason of causing large overvoltages which break down the power line insulation, it would for the same reason be objectionable from the standpoint of surges induced in neighboring telephone circuits.

It is fundamental, of course, that the Petersen coil cannot be used under conditions where it is incompatible with the service requirements of the power company. It would be fruitless to employ a preventive of interference to telephone service which would introduce interference to power service. However, the possibilities of adapting the Petersen earth coil to practical conditions encountered in this country have not yet been fully studied and it is obvious from the remarks of several speakers that some power engineers are more optimistic regarding the Petersen coil than the authors of the paper. If there is a lack of full understanding as to certain aspects of the functioning of this device and the effects and reactions which it produces under different conditions, the engineers interested should investigate these questions.

A. E. Silver: From the results brought out in Messrs. Conwell and Evans' paper, from the discussion offered and information from other sources, it is clear that the application and performance of the device is dependent upon several power systems characteristics, all subject to variation through a wide range for different systems and, for any specific system, each subject to variation, in a degree that cannot be predetermined, of such factors as total length of circuits interconnected, quality of line insulation changing with dust deposits and atmospheric conditions, and others that must be taken into account in adjusting the earth coil. The coil can function ideally, if at all, for only one assumed set of these conditions. Furthermore, the disadvantages that have been pointed out must be kept clearly in mind, especially the danger to apparatus insulation from rises in voltage to ground. Having learned, after much theorizing through the hard and costly school of experience, the value of the dead grounded neutral in protecting insulation and draining off abnormal potentials from our power systems, we must not compromise this essential safeguard without sufficient and well weighed reasons.

It would appear that no rule can, at this time, be set down of general practicability and benefit from this device. In the main any system under consideration must be taken up for individual study and determination as to successful performance, safety to apparatus and economy. Theoretical study alone, no matter how great, is inadequate and this determination cannot be made with assurance until sufficiently extensive experience with installations under service conditions has been gained to give a good knowledge of the range of conditions under which the device will function successfully without sacrificing safety of apparatus or imposing other undue disadvantages. It may be found that the limits of beneficial application will embrace only small ranges.

It therefore seems to me that operating results should be observed carefully and continuously for any installations of the earth coil now in service. While experience with additional installations is desirable it would, however, seem good engineering judgment that any early installations be added only in those situations that appear to offer the most favorable conditions.

Mr. Ferris in his discussion, has, very properly, touched upon the relation of this device to the problem of inductive interference control, and presented some of the theoretical aspects concerned. In this regard, also, the earth coil seems susceptible of extensive theoretical deduction as to results, but I believe that most of the foregoing points raised concerning it as a power system protective device, and other similar considerations, are applicable here and that conclusions cannot be drawn as to practical results, either beneficial or adverse, except from observations of actual performance.

To properly determine its effect upon telephone circuits, various telephone system characteristics as well as those of the power system, must be observed and given due weight. Under abnormal conditions in the power system, which I understand

is the situation offering opportunity for possible benefit from the coil, the practical need for it has a very intimate relation to the characteristics of the telephone protective devices.

Any studies or tests to determine the value or need of the earth coil as an inductive interference control device should, as Mr. Ferris suggests, be made cooperatively and with all information bearing upon the subject taken to account.

In this connection it seems pertinent to inquire the status of any relatively recent research work by the telephone companies upon their protectors that may bring improved characteristics, particularly as the arrester types with which engineers in general are familiar appear to have undergone no essential change for many years.

R. D. Evans: Mr. Lewis has questioned the order of preference of the various methods of grounding the neutral of power systems when viewed from the standpoint of continuity of service. The essentials for providing for continuous service are:

1st. Employment of measures for prevention or reduction of disturbances which may result in failure of apparatus lines on equipment.

2nd. The prompt isolation of apparatus lines on equipment in case of failure.

Relay protection for the isolation of faulty parts of the power system has developed to a much greater extent than means for the prevention or reduction of disturbances. Consequently, the dependence for continuity of service is rightly placed on adequate relay protection in connection with multiple lines. For this reason, preference is given to the grounded neutral system because it best insures desired relay operation. It is generally recognized that faulty part of a power system should be promptly isolated to prevent interference with continuity of service. The earth coil system does not permit adequate relay protection and, therefore, this system does not deserve better than fourth place in the order of preference, for the various methods of grounding from the standpoint of continuity of service.

With reference to the question for the conditions of resonance mentioned by Mr. Trueblood, it is to be pointed out that this condition may be determined in two ways:

1st. By adjusting the reactor to obtain a minimum current through a fault on one wire as indicated for the single-phase system of Fig. 2 of the paper.

2nd. With normal conditions on a power system to induce a voltage in series with a series resonance system and adjust a reactor for maximum current through it.

That these two methods of obtaining resonance are equivalent may be seen by the following analysis:

If a voltage be induced in series with the reactor exactly equal to the voltage between one conductor and the ground, that conductor may be grounded without changing conditions. The introduction of a voltage on this system cannot affect the capacities, and consequently, the two conditions for obtaining resonance described above are identical.

Under the conditions shown in Fig. 25, there was undoubtedly some effect of saturation of the iron in the transformer employed to connect the earth coil in the power system. Mr. Trueblood appears to believe that the maintenance of the arcing condition was due to saturation which produced dissonance, causing the large fault currents. It appears more logical to believe that the excess voltages were produced by the arcing condition and that the excess voltages were limited by the saturation of the transformer to approximately 1.3 times normal voltage.

If the earth coil consisted of an air core reactor, higher voltages would be produced accompanied probably by relatively smaller fault currents. The use of the transformer in such a manner to reduce excess voltages has been advocated in Europe by those favoring the earth coil system.

Mr. Trueblood's careful reading of the paper has revealed two statements which we would like modified. In case of a single make and break, the voltage between the sound wire and ground may rise to slightly less than 2.73 times normal voltage between line and neutral instead of slightly less than twice line voltage. For the single-phase system the voltage of the sound conductor may rise to slightly less than three times normal voltage to ground. The context of Fig. 5 indicates that the diagram was drawn incorrectly. It should be as shown in the accompanying diagram, Fig. 2.

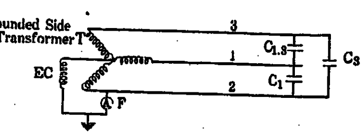

FIG. 2

Mr. Trueblood in his discussion appears to minimize the importance of excess voltages arising from abnormal conditions. He states that excess voltage between sound wire and ground will not exceed 125 per cent to 150 per cent of line voltage, these voltages correspond to 216 to 260 per cent of normal voltage between line wire and ground. Possibilities of excess voltages on the free neutral system were pointed out but the value of the dead grounded neutral in protecting insulation and draining away abnormal potentials was learned only through the costly school of experience, as Mr. Silver has just pointed out. The Petersen Earth Coil System in general approaches the characteristics of the free neutral system and both are subject to abnormal voltages. In this connection, we wish to refer to a discussion published in the E. T. Z., March 10, 1921, in which Dr. Roth cited a case where an open circuit on which wire of a 50,000-volt system produced voltages of 150,000 volts to ground due to the action of the earth coil. He further stated that these voltages, as might be expected, caused the failure of the transformer. The significance of this discussion lies in the fact that the series resonant relation is inherent in the earth coil system and that voltages may be induced in the system due to conditions such as the presence of other circuits and abnormals which can scarcely be avoided in practise. The tendency to minimize the importance of excess voltages would be as dangerous with the earth coil system as with the free neutral system.

Mr. Ferris has described some European installations of the earth coil including the opinions of the operators of the power system. In this connection, it is to be pointed out that the improvement in operating conditions secured by the installation of an earth coil is not significant unless compared with the operation of a grounded neutral system.

The inductive interference aspects of the earth coil system were considered by Conwell and myself during the preparation of the paper, and at that time, was deemed inadvisable to bring that phase of the subject before the Institute. The chief advantages of the earth coil from the standpoint of inductive interference are in comparison with the grounded neutral system. Two of the principle advantages are as follows:

1. Reduction in harmonic residual currents in normal operation, due to the high value of earth coil reactance.

2. Reduction of earth current in case of a fault.

Two of the principle disadvantages of the earth coil system from the standpoint of interference are:

1. The increase in fundamental frequency residual current, due to dissymmetry in line or load.

2. Under abnormal conditions the increase in residual voltage.

This latter point is of particular importance on inter-connected systems because with the earth coil system there is no adequate system of relay protection for isolating a faulty feeder. It would be necessary, therefore, to "hand pick" the lines to isolate the faulty feeder, and during this time the large residual voltage

might produce noise interference. If such a condition arises the change from a grounded neutral to an earth coil system would change the type of interference trouble from that due to high induced voltage at fundamental frequency existing momentarily to that of noise interference lasting a much greater length of time.

More important, however, than the considerations discussed above is the general question of the desirability of the earth coil from the standpoint of the power system. If the earth coil produces troubles similar to arcing grounds or produces excessive potentials, then failure of power apparatus will follow. Hence, the application of the earth coil as an interference remedial measure is dependent, primarily, upon its satisfactory operation from the viewpoint of the power system.

The most significant fact in connection with the discussion of the merits and limitations of the earth coil system is the fact that all the power men who have expressed themselves in the discussion are in agreement on the point that the Petersen Earth Coil System is not of general application. Mr. Lewis stated that the field of the reactor at the present time would seem to be limited to moderate voltage and moderate length systems. Mr. Hanker stated that it appears that the earth coil is not suitable for general application on power systems, and that the most suitable condition for the application of the earth coil is on moderate voltage systems of rather limited extent. Mr. Warren has stated that the Petersen coil (as an interference measure) cannot be used under conditions where it is incompatible with the service requirements of the power company.

R. N. Conwell: Realizing that the Petersen Earth Coil may be considered from two points of view, the authors preferred, in this paper, to consider the device only in the field which it was originally designed to fulfill, *i. e.*, as an arc suppressing device, for the suitability of the device as a remedial measure in cases of inductive interference must depend upon its acceptability and proper functioning as a suppressor. The tests were designed to show the suitability of the device both as an arc suppressor and as a remedial device for interference to signal lines. The effect of the Petersen Earth Coil on adjacent signal lines, based on these tests, has been covered in the report of the Inductive Interference Committee, N. E. L. A. and presented at the Forty-fifth Convention, Atlantic City, N. J. May 15-19, 1922. As a result of the information obtained, both with regard to the operation of the coil on the power system and its effect on adjacent lines, it was decided that the device was not suitable for the purpose for which it was recommended.

Mr. Ferris refers to an extensive installation of the Petersen system in Switzerland and states that "the coils in this case have air cores, whereas in all other cases they have iron cores." I have been advised that some of the coils on this system also have iron cores, installed to limit the overpotentials as explained by Mr. Evans.

Some difficulty has been experienced through over-potentials in those sections equipped with air core coils, which resulted ultimately, in the failure of transformers.

It is noticable that all of the power engineers taking part in the discussion, emphasize the advantages of the solidly grounded system and since the Petersen Coil System approaches the ungrounded system in characteristics, the use of such a device appears to be a step backward.

The Effects of Moisture on the Thermal Conductivity of Soils

With a Bibliography on the Heating of Cables

BY G. B. SHANKLIN

Associate, A. I. E. E.

General Electric Company, Schenectady, N. Y.

It has been appreciated for many years that the presence of moisture in the soil surrounding underground cable was of assistance in dissipating the heat generated within the cable. But little was definitely known, however, of the exact changes in the thermal conductivity of soils caused by the presence of moisture. The following article shows that moisture plays a predominant part. The relative thermal conductivity of various types of perfectly dry soils, such as sand, clay, gravel, etc., covers a range from only one to two, while the addition of moisture increases the range to five times or more that of dry soils.

The article also includes a bibliography on the heating of underground cables, giving reference to 59 papers on the subject in English, French and German.

WITHIN recent years numerous ways have been suggested of working underground cables at increased load capacities. Some of the most promising methods have been:

(a) To decrease the temperature coefficient of dielectric energy loss by improving the quality of the insulation in high tension cables, thus allowing the cables to be safely worked at higher temperatures.

(b) To use a blackened sheath, consequently obtaining a better surface radiation to the duct air.

(c) To use forced ventilation of the duct air.

(d) To fill up the air space in ducts with water, compound, etc. In fact, anything that offers better heat conduction than still air.

(e) To carry away the heat by circulating water either directly through the ducts or through piping laid in the empty spaces of the ducts.

(f) To keep the surrounding soil thoroughly soaked with water, especially at hot spots, by laying porous tile piping just over the conduit.

(g) To use very porous ducts in conjunction with a porous pipe through the center of conduit cross-section so that water would gradually seep through and in rapid evaporation to the surrounding dry soil carry away a large part of the heat.

(h) To avoid all sources of external heat such as steam mains or undue absorption of sun rays. In this particular, the black surface of asphalt streets when fully exposed absorbs a great deal of heat from the sun.

(i) Lastly, and most important of all, to study carefully each individual conduit system and determine where the hot spots are and at what period of the year they need the closest watching. By some one or a combination of the above methods the heating at hot spots can be brought down to correspond uniformly with the rest of the conduit length.

The heat conducting path is a series path through the cable insulation, duct air, duct walls, concrete shell (if any) and finally into the surrounding soil. Obviously, the relative temperature drops through the different sections of the series path will determine the effectiveness of the above cooling methods. For instance, if the greater part of the temperature drop occurred from copper to outer surface of duct walls, or concrete, there would be little gain in saturating the surrounding soil with water. Some other method would then have to be used, such as outlined in sub-heading (c) or (e).

Fortunately, it is now fairly well established that in the average well constructed conduit line a very appreciable part of the total temperature drop, especially at hot spots is in the surrounding soil. Anything that increases the thermal conductivity of this soil is therefore worth considering. It is the purpose of this article to describe some thermal conductivity tests made on soils containing different percentages of moisture and to compare the results with those of other investigators.

Two previous investigators have published results of interest.[1] With dry sand and soils the agreement between their thermal conductivity values is good but there is a very great difference with wet sand and soils. Kennelly found that the thermal conductivity of wet sand was 2.4 times that of dry sand and that the thermal conductivity of wet sandy soil was only 1.3 times that of dry sandy soil. Teichmuller, on the other hand, found a corresponding ratio for sand of 5.2 to 1. Now, it is apparent that if Kennelly's results are correct artificial soaking of soil would not prove a very effective means of cooling. Tiechmuller's results are much more encouraging. Our work was undertaken to determine why there was such a large discrepancy in their findings and, in particular, to make a closer study of moisture effects.

Presented at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

SUMMARY OF RESULTS

Profiting by the experience of the above investigators we were able to design our apparatus and conduct tests in a way that promised reasonably satisfactory returns. Before going into the details a summary will be given and a comparison made with the work of Kennelly and Teichmuller.

Thermal Conductivity of Sand. We first made a laboratory study of a representative unsifted builders sand. It was neither coarse nor fine but of medium texture and all pebbles of appreciable size were removed. When well tamped the amount of moisture required to saturate it completely was more than 15 per cent by weight but the sand would not hold this moisture long enough for test purposes, allowing some of it to drip gradually out of the test cylinder. From 9 to 10

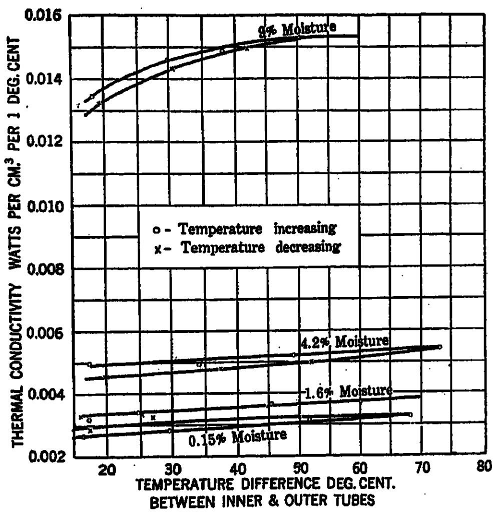

FIG. 1—THERMAL CONDUCTIVITY OF BUILDERS SAND

The curves represent the thermal conductivity of four samples of sand having respectively 9 per cent, 4.2 per cent, 1.6 per cent and 0.15 per cent of water by weight. The unit of thermal conductivity is defined as the watts flow of heat per square cm. per one deg. cent. temperature drop per cm. length.

per cent moisture by weight seemed to be the highest practicable amount. Teichmuller also found this to be true but Kennelly gives test data with 12.7 per cent moisture for a fine sifted quartz sand, mesh 0.25 mm. The much finer texture of his sand no doubt held the moisture better than the coarser sand we used. The practical lesson learned from this is that sand of the ordinary kind surrounding conduit lines cannot be expected to hold more than 10 per cent moisture without draining due to gravity unless water is continuously supplied either naturally or artificially.

After preliminary trials and checks of accuracy the curves given in Fig. 1 were taken on the builders sand described above. Each point on these curves represents a continuous run of about 24 hours. It required three months to complete the set of curves in Fig. 1 alone. The entire work extended over a period of more than one year. The water-jacketed cylinder used in this work is illustrated in Fig. 2 and will be dealt with in detail later.

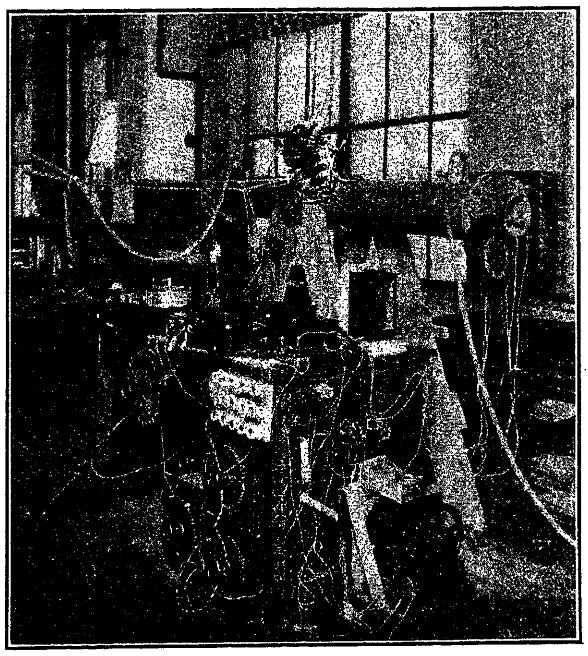

FIG. 2—APPARATUS USED IN DETERMINATION OF THERMAL CONDUCTIVITY OF SOILS

The near end of the tube is open for the removal of the soil sample. The felt, and the ring, which holds it in place over the end of the tube, are shown hanging on a bolt just under the brass tube. The wood plug which fits in the end of the tube is shown on the corner of the table beside the contact-making voltmeter. Tests were made with tube in a vertical position.

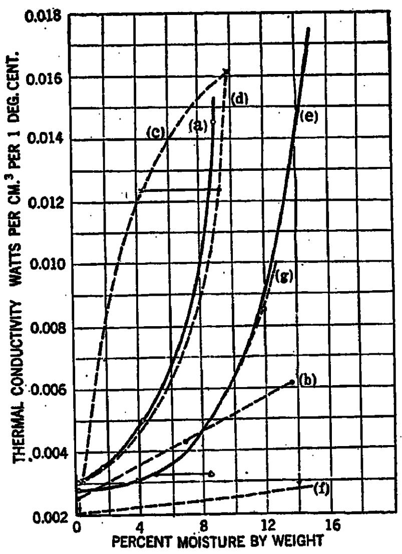

FIG. 3—COMPARISON OF THERMAL CONDUCTIVITY OF SAND AND SOIL AS MEASURED BY THREE DIFFERENT INVESTIGATIONS

(*a*) Clean yellow builders sand. (Author.)
(*b*) Fine white quartz sand, mesh 0.25 mm. (Kennelly.)
(*c*) Clean yellow sand. (Teichmuller.)
(*d*) Curve (c) reconstructed.
(*e*) Yellow sand clay soil. (Author.)
(*f*) Fine sandy soil. (Kennelly.)
(*g*) Normal or average sandy soil. (Teichmuller.)

The values in Fig. 1 were averaged and plotted as a thermal conductivity vs. per cent moisture curve in

Fig. 3 (see curve "a"). Now let us compare this curve with similar curves for sand obtained by Kennelly and Teichmuller. Kennelly used a fine grain quartz sand sifted through a 0.25 mm. mesh. His curve is given as (b) in Fig. 3. It would be expected, as will be shown later, that this curve should show slightly lower thermal conductivity than (a) because of the finer grained sand. With low moisture content (from 0 to 2 per cent) the agreement between (a) and (b) is reasonable but at higher percentage moisture the curves rapidly diverge.

Teichmuller used an ordinary sand, presumably similar to ours. His curve is given as (c). The thermal conductivity values agree almost exactly with ours at extremely low and high moisture contents. His intermediate value of 4.2 per cent is much higher however, giving his curve a different shape. The fact that the disagreement in only with the intermediate percentage of moisture content is significant in the light of our experience. We had a great deal of trouble in obtaining reliable data over this intermediate range of moisture content. The moisture had a tendency to migrate in the test tube, accumulating at one section and leaving another dry. These unstable conditions caused inaccuracies that were overcome only after several trials and a close study of "cause and effect."

If the 4.2 per cent moisture point on Teichmuller's curve (c) is ignored a curve can be constructed through the remaining two points that almost coincides with our curve (a). This reconstructed curve is shown in broken line as (d).

Thermal Conductivity of Clay Soil. After the measurement on builders sand were completed we tried a well pulverized yellow clay sub-soil but soon found it had a tendency to dry and cake around the heated inner tube because of the high temperature gradient here. The clay would "bake out" and cake at temperatures as low as 50 deg. cent. with a considerable decrease in its thermal conductivity. This same characteristic has been noted in the clay surrounding duct lines that have operated at relatively high temperature.

A mixture of 2/3 clay and 1/3 builders sand was then tried. This also had a tendency to cake in some instances but on the whole we were able to obtain some very satisfactory measurements. These are given in Fig. 4. The maximum percentage of moisture tried was 15 per cent by weight. The finely divided sandy soil seemed to hold moisture much better than the pure sand used in the first test, allowing this higher moisture content. The saturation point was higher than 18 per cent. A lower percentage of water was used to be on the safe side and to avoid instability of results by leakage of water during test.

The condition of the soil, the percentage and distribution of moisture, etc. were noted before and after each run. During the runs with 0.89, 3.87 and 15.0 per cent moisture all conditions remained quite stable throughout, but the run with 8.5 per cent moisture was disappointing. The moisture migrated to the outer radius of the tube leaving a dry shell of soil surrounding the inner heated tube. This point was therefore ignored in drawing curve (*e*) in Fig. 3. As can be seen from the curve the migration of moisture had the effect of lowering the 8.5 per cent point of thermal conductivity from 0.0056 to 0.00335 watt flow of heat per square cm. per one deg. cent. temperature drop per cm. length. (In brief, watts/cm.^{3}/one deg. cent).

Kennelly's curve for sandy soil is given as curve (*f*) in Fig. 3. It shows hardly any difference between dry and saturated soil and is likewise much lower in thermal conductivity than our curve (*e*). Curve (*f*) is similar in form to his curve for sand (*b*) and the relative proportions of these two curves fall in about the same order as our curves (*a*) and (*e*).

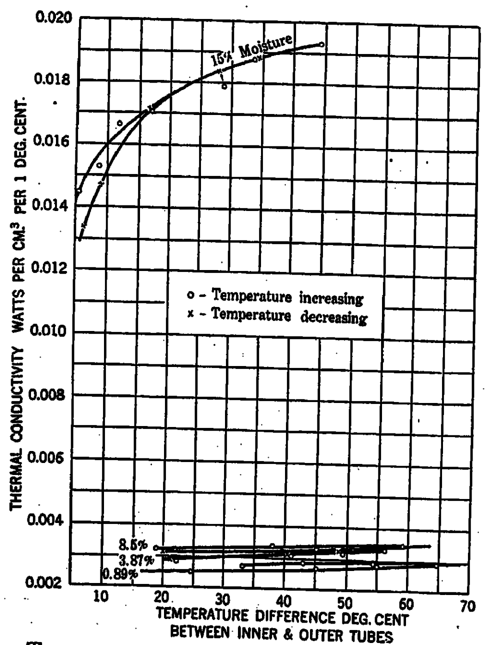

Fig. 4—Thermal Conductivity of Sandy Clay Soil

The curves represent the thermal conductivity of four samples of soil having respectively 15 per cent, 8. 5 per cent, 3.87 per cent and 0.89 per cent of water by weight. The unit of thermal conductivity is defined as the watts flow of heat per square cm. per one deg. cent. temperature drop per cm. length.

Teichmuller published only one measurement on a soil which he designates as "normal" or "average" soil. It is presumably an average sandy clay soil such as usually found in trenching or excavating. His one measurement was made with 12 per cent moisture in the soil and using this as a guide we have drawn in a short section of curve (*g*) in Fig. 3 to show how closely it can be made to agree without corresponding curve (*e*).

On the whole, our results and Teichmuller's agree satisfactorily. We do not claim absolute accuracy for these results but when the conditions of test are carefully considered it would seem that they are more accurate than Kennelly's. All three investigators followed similar methods in that they made use of

concentric cylinders with the soil packed in between. The inner cylinder served as the source of heat and the outer was water-jacketed. End effects were corrected for in all cases. The real difference lay in the cross-sectional dimensions of the cylinders. These dimensions are tabulated below:

TABLE I

Investigator	Length of outer tube Ft.	Diam. outer tube In.	Diam. inner cylinder In.
Kennelly	9.1	3.06	0.128 & 0.045
Teichmuller	12.5	7.90	2.05
Author	7.0	6.00	1.00

In an investigation of this type the cross-section of soil tested is relatively small and because of this the aim should be to assure;

(1) That there is always good contact between the surfaces of the soil and test terminals and that the soil remains well packed.

(2) That the moisture in the soil remains uniformly distributed, especially around the inner cylinder.

(3) That the area of surface contact between soil and inner cylinder be a maximum, consistent with a reasonable volume of soil and diameter of outer cylinder.

(4) That the ratio between the diameters of outer and inner cylinders be a minimum, consistent with above conditions, thereby reducing the temperature gradient around the inner cylinder.

An examination of the dimensions in Table I will show that the test cylinders used by Teichmuller and the author fulfilled these conditions while Kennelly's did not. As inner cylinder Kennelly used a wire of 0.128-in. diameter. He checked this with a still smaller wire of 0.045-in. diameter and found that they gave the same results. The reason for this is easily explained. The high temperature gradient in the soil immediately surrounding the wires forced the moisture towards the outer cylinder, leaving a shell of dry soil around the wires. In both cases, then, he actually measured the thermal conductivity of an inner shell of dry soil and outer shell of moist soil, and since the inner shell plays the predominating part his measurements are more representative of dry soil than wet. His measurements on well dried sand and soils are more acceptable and agree quite well with those made by the other two investigators as shown in Table II.

TABLE II
Thermal Conductivity of Dry Sand, Soil, etc.

Material	Investigator		
	Author	Teichmuller	Kennelly
Clean yellow sand	0.00305	0.00310	..
Clean white sand (fine)	..	..	0.00256
Yellow sandy soil	0.00280	..	0.00284
Fine sandy soil	..	..	0.00209
Crushed quartz (mesh 0.85 mm.)	..	..	0.00337
Fine sandy gravel (mesh 0.5 mm.)	..	..	0.00290
Clean gravel	..	0.00436	..

The above tabulation would indicate that the dry thermal conductivity is somewhat dependent upon the size, shape and arrangement of the particles making up the material, or rather upon the volume of air interspaced with the particles. Coarse grained materials such as sand and gravel have better thermal conductivity than fine grained soil, just the opposite result that one might expect, but it is a known fact that within certain limits the percentage by volume of air in granular materials is inversely proportional to the size of the particles. We made no attempt to investigate this phase of the problem and it is pointed out simply as an interesting side light.

A comparison of the above tabulation of dry soils with the moisture curves in Fig. 3 will show that moisture is the predominating factor rather than the kind of material. The thermal conductivity of the dry soils covers a range from 0.002 to 0.0047 watt per cm.[3] per one deg. cent., while the addition of moisture caused an increase to 0.017 and would have caused a still further increase if the test samples had been completely saturated. This would lead to the conclusion that it is immaterial what kind of soil surrounds a conduit line except in-so-far as the ability of this soil to absorb and retain moisture is concerned.

The investigation has proved conclusively that the presence of moisture in soils is very effective in conducting heat away from underground lines. Further study should be directed towards determining:

(1) Those soils that are best adapted to absorption and retention of natural moisture.

(2) Those soils that are best adapted to artificial means of moisture saturation.

Part II—Description and Details of Test

The first part of this article covers in a general way the more important and useful results of the investigation. In this second part the details will be dealt with.

When the work was first started the results were very erratic. As an illustration, some preliminary measurements on builders sand are plotted in Fig. 5. The temperature was raised and lowered in steps, as indicated by the arrows. In this way one or more "heat cyles" were completed and if the measurements and test conditions had been accurate and stable the "heat cycles" would have been narrow and uniform, similar in appearance to those in Figs. 1 and 4. Instead the measurements plot in a haphazard manner, especially those on very moist sand. By a process of elimination this erratic behavior was found to be due to:

(a) The high temperature to which the inner tube was heated, which caused the moisture to vaporize and then condense against the cold wall of the outer cylinder. A temperature of the inner tube of about 80 deg. cent. seemed to be the highest for accurate results.

(b) During the preliminary work we had no means of constant current control of heating element. Even

small fluctuations of current caused appreciable errors.

(c) The outer and inner cylinders were not connected together, electrically and grounded, at one end. Consequently when the sand was moist it furnished a resistance parallel to the inner tube and in attempting to measure the resistance of inner tube for determination of temperature an error was introduced.

(d) The inner tube used in preliminary work was of brass. The temperature coefficient of brass is smaller than that of copper and change in resistance, even when carefully measured with potentiometer, would not accurately indicate small changes in temperature. This trouble was eliminated by substituting a copper tube.

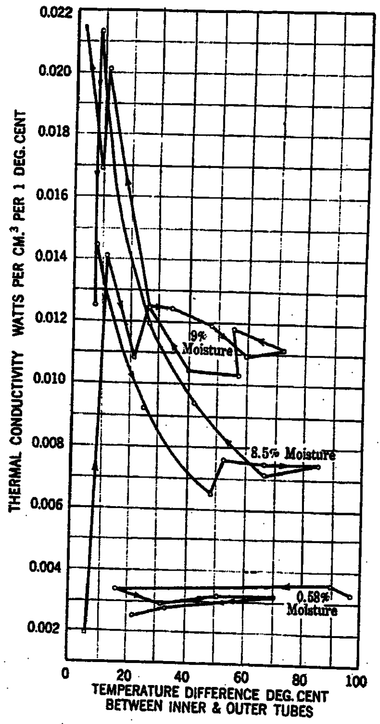

Fig. 5—Preliminary Measurements on Builders Sand
Showing the erratic results due to errors in testing methods. The arrows indicate the order of the respective readings.

The test equipment as finally developed is illustrated in Fig. 2. A dimensional sketch and a wiring diagram are shown in Figs. 6 and 7. A contact-making voltmeter held the heating current very steady. The cooling water for the jacket was taken from the city pipes and proved to be of very constant temperature (about 15 deg. cent.).

The resistance of the inner copper tube was carefully calibrated in an oil bath at different temperatures and the temperature drop across the soil under test was determined by subtracting the temperature of the inner tube, as measured by resistance, from the temperature of outer tube, measured by thermometers immersed in the water bath.

The general procedure was to place the concentric cylinders in a vertical position and fill the interstice with properly prepared soil, packing it down firmly during filling with a concentric disk spacer. In this way the inner cylinder was accurately centered. The cylinders were left in a vertical position throughout the heat run as we found this gave more satisfactory results. There

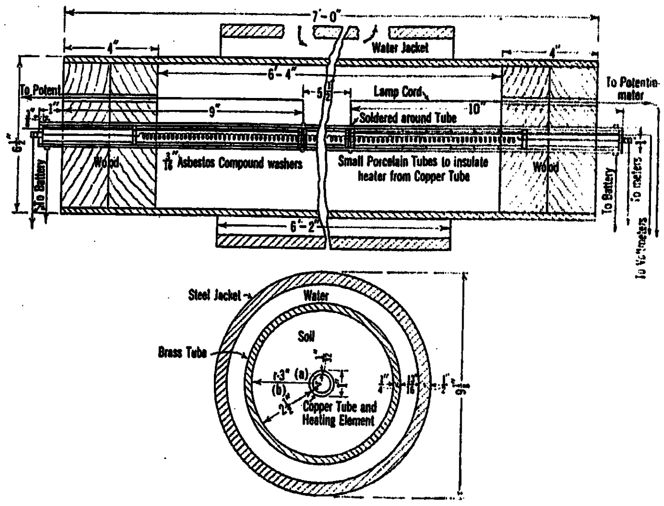

Fig. 6—Dimensional Sketch of Test Tube

was not only a better circulation of the cooling water but also the moisture in the soil would remain more uniformly distributed around the inner cylinder.

It required on an average about four hours to reach constant temperature conditions but for convenience and also to be on the safe side we usually let the run continue over night, taking all measurements the next morning.

Credit and appreciation are freely given to Dr. C. P. Steinmetz and Mr. J. L. R. Hayden for their valuable advice and aid in this work, and to Mr. D. A. Ballard for his untiring assistance.

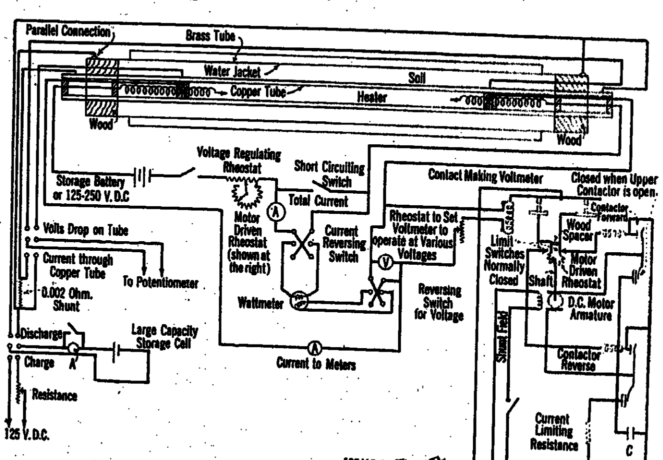

Fig. 7—Diagram of Connections for Apparatus Used in the Determination of the Thermal Conductivity of Soils

Appendix

Heating in Underground Cables

The foregoing laboratory work on the thermal conductivity of soils was completed a year and a half ago.

The results were not published at that time but were made available to engineering committees and operating companies actively engaged in a study of heating in underground cables. Publication at the present time is prompted by the Preliminary Report of the British Electrical Research Association on "The Heating of Buried Cables," which appeared in the *Journal* of the I. E. E., February, 1921. Recognition was made in this admirable and extensive report of the influence of moisture in the soil surrounding buried cables. No substantiating data, however, were submitted and it is felt that the present article contributes something in that respect.

Heating in underground cables has received a great deal of theoretical and practical consideration in the past and many articles have been published on the subject. During the course of our work a thorough canvass of the literature was made and a bibliography prepared containing reference to articles that throw light on the problem. The bibliography is given with the present paper in the hope that it may prove useful to other engineers.

Although this bibliography covers a great amount of work it is surprising how little progress has actually been made in placing the theory and practise of heating in cables on a practical working basis. In the writer's opinion this is due to a lack of coordinated and systematic effort. The problem is big and requires a really tremendous amount of coordinated work to place it beyond the preliminary stage in which it is now. The work undertaken by the British Research Association is a step in the right direction and should be supported by similar work in other countries.

Discussion

D. W. Roper: As Mr. Shanklin stated, the British Research Association is doing similar work along these lines, and their results show some variations that were unaccounted for, and which, perhaps, may be solved by Mr. Shanklin's data.

Their tests were all made on buried cables, out in the open, where the effects of moisture must have varied from day to day, and the tests extended over a period of several weeks or months, and apparently it must have rained now and then during that interval, so I think that some of the variations they discovered and did not account for in the heating of the cables would be accounted for by Mr. Shanklin's data showing that the percentage of moisture in the soil has a considerable influence.

In the latter part of his paper Mr. Shanklin states that the work of the British Research Association should be supported by similar work in other countries. In this country we have had for two or three years a Cable Research Committee of which the speaker is the Chairman, and which is a sub-committee of the proper technical committees of the American Institute of Electrical Engineers, the National Electric Light Association, and the Association of Edison Illuminating Companies.

We have recently undertaken an investigation on the maximum permissible temperature of paper-insulated lead-covered cables, and we were prompted to do that by the remarkable differences of opinion which were expressed at the symposium on the subject before this Institute at the Convention a year ago. We have, therefore, secured a fund for research and have arranged with the Massachusetts Institute of Technology to conduct the investigation on this question of maximum permissible temperature, and it may be of interest to you to learn that the first check covering the expense of the research has been forwarded to the Massachusetts Institute of Technology, and we are meeting with the research men today to start the investigation.

R. W. Atkinson: The author has rightly emphasized moisture as of far greater importance than any other variation of soil conditions.

Until we have complete data of underground conditions, such as this paper shows to be necessary, in order to be safe when designing new underground systems we must estimate carrying capacities by taking into consideration the conditions of poorest present systems.

Data on these variables will make it possible to predict conditions, to design cheaper systems and help in their operation. If conditions are found unfavorable steps may be taken toward improving them.

W. A. Del Mar: It is somewhat difficult to see how this work of Mr. Shanklin's can be applied to practical use at the present time, because we have no control over the soil conditions or over the moisture conditions, so that in estimating the carrying capacity of cables, it is in general necessary to assume very bad conditions of soil conductivity.

There is, however, another property of the soil which is of considerable importance, and that is the thermal capacity or specific heat. The carrying capacity of a cable is very much influenced by the thermal capacity of the soil. Usually a cable is operated at its full load only for a very short period of the day—during the hours of peak load—and the thermal capacity is of great importance, because it determines the overload capacity of the cable during the peak period. It is unfortunate that Mr. Shanklin did not give the thermal capacity of the soil at the same time. It might possibly be derivable from his test data, even now.

In Europe, cables are very largely buried in the ground without being placed in ducts, and it is obvious that the influence of soil moisture will be greater in the case of such cables than in the case of cables in ducts, because in the latter case there is necessarily a more or less dry layer through which the heat must escape in getting from the cable to the soil. When armored cables are buried in the soil, and the soil is fairly moist the carrying capacity is surprisingly greater than in the case of cables laid in ducts in ordinary soil. I have not the figures with me, but they are available in existing literature, and in many cases it is worth while to look into the advisability of burying the cables directly in the ground to obtain the extra carrying capacity.

G. E. Luke: The determination of constants which limit the flow of heat is theoretically very simple; practically, however, such problems offer many difficulties and can be solved only

by an untiring patience. This is especially so in this investigation described by Mr. Shanklin, where the unstability of the moisture content of the soil gave considerable trouble.

The conductivity curves Fig. 1 and 4 seem to indicate a decreasing thermal conductivity of the moist sand and soil as the heating continues. I take this to be due to a possible loss of moisture or a re-arrangement of the moisture in the material. Since the conductivity of dry sand clay soil was only 0.0028 $w/\text{cm.}^3$ deg. cent. and that of water about 0.0057 it indicates that the high value of 0.014 to 0.020 obtained on the 15 per cent moisture mixture was due to convection currents in the water.

The rapid decrease of the co-efficient of thermal conductivity with increasing temperature gradients for the 15 per cent moisture mixture also indicates convection currents, since the heat transfer curve for a steam heated pipe in a tank of water has a somewhat similar shape. Due to this convection, it is probable that the co-efficient of thermal conductivity will depend to some extent upon the depth of the moist soil through which the heat is flowing. It would be interesting in this connection to explore the moist soil temperatures radially in the sample tested and thus be able to see if the co-efficient of thermal conductivity remained constant for various points distant from the heater.

The author mentioned the fact that some difficulty was encountered in the measurement of the inner tube temperature by the resistance method. The writer has had similar experiences in experimental tests and prefers to measure temperatures of such inaccessible places by thermocouples.

This investigation shows the possibilities of reducing the cable temperatures by moist soil. Of the other methods mentioned by the author the most promising ones are by the use of forced air or water streams through the cable ducts.

C. J. Fechheimer: The author states on the first page that it is possible by blackening the sheath to dissipate somewhat more heat. I wonder whether that was appreciable. The increase in heat dissipation due to blackening must come in consequence of the increase in radiation. I am of the opinion that the amount of heat that is dissipated by radiation is comparatively small, because the heat thus dissipated is proportional to the difference between the fourth powers of the absolute temperatures; and unless there be considerable differences in temperature, not much heat is dissipated by that means. In general most of the heat that is dissipated at ordinary working temperatures from cables or even from the outside surfaces of machines, or from self-cooled transformers, is brought about by natural or free convection currents of air, rather than by radiation.

This question of natural convection currents brings up a second point, namely, the influence of air pockets in affecting the thermal conductivity of almost any kind of material in which such air pockets occur. The influence of such air pockets changes very materially with their size. If the air pockets are very minute, heat that passes through them must flow by thermal conduction, whereas when they become of any considerable size, some natural convection currents are added. It is well known that if the air pockets are, say, one-tenth of an inch across more heat is transmitted by natural convection currents than by conduction. That is a very important point in all thermal conductivity problems; the influence of air pockets must be considered very carefully.

The author speaks of the size of the granules and states that the larger the granules, the better is the thermal conductivity. If I read his paper correctly, I understand him to attribute this to the fact that the volume of air which is entrapped between granules is smaller the larger the granules are. That probably accounts for some of the difference, but I am of the opinion that the thermal conductivity was altered more by the fact that with larger granules the air pockets were larger, and therefore the natural convection currents were considerably greater; consequently the apparent conductivity of the coil was increased.

It is interesting to note also, in Fig. 3 in the paper, the rapid increase in thermal conductivity as the percentage moisture is increased for the higher values of moisture. As water begins to displace the air particles that are trapped between the solid particles of the soil, the thermal conductivity is not increased very much—there are still enough air pockets to offer considerable resistance to the flow of the heat. It is only when the voids begin to become negligible due to the last water that is forced into the soil, that the thermal conductivity is raised considerably. Perhaps that may account for some of the discrepancies between Mr. Shanklin's tests and those of the authors to whom he refers.

The question of air pockets comes up very frequently, indeed, in engineering practise. For instance, in the building of houses it is well known if hollow tiles are used, and the air pockets are very large, the apparent thermal conductivity is fairly high; but if some finely divided material such as sawdust is put in, so as to make the individual air pockets quite small, then the thermal conductivity is materially increased, and less fuel is required to heat the building.

Nature has also taken care of this matter of air pockets in the manner in which some of the animals have been provided with clothing—for instance, the sheep with wool, or the duck with its type of feathers, eiderdown, both of which are known to possess very low thermal conductivity, for the reason that the air pockets are quite minute.

G. B. Shanklin: In reference to Mr. Roper's remarks, I am cognizant of the valuable work just started by his Cable Research Committee and am sure all members of the Institute anticipate great things from this work. Regarding the work of the British Research Association, Mr. Roper is right in accounting for some of the variations in results as due to moisture content of the soil. In any study of thermal characteristics, the distribution of moisture must be known, and preferably under control. This is particularly so where cable is buried directly in the ground.

I agree with Mr. Del Mar that parallel data on thermal capacity of soils containing different percentages of moisture are equally desirable. It is unfortunate that the procedure of our work made it impossible to obtain complete heating and cooling curves, necessary in determining thermal capacity. In a few cases we did get complete heating curves from which at least an approximate idea of thermal capacity can be derived. Without careful checking, however, these data could not be relied upon.

Mr. Fechheimer's discussion of air pockets is quite timely. It is generally recognized that they play an important part. In this respect the variations in thermal conductivity of paper insulated cables should be borne in mind. The degree of filling and looseness of lead sheath account almost entirely for these variations.

Five Hundred Tests on the Dielectric Strength of Oil

BY J. L. R. HAYDEN and W. N. EDDY
Member, A. I. E. E.
Both of the General Electric Company, Schenectady, N. Y.

While developing a dependable method of taking experimental data with a sphere gap in transil oil, considerable study was made of the behavior of oil under disruptive dielectric stress. The following notes on the dielectric strength of oil are offered as evidence that the nature and character of the dielectric breakdown of oil may be entirely different from that of air.

Five hundred successive breakdowns were taken on a sphere-gap in oil at the same gap setting. Because of the well known inconsistency of breakdowns in oil these observations showed wide variation. A curve was plotted to show the relation between the breakdown voltage and the number of breakdowns at each voltage. If the disruptive breakdown of oil is due to the voltage exceeding the dielectric strength of the oil, as is the case with air, it should be possible to represent such a curve of probable error, or "probability curve" as it is usually called, by an exponential equation. In the following paper this is seen to be impossible, the most representative exponential curve being higher than the observations at higher voltages. The explanation is offered that this discrepancy is caused by foreign particles of low dielectric strength being drawn into the gap and that therefore the dielectric strength of oil differs from that of air in that it does not represent the true breakdown value of the oil but is instead a measure of the presence of foreign particles in the oil.

AIR gives a definite dielectric strength (30 kv. per cm. at 0 deg. cent., 76 cm. barometer), as shown by the work of Peek, Ryan and Whitehead, and disruptive tests in air gap give consistant results within the errors of observation. Not so, however, oil. In spite of the greatest care taken to reproduce identical conditions as nearly as possible, successive disruptive tests made on the same oil differ from each other far beyond the possible errors of observation.

To study this phenomenon of the erratic behavior of oil, and its possible cause and explanation, 500 successive tests were made with the same sample of oil under constant conditions. A large sample of oil was chosen, the circuit opened immediately after each discharge, and the discharge current limited by resistance in the low-tension circuit, so as to give little deterioration of the oil (by carbonization, etc.) during the test, and the deterioration allowed for, as further described. In commercial testing of oil, usually small flat disks with sharp edges are used as electrodes, to give a combination of the effect of a uniform field and the edge effect. When, however, determining the dielectric strength of a material, as nearly a uniform field as possible must be used, and a field which can be accurately calculated. This is the case with the field between spheres at moderate distance from each other. Therefore a sphere gap was used. In view of the high dielectric strength of oil, and to avoid excessive voltage a gap of two mm. was used between spheres of one cm. diameter. The spheres were of molybdenum, as experience had shown that tungsten and molybdenum are least liable to pitting under the discharge. After each test the spheres were wiped off in the same manner, under the oil, by a wiper kept under the oil and the oil allowed to settle the same length of time before each test. The oil was filtered hot through a number of layers of hot and dry filter paper, and carefully protected from dust and moisture. The same source of voltage supply, 60-cycle alternating current, and the same transformers were used, and the voltage controlled by the potentiometer method (shunt and series resistance), being the method least liable to give voltage wave distortion. The voltage was raised at the same constant rate in all tests, one volt per second on the low-voltage side of the transformers, at a transformation ratio of 580; in short, the conditions were kept as nearly the same as could be determined, and much more uniform than is necessary to get consistent results in air. The voltage was read on the low-tension side of the tranformers, as this checked to be accurate within less than one per cent.

Nevertheless, the observed breakdown voltages in the successive tests differed enormously, and in entirely erratic manner, by as much as a hundred per cent.

In spite of the large volume of oil used, there was a slight deterioration which became noticeable after more than 200 tests. Therefore the tests were divided into five successive groups of one hundred each, and the average value calculated for each hundred. This gave the average breakdown voltages (low-tension side, ratio 580 to 1) for the successive five sets of hundred tests,

$$e_0 = 95, 96, 91, 89, 86$$

showing a slight and increasing deterioration.

To allow for this, in working up the tests, not the voltage e of each individual test was used, but its difference from the average voltage of the hundred tests to which it belonged, that is $x = e - e_0$.

Using these differences $x = e - e_0$, the effect of deterioration was sufficiently eliminated, and all 500 readings could be combined. The number of breakdowns y observed at each voltage difference x is given in the second column of the following table, and plotted as y in Fig. 1, marked by circles, with x as abscissas.

As seen, the values of y do not lie on a smooth curve, but vary erratically, but their grouping is similar to that which would be expected from a set of values scattering by probability around an average value.

Presented at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

TABLE I

$x = e - e_0$	y:	$x = e - e_0$	y:	$x = e - e_0$	y:	$x = e - e_0$	y:
− 31	0						
− 30	2	− 17	1	− 4	14	+ 9	20

− 19	2	− 6	23	+ 7	23	+ 20	2
− 18	2	− 5	9	+ 8	20	+ 21	0

A number of probability curves were calculated by the $\Sigma\ \Delta$ method[1], in the attempt to fit the relation between x and y.

It was found that all the data could not be represented by one probability curve, but the probability curve calculated from the positive x values—that is, the voltage e above the average e_0—did not fit the negative x values, and inversely.

However, the y values from $x = +9$ to $x = -22$, comprising 84 per cent of the observations, can be well represented by the probability curve

$$y = 24.8\ \epsilon^{-0.0051(x-3)^2}$$

This probability curve is shown in Fig. 1. It fits the observations fairly well, except that for high values of voltage, the observations drop below the probability curve, the more so the higher the voltage; that is, the breakdown occurs at lower voltage than given by the probability curve. At very low voltages, the observation seem to be higher than the probability curve, but in this range their number is too small to be conclusive.

The explanation which suggests itself is as follows:

The disruptive breakdown of oil under dielectric stress is not due to the voltage exceeding the dielectric strength of oil, as is the case in air, but is due to something being carried into the dielectric field, or being produced in the dielectric field, which weakens the dielectric strength so as to cause a premature breakdown. The breakdown therefore does not occur at a definite value of voltage, as is the case with air, but at values scattered over a wide range of voltages in accordance with the probability curve of the appearance of such dielectrically weaker material in the field. What this material is, we do not know; it may be moisture, or dissociation products of the oil, or olefines or fats or fatty acids, or dust or fibers, or combinations of them, in solution or collodial solution or suspension in the oil.

On the higher-voltage part of the probability curve, the approach to the true dielectric strength of oil increases the frequency of breakdown beyond the probability curve, and thus causes the observations to drop below the probability curve. This also causes the maximum point of the probability curve to be at a higher voltage than the average breakdown voltage.

1. Steinmetz, "Engineering Mathematics," Chapter VIC.

This opens up a very interesting, and in view of the great industrial importance of oil as insulating material, important field for further investigation. Hitherto, usually the assumption has been made that the dielectric breakdown of oil and other similar insulations is of the same nature and character as that of air, that is, it depends upon a definite breakdown value, though the experimental behavior of oil in the dielectric field, such as its erratic breakdown voltage, the very pronounced time lag, etc., point to the possibility that the mechanism of the dielectric breakdown of oil and similar materials is materially different from that of air.

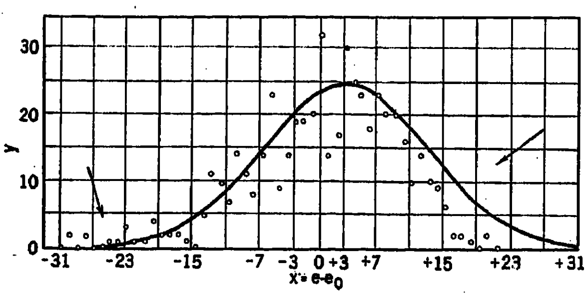

FIG. 1—PROBABILITY CURVE OF DIELECTRIC BREAKDOWN OF TRANSIL OIL AND THE PLOTTED VALUES OF THE OBSERVED TESTS.

The ordinates (y) are the number of punctures that have been found, by observation, to take place at each value of the abscissas.

The abscissas are the difference between the particular average value and the actual value of puncture voltage for each test. The numerical values are given in low-tension volts. The actual voltage difference may be found by multiplying the particular abscissa by the transformer ratio, 580 to 1. Thus the maximum difference from the average breakdown (say 55,000 volts = 95 × 580) is minus 31 volts which is actually 18,000 volts less than the average puncture value of 55,000 volts.

On the other side of zero, the highest puncture voltage above the average is 21 which corresponds to 12,200 volts = 21 × 580. It should be noted that all the observations in this neighborhood fall far below the solid line, which is the mathematical probability curve given by the particular formula

$$y = 24.8\ \epsilon^{-0.0051(x-3)^2}$$

This equation, by several trials, was found to be the nearest obtainable representation of all the values given by the tests and shown by the circles.

Discussion

C. E. Skinner: I have been familiar with the dielectric tests of oil for a good many years, and have personally made many thousand of tests, and have been familiar with many thousands of others, but I do not think I have ever had the idea that oil could be compared to air for uniformity as an insulating medium.

Oil has a very complicated chemical structure—it carries in it many impurities, and I have frequently observed the lining up of small impurities in the oil, such as fibers, etc., and have frequently noticed that if the potential is applied for a considerable period at a value somewhat below the instantaneous breakdown, breakdown will finally occur.

Relatively high values for a group of tests insures good oil, but low values may indicate accidental troubles with the test and not necessarily poor oil unless every possible precaution has been taken. It is for this reason that we have established an oil testing service with experts in charge.

A few years ago, we in the more or less fundamental study of insulation, wished to get some material which would be as

nearly constant as possible, and we undertook, as did Mr. Hayden and Mr. Eddy, to use oil. We found that only with the most extraordinary precautions could we get anything approaching uniformity of results, such as to allow the use of oil as a standard.

In the commercial use of oil, we must expect a considerable variation in insulating value, and designs for its use must be so made that the average, or even the lower values, are those which are depended on, and used under extreme conditions and not those high values which can be obtained only with extraordinary precautions.

A. B. Hendricks, Jr.: It requires about 500 tests to prove anything regarding the dielectric strength of oil. The results of the present investigation are more erratic than usual, considering the care taken to obtain uniformity, but this may be explained by the form and small size of the spark gap used.

The maximum stress with a sphere gap is along the axis, hence is confined to a line, as contrasted with the large area of uniform stress between disks. This leads to a selective action instead of an averaging effect.

If the entire cylindrical volume of oil between the electrodes is considered as under stress, both volume and cross-section are much less than in the usual form of disk gap (about 1/7).

The authors state. "Usually the assumption has been made that the dielectric breakdown of oil . . . . is of the same nature and character as that of air." If so, the assumption was in error, as the ordinary factory and laboratory tests do not give an absolute value for the dielectric strength as with air, but an approximation to the probable average value, which should be interpreted as an indication of relative purity but not as an absolute value of dielectric strength.

The dielectric strength increases and approaches a maximum value as the amount of impurities decrease and this maximum may be taken as an absolute value, but oil containing impurities has no definite dielectric strength the results of tests being a matter of chance as pointed out by the authors.

These facts lead to uncertainty and dissatisfaction in the use of oil as a dielectric and cooling medium, but it is still the best and practically the only available material for the purpose (except gases), and the defects and variations are inherent and should be recognized.

The form of spark gap now in general use as a standard has as electrodes flat brass disks 1 in. in diameter with square edges and set 0.1 in. apart. I was responsible for the design and introduction of this form and desire to give some of the considerations which led to its adoption.

It is true that the voltage gradient is indeterminate and highest at the edges and can be calculated only for simple geometrical forms, as spheres.

This may be of theoretical interest but is of no practical consequence as the absolute dielectric strength of oil is indeterminate unless pure, which it never is, and depends on the tendency to a fortuitous collection of conducting particles in more or less continuous chains between the electrodes. The oil is kept in violent circulation between and near the electrodes, when approaching the arcing voltage, so that the chains are continually being formed and ruptured.

"It stands to reason, is a well known fact, and is obvious" that the stress is greatest at the corners and that the arcs tend to form there. The trouble with this imaginary statement is that it is only partly true, the actual effects being quite different from those which might be expected from superficial considerations.

Breakdown does not necessarily occur at points of maximum stress, as on corners, nor along the shortest path. It occurs at the time and place where the stress first exceeds the dielectric strength, the time element being important since the voltage is usually increasing at a rapid rate and the arcing voltage varies more or less inversely with time.

There is a large and nearly uniform field between disks and the effect of the edges seems unimportant in practise. I have just examined the disks from a standard spark gap which has been used for about 15,000 tests (one shot only on each filling) during the last two months. These show but slight burning from the arcs, which were confined almost exclusively to an area about ¾ in. in diameter at the center of the disk. A zone about ⅛ in. wide at the edge shows little evidence of arcing, but arcs occur quite frequently from the cylindrical surface. The samples come in quart cans, the spark gap being filled five times from each can, and one shot taken on each filling. The average of five shots is taken as representing the contents of one can. The ordinary variation of single shots from the average is about 10 per cent plus or minus and seldom exceeds 20 per cent. The maximum average value of five shots is about 40,000 volts, and there is reason to think that this represents closely the absolute dielectric strength of the oil for 0.1 inch, although the tests are between disks.

This form of gap was adopted as combining the greatest number of advantages after long experience with other forms and careful comparison with the previous standard which consisted of 0.5 inch disks 0.2 inches apart. The latter gap was used with a much larger volume of oil, it being standard practise to take five shots on one filling, stirring the oil before each shot. This older form (introduced by J. A. Capp) was used in determining the effect of water on dielectric strength, the resulting curve being widely published (See Pender's Handbook). In this test 11 points on the curve were determined, each by 5 shots on 8 samples or 440 shots for the curve, the results being quite regular and consistent and being duplicated at another time on a different kind of oil and by another operator.

The results gave a straight line on logarithm proper and the curve plotted from the resultant equation came on or near all the points.

The equations of the curve as originally given was

$$Y = 19.2\, X^{-0.284}$$

where Y = breakdown voltage—kilovolts
and X = water—parts in 10,000 by volume.

The results may be expressed in round numbers, with sufficient accuracy by:

$$Y = 20\, X^{-1/3}$$

The regular and consistent results give confidence in the method. A careful comparison of this spark gap with the present standard one shows the latter to be fully as reliable but more sensitive. For 30 kilovolts in the old gap the new gives 15 kilovolts, but for higher values the new gap gives more than one-half the voltage. for lower values, less than one-half.

F. M. Farmer: Last evening the first discusser of the lightning arrester papers gave experimental evidence which apparently indicated that there is a certain minimum dielectric strength in all layers of air, irrespective of the thickness: that is, as the thickness of the layer is reduced, the puncture voltage falls, a minimum value is reached, and if the thickness is still further reduced, the breakdown voltage goes up again. Thus we have another example of our lack of knowledge of the molecular mechanics and the electrical breakdown of insulating materials.

Very recently a paper was published in England in which the dielectric stresses in cables is discussed. Experimental evidence is given which appears to show that the limiting feature is the minimum stress at the outside of the cable, and not the maximum stress at the conductor, which has been the most generally accepted theory.

Here, in this paper by Messrs. Hayden and Eddy, we have further experimental evidence of our lack of knowledge of just what goes on when solid and liquid insulating materials break down under dielectric stress. The phenomena and laws in regard to air are fairly well established, but our ignorance of solid and liquid insulations is very evident.

While this paper does not deal with the commercial testing

of transformer oils for breakdown strength, I would like to call attention to a recent specification which has been issued by the American Society for Testing Materials. The electrodes and gap which were adopted for the dielectric strength test are one-inch flat disks with square edges and 0.1 inch separation. That standard was adopted after a series of tests involving something like 2200 determinations made by the Vacuum Oil Company, the Westinghouse Electric and Manufacturing Company, and the Bureau of Standards, in cooperation. A very careful mathematical analysis of the results by Dr. Silsbee of the Bureau of Standards showed rather conclusively that the most reliable results were obtained with one-inch disk electrodes spaced 1/10th inch apart.

Another feature of the prescribed procedure for this test is that five punctures are made on each of at least three specimens of a sample. If any one of the three averages differs from the grand average by more than ten per cent it is to be discarded and another specimen tested.

F. W. Peek, Jr.: The authors of this paper have done some very interesting work in applying the probability curve to the variation in the breakdown of oil. This apparently confirms the general belief that the variations are due to impurities. It is a well known fact that when a series of breakdown tests are made on a given oil with electrodes set at a small spacing there is very likely to be a considerable variation in the disruptive voltage. There is usually less variation when larger gap spacings are used. For instance, with a 2-mm. gap the authors find a a variation of ± 30 per cent from the average and 85 per cent between maximum and minimum. Tests that we have made show the same variation for the 2-mm. gap. With a 1-cm. gap, however, we find that the variation is ± 10 per cent from the average and 30 per cent between maximum and minimum. The variation may be much less even at small spacings, depending upon the condition of the oil and the type of the electrode.

While the variation is of theoretical interest, it is readily eliminated in practise. Skillful designers never use free oil spaces. Solid insulating barriers are always used between electrodes. Even with a 2-mm. oil space, which is smaller than is used in practise, the variation is cut in half by the insertion of a thin cambric or paper barrier between the electrodes. The variation is also less in practise because other types of electrodes than spheres are used. The spheres are the most useful electrodes in theoretical investigations because the dielectric field can be readily calculated.

The variation in free oil spaces is not surprising. There are a number or reasons why this variation should occur. In an oil gap under high stress there is the greatest degree of turbulence. The oil is forced back and forth between the electrodes. Another cause of variation is moisture and certain impurities in the oil. In a regular dielectric field the particles tend to line up along the lines of force and bridge between the electrodes. Moisture can, in fact, be separated from oil in this way and electrostatic separators have been devised and used. Occluded gases may also be a cause for low breakdown.

It is, of course, not necessary in practise to make 500 tests or even 100 to obtain the maximum, minimum and average characteristics of a given oil. The complete characteristics are in fact generally included in from 10 to 20 breakdown tests.

In practise oil is probably the most generally useful and reliable insulating material that is available.

John B. Whitehead: I have often wondered whether it would not be possible to get more uniform results on the dielectric strength of oil by observing the appearance of corona around a wire. In the case of a perfectly smooth wire in air, the appearance of corona is sharply marked, and even if the wire is soiled and has an irregular surface, it is very possible to separate the value of voltage at which streamers appear in the inequalities of surface, and the value at which corona appears more uniformly over the whole wire. It would seem to me that the same thing may be true of impurities in the oil, and that there might result greater uniformity of observations if it were possible to detect the appearance of corona in the oil. This detection of the start of corona is the only apparent difficulty.

Some years ago I set up in our laboratory an oil chamber in which a round wire was centered in a cylinder filled with oil, with the idea of studying the appearance of corona in the oil. The work was stopped largely because of the pressure of other matters, and because I ran into the difficulty of not being able to tell in a dark oil just the value of voltage at which the corona appeared uniformly. However, it would seem to be possible with little effort to obviate this difficulty. The apparatus mentioned used an optical method. A beam of light of high intensity passed through the oil and close to the surface of the wire. It is probable that a variation in the optical constants in the oil will be found in the presence of corona. I am quite sure that Mr. Hayden and his associates have worked with the corona in oil, and I think it would be interesting to have their opinion upon this suggestion.

Delafield DuBois: During 1905, I attempted a research on the dielectric strength of oil to determine the relation between dielectric strength and temperature. I found the same difficulty experienced by Hayden and Eddy, namely, that it was not possible to get consistent results for any given condition, and therefore I was not able to obtain exact data to show the variation of dielectric strength due to changes of temperature. But there were certain observations made during those experiments that may be of interest.

Breakdown voltages apparently increased as temperature increased. But on several mornings after the oil tank had been cooled over night, undisturbed, the first test gave a higher breakdown voltage than any made with the oil hot. This was taken to indicate that moisture was normally present in the gap, so that when the oil was heated the effect of this moisture became less, due to some kind of absorption by the oil, but that when cooling, undisturbed, the moisture condensed upon the sides of the tank, leaving the gap free from moisture.

With the oil cold and perhaps slightly moist, the well-known partial breakdowns of the oil gap, were, of course, noted. As to the breakdown at short intervals, and in order to study this phenomenon, the following experiment was made: With a needle gap set fairly wide, there were interposed in the gap, two parallel partitions of cheesecloth, dividing the gap into three equal parts. These cheesecloth separators were brought up flush with the surface of the oil, and on the surface of the oil a thin paper was floated. The bubbles rising from the gap were thus held under the paper, and indicated in what part of the gap they originated. It was noted that often the bubble was from the middle section of the gap only. This suggested that streamers of moisture were building out from the electrodes and that the breakdown was from their ends. It is obvious that these premature breakdowns do not become total breakdowns, because the moisture baths are at once dissipated by the passage of the current. However, when the breakdown between the ends of the streamers is half the oil gap, it is probable that the breakdown of the remaining half will follow. This explains why only a little moisture in the oil lowers the dielectric strength by half, or more than half, if the current of breakdown is not limited by resistance in series with the gap. The resistance of these moisture streamers and the series resistance of the testing set are two factors in determining breakdown. It is remarkable that such streamers should exist at all under the violent motion due to an electrostatic stress; undoubtedly all moisture brought into the field by the moving oil is captured and strongly held. Dry oil is, of course, not absolutely free from moisture, and under stress this moisture would accumulate in the gap, giving erratic results in any such tests as those made by Hayden and Eddy.

Carl Hering: In liquid conductors of mixed composition, as in some electric resistance furnaces, the so-called pinch-effect,

which is an electro-magnetic force tending to crush the conductor radially,—has the peculiar property of tending to move the better conducting material to the central axis of the conductor; thus a rod of copper floated on a channel of mercury will be sucked down to the middle axis quite violently when a sufficiently large current flows.

This force is electromagnetic, it may be that a similar electrostatic force exists also. which tends to move the materials of lower dielectric strength into the more direct path of the disruptive discharge. The authors admit that such materials may exist as they no doubt exist in the form of disconnected particles, a uniformity of the results cannot be expected.

C. P. Steinmetz: The disruptive strength of insulation is one of the most important in electrical engineering.

Since the early days it was suspected that there is a definite dielectric strength similar to the rupturing strength of mechanics, although experience did not seem to confirm this.

For air, this matter was finally cleared up by the work of Mr. Peek, Dr. Whitehead and others, who proved that in air there is a definite disruptive strength which determines the breakdown of an air gap, but that the action is complicated by two additional phenomena, the energy distance and the time lag, and that these additional phenomena account for the disagreements in previous investigations.

Since that time, the same assumption has usually been made, and the conclusions and results on the disruptive strength of air gaps, have been transferred and applied to liquid and solid insulating material, such as oil, although such applicability was not proven, and experience did not well agree with the application of the laws of the disruptive strength of gases to liquid and solid dielectrics.

As I understand it, the object of Mr. Hayden's and Mr. Eddy's paper is to investigate the laws of disruptive strength of oil and the existence of a definite disruptive gradient which determines the breakdown of the oil gap, and to ascertain whether the laws of the dielectric strength of air can be applied to oil and solid insulation. The paper shows that such is not the case, and that the phenomenon of dielectric breakdown in oil or solids is different from that in air, since under conditions where an air gap gives constant results, as has been found by observation, an oil gap gives results scattered by the probability law over a range many times greater than the possible error. It also shows that the breakdown in oil and in solids is subject to additional phenomena which do not exist in air, and therefore the subject, in view of its importance, requires more extended and further investigation.

In my opinion, the results of the paper are not intended to apply to the problem of the commercial test of oil, but they deal with the question whether there is a definite breakdown strength of oil, and whether this breakdown strength determines the electrical behavior of oil. It seems to me the conclusion which must be drawn from the paper is that there probably is a definite breakdown strength of oil, but that the commercial and industrial behavior of oil is not determined by this breakdown strength, but that the actual breakdown of oil is very much below its probable dielectric strength, and is determined by a probability law—by which the impurities or whatever we may call it— determine the actual breakdown strength.

It seems to me that the additional data given in the discussion rather corroborate this conclusion by showing that where the tests are made under such conditions, that each test averages up, as by having a large section of oil gap, or great lengths of the oil gap, or barriers, etc., so that each individual test thus averages a large mass of oil, then the variations under the probability law necessarily are less, that is, the results are more consistent. As however, the paper does not deal with the commercial testing of oil, but with the question of the existence of a definite dielectric strength of oil the test had to be made under conditions where you have a definite gradient so as to know what you get, and where the gradient is as uniform as possible. This means a sphere gap. Therefore when the matter is further investigated by other investigators, I especially wish to draw this to their attention, and ask them to utilize the sphere gaps, and utilize them under conditions where the surrounding elements are as uniform as possible.

N. S. Diamant: I would like to ask the authors to tell us, if possible, the kind of oil used in these tests. It would be also well to know what some of the physical and chemical characteristics of the oil in question were. They go into a lengthy and welcome description of electrical test methods explaining how the voltage readings were accurate to within less than 1 per cent. However, it would be very useful to the profession to know also what kind of oil behaved as erratically as the oil under question. It seems to me this paper is an excellent example of how investigations should not be conducted. Personally, I can see nothing in their mathematical gymnastics and probability curve. These are very interesting elementary mathematics to my mind, but it would be very interesting to know the per cent of moisture in this oil and some of its physical and chemical properties.

It seems to me that the fact that the average breakdown voltages for the successive five sets of hundred tests was, e_0 = 95, 96, 91, 89, 86 shows fairly definitely at least for the sample under consideration, an increasing deterioration.

Now I would like to ask the authors if they can tell us what kind of oils show this erratic behavior for the first fifty or one hundred tests; also what they may expect in the way of average per cent variation in the values of successive disruptive voltages. As to the cause of the variation between the different successive values of breakdown voltages, I am sure they will agree that we will have to look more into the mechanism and theory of breakdown and its effect on the physical and chemical properties of oil.

J. Slepian: The authors contrast the uniform dielectric properties of air with the more erratic behavior of liquid insulating medium such as oil. With the great development in the past decade of the theory of ionization by collision in gases, a clear insight has been obtained into the mechanism of breakdowns in gases. The reasons for the uniformity of breakdown of airgaps under ordinary conditions are well known and it is even possible to produce special conditions in which airgaps will break down in quite as erratic a manner as the oil gaps described in the paper.

According to the theory of ionization by collision, electrons or charged molecules, called ions, when moving in a gas under a sufficiently high gradient may, by their impact with neutral molecules, break these latter up into new positive and negatively charged ions. These newly formed ions, if the gradient continues to be maintained, may also generate more ions by collision. Thus, starting with only a few charged particles in a gap, by the application of a sufficiently high voltage great conductivity may be developed. After a considerable number of these ions have been produced, due to the opposite directions of travel of the positive and negative charges and also their different velocities, space charges develop in the gap and the electrostatic field becomes distorted. The gradient becomes greatly increased in some portions of the gap and it then becomes possible to maintain the ionization by collision process with much lower voltage than was required to initially break down the gap.

It may be shown that for plane electrodes, for any gap length in excess of a certain length which is very small for air at atmospheric pressures, there exists a critical gradient such that any initial ionization, however small, will be so greatly multiplied by ionization by collision that the uniformity of the electrostatic field will be disturbed and the gap broken down. This gradient may properly be called the breakdown gradient of the gap.

Now, there are two requirements necessary if the gap is always to break down at this gradient. First, there must be some initial

ionization, for otherwise there would be nothing to start the ionization by collision process when the breakdown gradient is applied. This initial ionization in practical spark gaps is produced by ultra-violet light and penetrating radiations which exist normally in the atmosphere. If this initial ionization is reduced to a very small amount by enclosing the gap in a dark chamber for the time for the ionization to build up sufficiently to unbalance the electrostatic field may become quite large. Thus, Townsend in his "Conduction in Gases" states that for a gap enclosed in a dark chamber a voltage in excess of the normal breakdown voltage may be applied for several seconds before breakdown occurs. Hence, under these conditions, a gap tested under rapidly increasing voltage would show erratic breakdown values.

The other requirement for uniform breakdown properties is that the initial ionization must not be too great. For then even with fields too weak to normally produce a great multiplication of ionization by collision, the space charges developed by the initial ionization may so greatly distort the electrostatic field as to produce an excessive gradient in some portion of the gap, and in this portion a rapid multiplication of ions by collisions may occur. Thus we all know that if a gap is so situated that the ionized vapors from a nearby arc reach it, the breakdown voltages become erratic with abnormally low values.

Ordinarily there will not be a high density of ionization in air because of the high mobility of the ions. They rapidly diffuse away from the spot where they were generated, and are quickly lost by recombinations between the positive and negative ions. Hence an airgap may be given successive tests with fairly short intervals and still not show any progressive weakening.

We do not know whether all these considerations can be carried over to a liquid dielectric like oil but it seems very likely. Some recent work of German physicists showing that ultra violet light increases the conductivity of ordinary insulating materials, points fairly definitely to an ionization process. In any case, if the mechanism of breakdown in oil is at all similar to that of air, we can very readily see why the breakdown of oil should be more erratic. For the ions in oil must have a very low mobility, partly because of the very great viscosity of the medium in which they move, and partly because of the great tendency for polymerization in liquids, so that the individual ions consist of slow moving large groups of molecules. Hence the rate of diffusion must be very slow, so that it is possible to have spots of high ion density and spots of low ion density, with only feeble equalizing tendencies.

Ionization may also persist for a long time because of the slowness with which positive ions and negative ions will meet and neutralize each other. Hence, any slight ionizing agent will produce a relatively large density of ions because this will be determined by the equilibrium when as many ions are lost by recombination as are being generated by the ionizing agent.

The feebleness of the forces tending to make uniform and small the initial density of ionization are quite enough to explain why the breakdown of a small oil-gap is erratic. Add still further the turbulence of the oil under stress, which may at any moment in a haphazard fashion sweep a highly ionized portion of oil into the gap, and the wideness of the probability curves obtained by Messrs. Hayden and Eddy are no longer to be wondered at.

The point which I wish to bring out in this discussion is that there may be no fundamental difference between the mechanism of breakdown of an air gap and an oil gap. The apparent difference is one of degree only and due to the high mobility of particles in air. If air gaps were tested with voltages applied for very short times, say fractions of a micro-second, the results would probably be as variable as those obtained for the oil gap and conversely, if the oil gaps were tested by the application of continuous voltages for very long times, say hours, quite uniform results should be expected.

An Analytical Investigation of the Causes of Flashing of Synchronous Converters

BY E. B. SHAND

Associate, A. I. E. E.

Westinghouse Electric & Manufacturing Company, E. Pittsburgh, Pa.

The object of this paper is to show on what factors the flashing tendency of synchronous converters depends, and how, on the broadest considerations, an improvement of their momentary overload characteristics can be obtained. From the interpretation of a number of oscillograms, and other experimental data, it is shown that a heavy load surge produces unbalanced armature reactions, resulting in abnormal voltage conditions on the commutation, which are in turn largely responsible for the flash. Synchronous stability, stability of commutating conditions, and means of choking down the flash, are the means enumerated by which the momentary overload capacity may be increased.

DURING the past few years, a noteworthy effort has been made to improve the flashing and the momentary overload characteristics of 60-cycle, 600-volt synchronous converters for railway service. This important work has covered a number of different phases of the problem and has been carried on by the various organizations keenly interested in its success. Some of these phases have been covered by articles and papers published from time to time, describing modifications of design and new methods of protection, while some of the less recent papers explain clearly

FLASH ON A 500-KW. 60-CYCLE CONVERTER

the very difficult design limitations existing in this type of machine. This literature is referred to in a limited bibliography appended hereto. In the present paper, however, it is intended to deal solely with the processes through which, as a chain of cause and effect, a primary cause leads up to a flash at the commutator. It is particularly important to have a knowledge of this, both to determine effective means of protection and to interpret the varied results of tests.

There has been a tendency, it is thought, to consider the momentary overload capacity of a converter in too nearly the same terms as that of a direct-current generator. Actually the conditions existing in the two types of machines may be widely different from each other. So long as the converter is operating under steady loads these differences may not be greatly apparent because the alternating and direct currents bear a practically constant relation to each other, and, since they may be considered to flow in opposite directions, the reactive effect is small—less than in any other machine except a fully compensated direct-current generator or motor. The type of overload which is dangerous to the operation of a converter is one which comes on as a heavy surge considerably above the overload setting of the circuit breaker protecting the machine and is consequently relieved in a sudden interruption after a sufficient period has elapsed to permit the circuit breaker to operate. In these circumstances, the internal balance of currents will be severely upset by transfers taking place between the energy of the rotating masses and the energy being converted directly in the armature; resulting in abnormal commutating conditions conducive to flashing. This action then becomes a factor in the overload limitation of the converter. On the other hand, in the case of a direct-current generator the same condition cannot occur; there is but one current in the armature windings and consequently it makes little or no difference whether the input energy is supplied from an external source—a synchronous motor for example—or from the stored energy of its rotating armature.

When a load is applied to a converter, there is a slight momentary drop in speed which results in a permanent phase displacement of the armature behind its position when running light; the displacement being, within certain limits, proportional to the load applied. This action is common to all synchronous machines and is produced by the combined effect of armature reactances and armature reaction. Although the algebraic sum of the alternating-current and the direct-current armature m. m. fs. when summed up over a pole-pitch may be shown to be roughly zero, a study of Fig. 1 will show that in particular points one may be in excess of the other. The direct-current m. m. f. is greater under the interpolar space where the reluctance is high, and the alternating-current m. m. f. under the main pole where the reluctance is much

Presented at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

lower. It thus happens that the alternating-current part of the resultant m. m. f. is the greater in its influence for reaction than the direct-current part. In addition to this, the resultant direct-current m. m. f. in the commutating zone is neutralized, or even reversed, by the excitation of the commutating-pole winding. The total effect is an appreciable alternating current, or motor reaction, which distorts the main flux backward. The distortion is, naturally, much less than in a synchronous motor, but that it is quite perceptible is shown by Fig. 2, which is an actual field form mea-

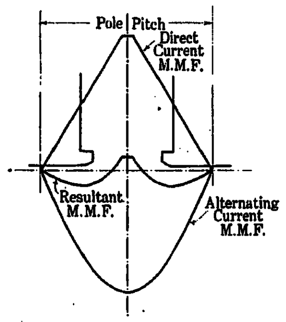

FIG. 1—ARMATURE M. M. F. DIAGRAM FOR A SYNCHRONOUS CONVERTER

surement of a 300-kw. 25-cycle converter. It will be evident that the voltage generated between diametrical rings is no longer a maximum at the instant when the tap-coils pass beneath the direct-current brushes, but at a position on the commutator slightly to the rear, or in the direction against rotation. This point corresponds roughly to the phase displacement.

In order to obtain direct quantitative measurements of this phase displacement, an oscillographic method was developed by which the internal phase relations could be determined. Briefly, the method consisted in recording two voltage waves; one, the voltage

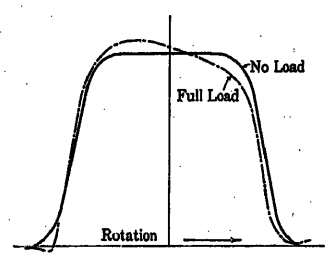

FIG. 2—CONVERTER FIELD FORMS

applied across two collector rings, and the other, the voltage of an auxiliary machine rigidly connected to the converter armature. The voltage of the auxiliary machine corresponds to a voltage generated by the field winding of the converter alone, without any reactive effects and, therefore, the relative phase positions of the two recording voltage waves may be used to indicate the phase displacement of the converter armature. A very pronounced advantage of such a method is that it may be used for both stable and transient conditions of operation.

The phase displacements under various conditions of load were measured on a 500-kw., 60-cycle, 600-volt converter which was used extensively in all the work which these notes cover. It was not used exclusively, however, and the data obtained on it were supplemented to a considerable extent with more from larger machines. The phase displacement results of the 500-kw. converter are shown in Fig. 3. Under stable conditions of load, the results for beyond two and one-half times the rated load, unfortunately, had to be discarded because a sufficient power supply could not be maintained to give steady values. The initial displacement of about one degree is due to the no-load losses of the converter and is, incidentally, purely the action of a synchronous motor. The full-load displacement of six electrical degrees is, as has already been stated, much less than for a corresponding synchronous motor—perhaps only one-fourth of it. To proceed with such a comparison, a synchronous motor may be expected to

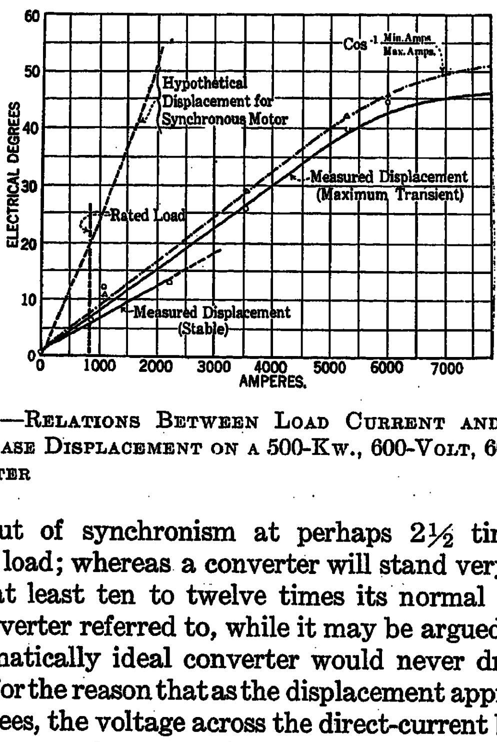

FIG. 3—RELATIONS BETWEEN LOAD CURRENT AND ARMATURE PHASE DISPLACEMENT ON A 500-KW., 600-VOLT, 60-CYCLE CONVERTER

drop out of synchronism at perhaps 2½ times its normal load; whereas a converter will stand very much more, at least ten to twelve times its normal load in the converter referred to, while it may be argued that a mathematically ideal converter would never drop out of step for the reason that as the displacement approaches 90 degrees, the voltage across the direct-current brushes would approach zero while the synchronizing torque approaches a maximum[1]. For practical converters

1. When a synchronous machine connected to a source of constant voltage is placed under load, its rotor is angularly displaced by an amount depending upon the impedance drop in both the intervening circuit and in the machine itself. This displacement is a measure of the stability of the machine; the greater the displacement the less the stability. In a simple diagram, such as Fig. 4, where the resistance drop is neglected, it can be shown that the power flow is proportional to the area between the vectors E_0 and E_{01} and as this varies with the size of the included angle it will be consequently a maximum when the vectors are at right angles, as shown in the second diagram. In other words, this latter condition marks the limit of stable operation and beyond this point the machine will pull out of step. This limitation applies not only to the synchronous machinery but to combinations involving synchronous machinery transformers and transmission lines, etc.

however, high internal losses and flashing will occur before this condition is reached, so that the actual torque will be largely independent of the output and will cause the converter to pull out of synchronism. The tests seem to indicate the displacement may reach a maximum value of 45 electrical degrees before trouble from flashing results.

It is, of course, to be understood that the value of phase displacement of other converters under normal load is not necessarily the six degrees cited above. This quantity depends upon the design of the particular machine involved. The stability of the converter used in these tests is appreciably greater than what is found in machines of larger ratings. It would be expected, and is a fact, that many machines have a considerably larger displacement at their rated loads.

A factor of considerable importance in the determination of the overload capacity of a converter is the characteristics of the circuit supplying the power. The stability of a synchronous motor, for instance, will be sensibly decreased when operated from a circuit of high reactance and the same thing is true of a converter, but to a greater degree because the small reactive effect of the converter itself forms a smaller fraction of the whole; and, conversely, the external reactance will form a *greater* fraction of the whole. For railway substation installations, where it is usual to install transformers with 15 per cent reactance, it will be expected that stability of the converter will be somewhat reduced. To be exact, the above value of reactance is not maintained on heavy overloads, due to the saturation of the leakage paths, but it will be relatively high to the point where the converter drops out of synchronism. Fig. 4 shows this effect quantitatively with very rough assumptions. It is assumed that external reactance amounts to a constant value of 17½ per cent while the converter displacement at normal load is six degrees. The second diagram shows that the maximum load which the converter could carry under these conditions would be about five times its rated value. Since the external displacement is relatively greater than the phase displacement of the converter armature it therefore becomes largely responsible for the machine dropping out of synchronism.[1]

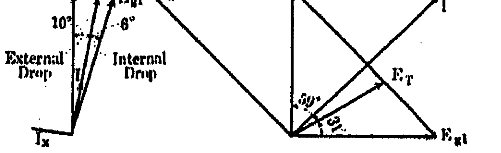

Fig. 4—Reactive Voltage Drops in a Converter and Supply Line

It is to be realized that such a diagram is necessarily very crude and that it can only serve to illustrate a point rather than to give accurate data. Certain factors which have been neglected may however lack the importance which might be given them at first sight. For example, the effect of the series field during such a transient period is not great because any tendency toward sudden changes in flux will be almost completely counteracted by current in the damper winding and shunt field winding for a longer time than it takes the converter to drop out of step. The effect of resistance in the alternating-current circuit will naturally be detrimental although it is usually so small that it is not important except under the heaviest loads.

It follows from the preceding discussion that due to phase displacement in the converter and an additional displacement in any external reactance, the armature takes up a definite phase position for each value of load applied and when a change of load occurs the armature must change its phase position to correspond, moving forward or backward (relatively), depending upon whether the load has been increased or decreased. If the change takes place gradually there will be no resulting disturbance, but if the load changes suddenly the internal balance of currents and reactions will be upset until such time as the armature will have settled into its stable position. When the armature drops back, it delivers a portion of its rotational energy as output at the direct-current brushes which is in addition to the alternating-current input; when it moved forward, extra alternating-current power is required to accelerate it. In consequence of these actions, there is no set instantaneous relation between the alternating-current input and the direct-current output for a transient condition of load, for it will be modified by the rate and direction of energy transfer in the rotating masses.

Hunting is the condition existing when the changes of displacement become oscillatory. In this case, the energy stored in the armature may be taken as fluctuating about a mean value represented by the energy at synchronous speed, and the magnitude of these fluctuations determines the severity of hunting. The relation between the alternating-current input and direct-current output, however, if summed up over an appreciable period is the same as that for the steady load condition.

The sequence of action on the application of load to a converter may be stated in somewhat the following manner: On the closing of the direct-current circuit, the current rises following the ordinary exponential law, being limited at the first instant by only the total inductance of the circuit. The rate of power increase during this period may be high, necessitating a correspondingly high rate of change of armature displacement. If the converter does not fall out of synchronism, the total displacement will be limited to a maximum of less than 90 electrical degrees (see Note 1), but the time in which this movement takes place may be so short that the energy will be given up at a rate comparable to the coincidental output which means

that the converter will absorb a considerable part of the shock of the sudden load change and prevent it from passing into the alternating-current system. This cushioning effect may be achieved in severe cases, however, only at the expense of a flash. Fig. 5 is an oscillogram taken to show the effect of the application and interruption of a heavy load on the 500-kw. converter. The alternating-current wave may be taken as a rough measure of the power input. The alternating current, it may be noted, rises at about one-half the rate of the direct current, and reaches a maximum value only after the direct current has begun to decrease. It eventually exceeds the corresponding value of direct current, which shows that the armature has begun to oscillate freely—that is, to hunt. This effect is much more noticeable after the circuit breaker opens, when the indications of hunting are unmistakable. It is of interest to note that the point of minimum alternating-current input occurs about two cycles after the direct current has been completely interrupted, while at the point at which the direct current reaches zero the power required to accelerate the rotor is scaled at about double the rated input of the converter.

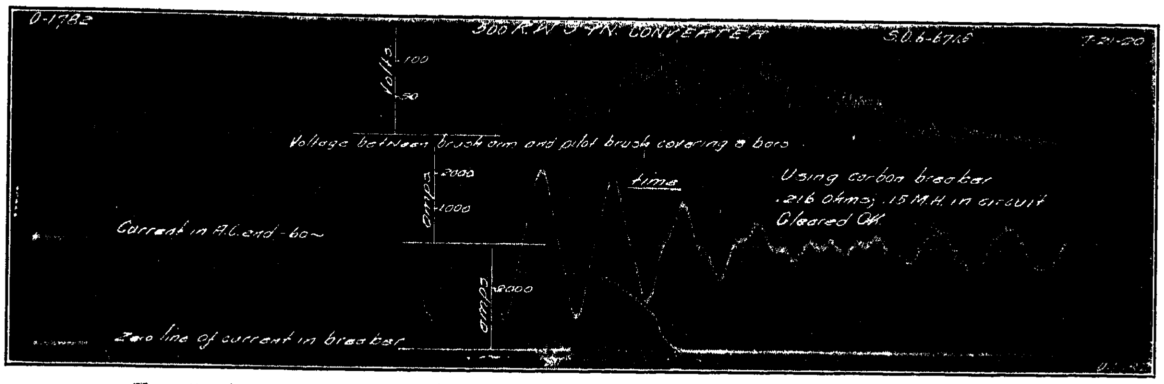

FIG. 5—APPLICATION AND INTERRUPTION OF A LOAD ON A 500-KW. CONVERTER

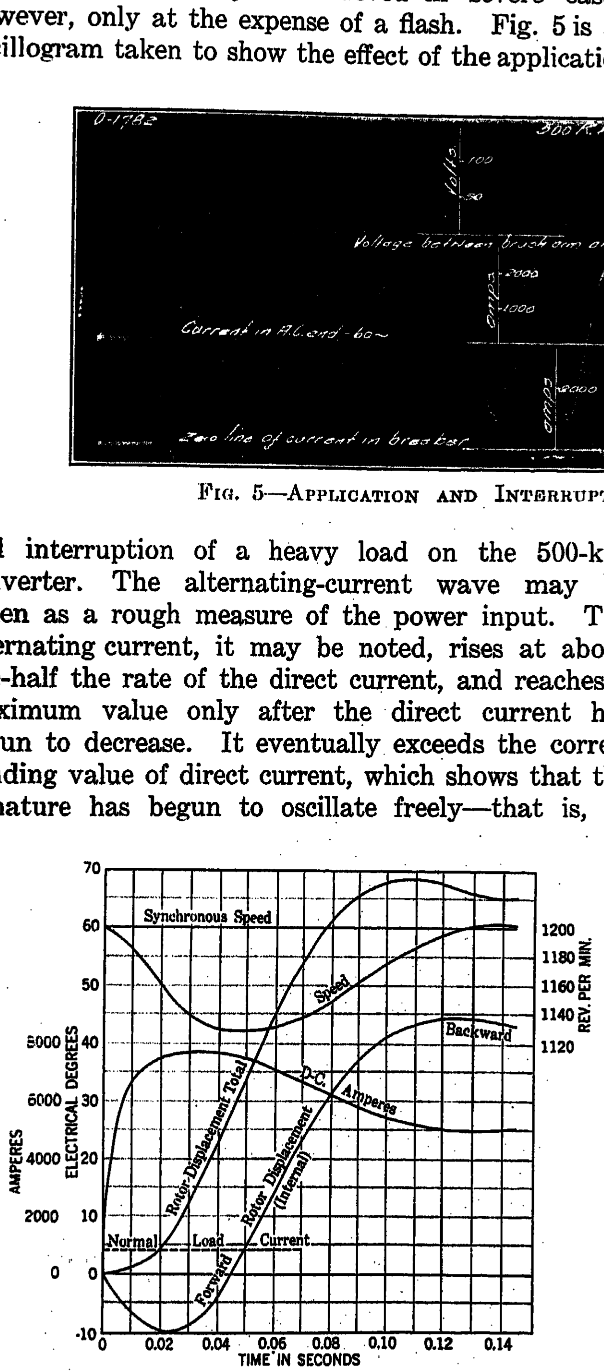

FIG. 6—TRANSIENT RELATIONS OF SPEED AND DISPLACEMENT IN A 500-KW., 60-CYCLE CONVERTER

This brief analysis gives a general idea of the power fluctuations under such circumstances; but, while very interesting, it fails to give a quantitative measurement of the displacement angles involved. To obtain these data, a series of tests was made while loads of various magnitudes were thrown on the converter, the results of which are plotted in Fig. 3 where they can be compared with the corresponding displacements under steady load. The maximum transient displacement is the greater as is logical. The curve shows a tendency for the internal displacement not to increase beyond 45 electrical degrees which may be the actual case.

The complete results of one test are combined in Fig. 6. The short-circuit current rose to a maximum value of about 9½ times the normal value in 0.03 second, and then decreased to about six times full-load current. This load is obviously too great to be maintained by the converter, but, if this had been possible, the final and stable value would have been between these two, though considerably nearer the lower one. The maximum angle of internal phase displacement recorded was 43 degrees which occurred roughly at the instant of minimum current. This is again indicative of oscillatory action. A distinction is made between total displacement and internal displacement; the former term applies to the amount by which the converter drops back into phase position behind the source of power, and thus is the result of the entire reactive drop between that source of power and the armature as well as that in the converter itself. It is this quantity which determines the amount of rotational energy given up by the rotating parts. The internal displacement includes only that which is produced within the converter due to the effective armature reaction and reactance. One point which is worthy of note, and which came as a surprise, is the fact that the initial *internal* displacement is forward instead of backward as might be expected. This simply means that the external displacement due to line reactance, etc., increases faster than the armature can initially drop back. The total displacement is, of course, always backward. This short-circuit test approached

the limit of severity which could be thrown on the converter without having it drop out of synchronism. An indication of this is the fact that the total displacement reached a value of 70 electrical degrees. As a matter of fact, it was only the very low value of external reactance which explains why the converter remained in synchronism at all at such a load.

It might be noted in passing that the decrease of load current after the maximum value is reached is closely associated with the phenomenon of phase displacement; and, incidentally, the relation between the two was at first made use of to obtain quantitative measurements of internal displacement. With a constant sinusoidal voltage applied to the rings, the voltage across the direct-current brushes will drop with the cosine of the angle of displacement. If the load current were assumed to drop off also according to this same law, then the ratio of the current at the first dip to the maximum value will represent the internal displacement. That this assumption is more or less justified may be drawn from the comparison of curves of Fig. 3. In the case of another machine the agreement might not be so close, although the method ought to serve at least as a means of comparison between different tests on the same machine.

The magnitude of the energy fluctuations in the converter during short circuits can be estimated from the inertia of its rotating masses and the data of Fig. 6. In this particular case, the energy given up by the armature in the first 0.04 second was about 30,000 ft-lb., and at a maximum rate of 1250 kw. This is about two and one-half times the rated capacity of the machine and amounts to about 50 per cent of the actual output during this period. These figures, therefore, agree with the conclusions drawn from Fig. 5, and serve to demonstrate the fact that the fluctuations of energy which disturb the balance of the reactors are severe.

These figures may also be used as a means of showing the resultant effect on commutation. Assume that the instantaneous ratio of output to input is 2:1; the m. m. f. acting in the commutating zone instead of being the 10 per cent of Fig. 1 becomes 55 per cent of the full direct-current armature ampere turns and if, as was formerly quite usual, the commutating-pole ampere turns amount to only about 40 per cent of this same value, there will be a negative m. m. f. of 15 per cent to produce a flux in the reverse direction. Under such conditions it would be much better for the converter if the commutating poles were removed.

The obvious way to reduce the amount of trouble from this source is to increase the magnetic strength of the commutating pole in relation to the armature until it becomes comparable to that of a direct-current generator. If this be done, the extra ampere turns under normal operating conditions will be used up in a greatly increased reluctance of the commutating pole, while under load surges they will prevent the commutating-pole flux from becoming greatly decreased (relatively) or reversed. This arrangement has become known as a high-reluctance commutating pole, the reluctance being obtained by placing non-magnetic material (which includes air) in the magnetic circuit of the pole. If the strength be increased to 100 per cent, for instance, the conditions referred to above become as follows: In the case of stable operation, 10 per cent of the total m. m. f. is utilized in neutralizing the resultant m. m. f. of the armature and the remaining 90 per cent in overcoming the reluctance of the magnetic circuit. In the case of the assumed surge, 55 per cent neutralizing m. m. f. is required, leaving 45 per cent to produce the commutating flux which means that the latter will be one-half of what it would be under the corresponding stable condition.

These rough calculations have been verified experimentally, using the same converter as in the former tests furnished with high-reluctance commutating poles of approximately 100 per cent strength. The data obtained are plotted in Fig. 7. The flux changes were recorded by an oscillograph connected to search

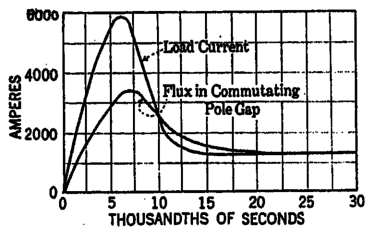

Fig. 7—Relations Between Load Current and Commutating-Pole Flux under Transient Conditions

coils in the commutating zone. The flux harmonics are large under short-circuit conditions, so that to reduce the possibility of error from this cause two oscillograms were used to produce the one composite curve. As there was no pronounced difference between the separate curves, it is probable that the result is reasonably accurate. The ordinates of flux and current have been made to coincide for purposes of comparison.

The phenomena following the interruption of a heavy load are equally important to those of an increasing surge. It has already been mentioned in connection with Fig. 5 that when the direct current was completely interrupted the alternating current still amounted to double its rated value. At th s t me there were no other m. m. fs. acting in the commutating zone, and the only obstruction to the passage of flux was the reluctance of the magnetic circuit. The condition corresponds to a strongly over-compensating commutating pole[2] and tends to occur on all occasions when the load is suddenly reduced.

In Fig. 7, the period intervening between 0.01 to 0.02 second is one of over-compensation due to the sudden operation of the circuit breaker. The excess

2. The alternating-current m. m. f. of the armature acts in the same direction as the m. m. f. of the commutating-pole series winding.

here is not great for the armature was never displaced to any great extent, and therefore required little accelerat ng current.

Referring again to the results of Fig. 5, it is possible to make a rough estimate of the flux produced by the unbalanced armature current at the interruption of the direct-current circuit on the same basis as those already made. Assuming then the alternating current to be double the rated value and a commutating pole of 40 per cent of armature strength, the commutating flux will tend to increase to a maximum value of between five and six times that at normal load and will, naturally, generate high voltages under the brush. If a high-reluctance commutating pole of 100 per cent strength is supplied to the converter, the corresponding flux will tend to be only about double the normal value at full load. The pronounced advantage of the high-reluctance commutating pole for the condition of quickly decreasing loads is, therefore, also evident. It might be remarked parenthetically that there is a practical limit to which the increase of reluctance of the commutating pole may be carried. This comprises only one of the possible paths for the flux (others being slot leakage etc.), so that when the reluctance of the commutating-pole circuit become relatively high compared to that of the other paths, the practical limit is reached. The constructional difficulties, of course, increase with the reluctance.

The amount of energy unbalance under transient conditions of load is a measure of the combined effect of several factors which may be conveniently grouped under two headings: First, the extent of change and the rate of change of the load; and second, the relation between the moment of inertia of the rotating element and the electrodynamic stability between the converter and its source of power. The 500-kw. converter used particularly for these tests was one of low moment of inertia and high stability at its rated load due to the design limitations for this type of machine. As a consequence, the overload capacity under both stable and transient loads was exceptionally high. Converters of greater ratings are not so fortunate in this respect; their inertia is relatively greater and their stability less. The data submitted here, therefore, cannot be taken to apply indiscriminately to all classes of machines but must be modified to suit the design proportions for individual cases. The test represented by Fig. 6 for instance, showed that the 500-kw. converter used will carry 9½ times its rated load without dropping out of step or flashing. This cannot be considered a representative figure, by any means, for converters in general, and in addition to this the same converter when operated from high-reactance transformers would not have this overload capacity.

Up to the present point, the converter has been dealt with as a piece of synchronous apparatus entirely, particular attention having been paid to the character of reactions resulting from transient load conditions. The phenomenon of flashing itself is a characteristic of commutating machinery; therefore to show the relation between these reactions and the flashing which may result the converter must be dealt with as a commutating machine. From a careful examination of the available data in the form of oscillograms, high-speed photographs, etc., the immediate causes leading up to a flash-over were ascertained to be in the majority of cases as follows: Sparking under the brushes occurs with heavy overloads in all commutating machinery and is due partly to the heavy currents flowing across the brush contact surfaces, but more to the imperfect compensation of inductive voltages generated in the short-circuit coils effected by the excitation of the commutating pole. Sparking will naturally precede a flash, even though perhaps only for a few thousandths of a second. It produces ionization of the atmosphere at the surface of the commutator which decreases the ability of the converter to resist the first formation of an arc. In nearly every case capable of investigation, the flash developed through the sparking at the brushes being drawn out as the commutator bars receded from the brush until the arc extended through an entire pole-pitch. When this occurs and the arc is between brush arms of opposite polarity, or between brush arm and ground, the flash may be considered completely developed. Experience with electric welding has shown that 20 volts are sufficient to maintain an arc, and although conditions are somewhat different on the commutator, the presence of ionized gases due to sparking is favorable to the initiation of an arc, and the above voltage or probably a higher value indicates the magnitude necessary for flashing. If the above conclusions be generally correct, it means that the voltage conditions and distribution over the commutator, in particular directly ahead of the brushes, *i. e.*, in the direction of rotation, are critical for the propagation of an arc and the development of a flash.

It has been generally appreciated that a converter is far more liable to flash on the opening of the circuit breaker than at the point of maximum current. An investigation of the voltage distribution over the commutator under the two conditions—that of increasing loads, and that of decreasing loads—gives the explanation for this. Take the case of a non-commutating-pole, direct-current machine; here, when loaded, the neutral shifts forward for a generator, and backward for a motor, as is evidenced by the necessity for the shifting of the brushes. In the case of the converter when hunting takes place, very much the same thing is true; the fluctuations of energy in the rotating element represent unbalanced motor or generator reactions and the neutral swings backward or forward of the brush as the machine oscillates in phase position. This effect is plainly observable from the sparking under the brushes which will rise and subside with each oscillation. When the generator reaction is in excess and the neutral is ahead of the brushes, the

voltage between a brush and a receding bar is of opposite polarity from normal until the bar is somewhat past the neutral. It is evident that there is no voltage between the brush holder and the commutator capable of propagating an arc forward until after the bar has reached a point where the voltage has risen to an appreciable value in a positive direction, and as this point may be an inch or more from the brush on the commutator surface, the conditions are very unfavorable for production of a flash.

In the case of an excess motor reaction, the neutral has moved backward and the bar, on passing the brush, is moving into a field of steadily increasing intensity, and the voltage gradient over the commutator directly in front of the brush may be much higher than it normally is. A critical voltage, which is readily able to carry the arc forward to the next brush arm, may exist on the commutator almost at the brush itself, and thus the danger of flashing is imminent.

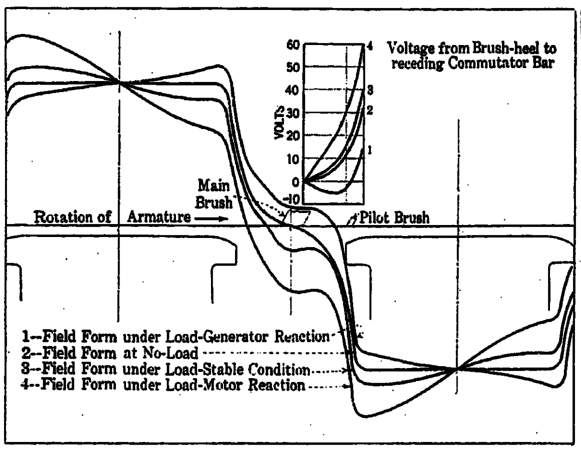

FIG. 8—FIELD FORMS AND VOLTAGE CONDITIONS FOR VARIOUS TYPES OF LOAD

To present this condition in a more definite manner, Fig. 8, which gives several calculated field forms of a converter, has been included. The field forms are drawn up for four different conditions of load, which are, referring to the numbers on the curves: (2) at no-load, (3) under a stable load condition, (4) under load with excess motor reaction, (1) under load with excess generator reaction. The same output has been assumed in each of these last three cases to allow direct comparison; the difference of field form being produced, therefore, by the transfers of rotational energy causing unbalanced reactions.

The changes of flux in the commutating zone between the conditions (1), (3) and (4) are quite marked, although the flux for proper compensation should be the same in each case. The corresponding shifts of the neutral are equally pronounced. If, for instance, the converter were hunting with sufficient severity to produce the unbalanced reactions of this figure, the neutral would swing between the two extremes (1) and (4) with each oscillation.

The inset voltage curves refer to the voltage difference between the heel of a brush and a commutator bar, as it moves forward. They represent in a way the relative tendencies toward flashing for the conditions of operation assumed. At no-load this voltage at the point marked "pilot-brush" is given as 12 volts, which corresponds to that actually measured on the converter. Under the stable load, this voltage is increased only slightly. The same load, while increasing, produces a voltage of -3 volts at this point, and while decreasing $+30$ volts. The significance of these voltages may be inferred from the consideration that if 25 volts are required to maintain an arc on the commutator, in the former case no such voltage will exist on the commutator until the bar has receded a considerable distance from the brush, and it is unlikely that an arc will be propagated forward. In the latter case, a critical voltage may exist almost at the heel of the brush, and the conditions are entirely in favor of the propagation of a flash. It may be said, therefore, that during a period of increasing load a converter is in a sense self-protecting against a serious flash; but that when a load is suddenly decreased, as when a circuit breaker opens, a flash is much more likely to occur, a conclusion thoroughly borne out by experience.

In order to obtain some direct information on this particular action, a number of short-circuit tests was made on the converter having a small pilot-brush located on the commutator at the point indicated in Fig. 8. By this means, the voltages in the commutating zone, critical from the standpoint of flashing, were measured under various transient conditions and the results form a striking confirmation of the theory outlined above. In Fig. 5, the upper line is a record of this voltage. Before the application of the short circuit this "pilot-brush voltage" was about 12 volts, but during the sudden increase of load it dropped slightly below zero, meaning that the neutral had swung forward. Under the steady load condition, it rose to nearly 50 volts above zero, indicating that the neutral was permanently displaced backward. At the opening of the circuit breaker, the voltage exceeded 100, indicating that the decreasing load forced the neutral backward although the armature itself was being accelerated forward. Unfortunately, the oscillogram ended just as a period of free oscillation was beginning, although the commencement of the characteristic indications are evident.

Fig. 9 is a somewhat similar oscillogram but taken during a much heavier short circuit. The current reached a value of 9750 amperes or about 11½ times normal value and the effects are, therefore, sufficiently pronounced to repay a rather detailed study, through which a relatively complete history of the internal actions during the test may be traced. The negative pilot-brush voltage indicates the release of stored rotational energy as in Fig. 5, but at a higher rate for the voltage here drops to 80-90 volts. This is sufficient

to convert the sparking at the brushes into a flash which is indicated by the dip in the current wave. However, as the position of the neutral was far forward, the flash was not propagated to the next brush arm and it existed more in the form of a momentary "spit" of considerable severity. As the neutral receded backward with the increase of phase displacement, the voltage initiating the flash decreased to a point in excess of anything which might reasonably be expected of the converter. To permit this performance, the apparatus used included several special features. The converter itself was furnished with high reluctance commutating poles, such as have already been referred to. Flash-guards were placed on either side of the direct-current brush arms to insulate the brush holders from conducting gases, and a special arrangement of

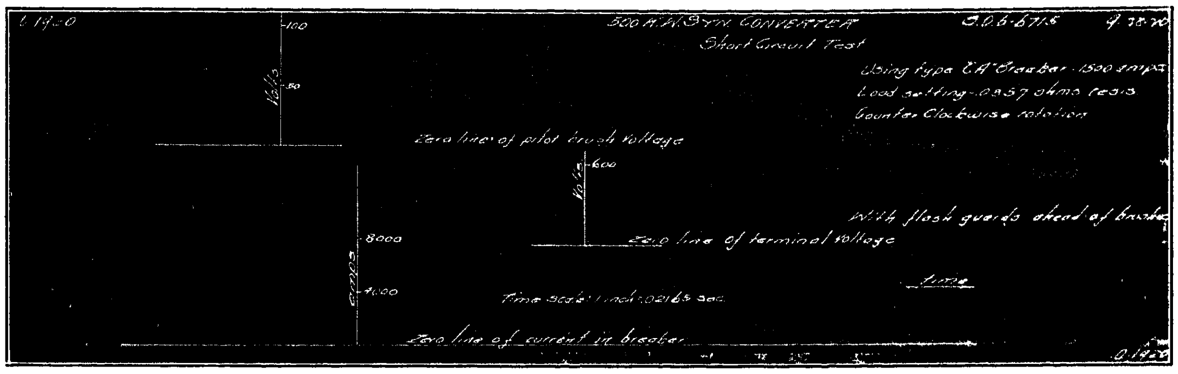

FIG. 9—HEAVY SHORT CIRCUIT ON A 500-KW. CONVERTER

where this flash stopped entirely (where the current dip ends). The transition to the stable condition was never completed in this phase of the test, for the circuit breaker opened while the armature was still moving backward. At the interruption of the direct-current circuit, the pilot-brush voltage rose immediately to a maximum value of perhaps 120 volts, which represents a greatly aggravated case of (4) of Fig. 8. At this point the converter flashed the second time but with the reversed voltage conditions on the commutator and as there was nothing to stay the progress of the flash, it progressed completely to the next brush arm where it would have developed seriously had it not been for flash guards supplied to the forward side of the brush holders which isolated the arc on the moving surface of the commutator. This effect greatly limited the severity of the flash and choked down the amount of power expended, so that the armature was allowed to move forward in phase displacement. Thereupon, the unbalanced reaction dropped in value and the neutral approached its normal position again. This proceeding cut off the means whereby the flash was continually being propagated forward and the arc naturally died out. The beginning of the regular descent of the pilot-brush voltage, in Fig. 9, indicates the cessation of flashing. This second flash was of rather short duration as well as the first. If the flash had reached some unguarded point of opposite potential, as would have been the case without the protection of flash guards, it would have been necessary to shut down the machine to kill the arc and protect it from serious injury.

This test fairly exemplifies the principles advanced in the previous part of this paper. It represents as well, a service of extreme severity and considerably brush-holder cross-connections was used to control the flash to a certain extent. The transformers used were of lower reactance to reduce the external impedance to a minimum. The circuit breaker was set for a slightly higher speed than would ordinarily have been considered necessary so that it might operate before the armature had reached its maximum displacement. This was essential to prevent the converter from dropping out of synchronism on extreme momentary overloads. The circuit breaker actually began to open in 0.06 second while the maximum displacement occurred in the neighborhood of 0.08 second. It may be observed that the circuit breaker did not completely open the direct-current circuit in this test; this is because a resistor had been connected across its contacts for previous tests, but there is no particular significance of it in the present connection. This general arrangement, however, tends to reduce the probability of flashing.

This short-circuit test did no injury to the converter beyond a certain amount of erosion of the brush surfaces caused by the heavy load current and circulating current in the brushes. The machine was not shut down and it was found practicable to place it under load again immediately, although not to its full rated capacity until the brush surface conditions had become somewhat improved.

Two more tests taken under a different condition will be referred to. For these tests, the converter was protected by a high-speed circuit breaker by which is meant one which will completely operate within 0.01 of a second. Fig. 7, although not quite typical on account of the time of operation being slow, shows the characteristic current curve very plainly. By making a comparison between this figure and Fig. 6

on a time basis, it may be noted that the initial rates of current rise are not widely different so that the displacements for the two tests may be assumed to correspond with the same accuracy. With the current limited to a time of 0.006 or 0.007 of a second the resulting displacement must be very small; and in fact the internal displacement of the converter will be forward, as has been independently verified. In order that an idea may be gained of the transient phenomena involved Fig. 10 is referred to. The test shown here duplicates that of Fig. 7 except that different quantities were recorded. The fluctuations of both alternating current and of the pilot-brush voltage are so small that it is evident that the great speed of the circuit breaker forestalls any pronounced internal disturbance. Both of these tests represent dead short circuits thrown on the converter, demonstrating that complete protection may be obtained in this manner. Fig. 11 is reproduced from a photograph taken during one of these tests.

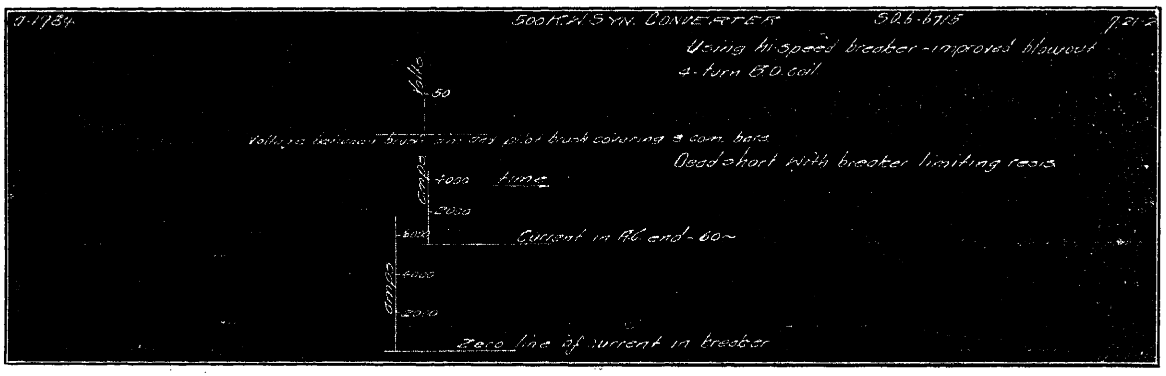

Fig. 10—Action of a High-Speed Circuit Breaker

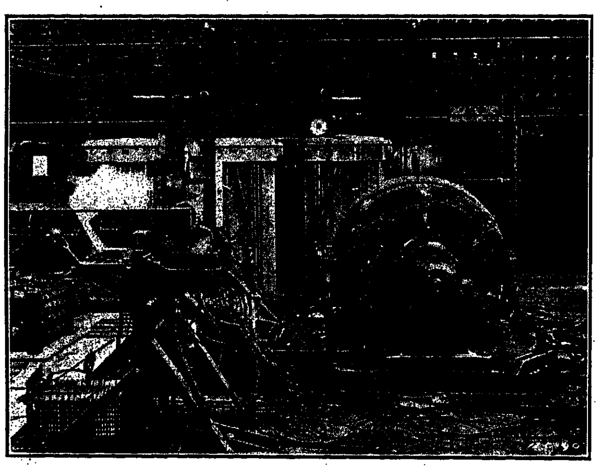

Fig. 11—Dead Short Circuit on a 500-Kw. Converter Portected by a High-Speed Circuit Breaker. (See Fig. 10.)

Fig. 12 is from a multi-exposure photograph taken with a high-speed camera[3] to study the development of a flash on the commutator. To compress the phenomenon within the limited time, the high-speed circuit breaker was used with certain modifications to permit the formation of a flash. The exposures are numbered consecutively 1, 2, 3, etc. and are taken 0.001 of a second apart. From comparing these exposures with the oscillogram taken on the same occasion, exposure No. 6 is found to occur at the instant of maximum current, which was 8200 amperes. Up to this point, it may be noted that the flash did not develop beyond the category of a severe spit; at the sudden opening of the circuit breaker, however, the following exposures 7, 8 and 9 show sudden expansion forward of the flash which takes place at even a faster rate than the motion of the commutator itself. These photographs, which record the actual state and confines of a flash at successive intervals over a period of rise and decay of load current, form an important support to the conclusions regarding the propagation of an arc under these two conditions, as set forth in some of the foregoing paragraphs.

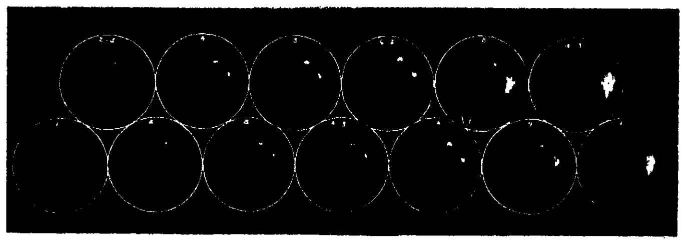

Fig. 12—Development of a Flash on the Commutator

The principles set forth in this paper showing the very intimate connection between the synchronous action of a converter and the flashing at the commutator are the outcome of a series of tests extending over several years and a careful analysis of all available data whether derived from these tests or from other sources. It is believed that the conclusions are substantially correct and that they can be used to cover other similar phases of the problem not mentioned here. By applying these principles to the problem of increasing the

3. J. Legg. The Polar Multi-Exposure High-Speed Camera, *Electric Journal*, December, 1919.

momentary overload capacity of converters, the following main lines of progress are suggested:

(1) The improvement of synchronous characteristics of the converter installation to obtain high stability and the reduction of the moment of inertia of the rotating masses of the converter.

(2) The reduction of the effectiveness of the unbalanced reactions in producing high voltages in the commutating zone. (High-reluctance commutating poles are an instance of this).

(3) The prevention of the complete propagation or culmination of the arc by the insulation of conducting parts around the commutator by means of flash-guards and other devices.

(4) The limitation, by external means, of the maximum severity of the surges thrown on the machine. (In which might be included the high-speed circuit breaker).

These principles have been utilized in devising suitable means of improving the characteristics of commercial types of 60-cycle railway synchronous converters with the result that they have proved themselves much superior to their predecessors.

Discussion

J. L. Burnham: I would like to discuss the paper in the reverse order from which it is given. To show the relation of Mr. Shand's paper to previous discussions on this subject, a brief review of the bibliography he has appended seems desirable. In 1910 Messrs. Lamme and Newbury presented a paper on the use of commutating poles in synchronous converters in which they implied doubt of their usefulness. Their reasons, broadly stated, were:

Pulsation in the armature reaction and disturbances of the normal relation between alternating and direct current with quick changes in load, which caused wide variations in the resultant commutating field excitation for a given load. The phenomena discussed in Mr. Shand's paper were qualitatively stated at that time and since have been enlarged upon by others. Mr. Shand now gives a more definite picture of what occurs during sudden changes in load and short circuits.

In the discussion of Messrs. Lamme and Newbury's paper I gave results of tests on 25-cycle, 1200-volt converter with a large air gap for the commutating pole which gave decided improvement in performance for heavy loads thrown on and off. Since that time it has been the practise to use large air gaps for commutating poles of 25-cycle synchronous converters. For 60-cycle railway converters the large air gap was not sufficient to give the desired performance. The effect has been increased in the development of high reluctance commutating poles.

In 1914 Mr. Yardley presented a paper on the use of reactance for protection of synchronous converters. The results obtained did not seem encouraging and reasons were presented in the discussion at that time showing the inherent difficulties that would be introduced by the use of reactance, particularly in the a-c. circuit. These reasons are further emphasized in Mr. Shand's paper.

Recognizing these inherent characteristics of converters we began work to devise means for eliminating the effects with the view of avoiding damage to the machine and minimizing interruptions to service. Two lines of investigations were followed.

First: To take care of the flash so it would not spread and would be stopped when the short circuit was removed and

Second: To prevent formation of the arc.

The first line of investigation resulted in the development of flash barriers and the second in the high speed breaker. A paper presented at the annual convention in 1918 by Messrs. Linebaugh and Burnham described the investigations and the devices then developed. At that time we made the first claim for complete protection of a converter against any disturbances in both a-c. and d-c. systems, that would give interruptions to service no longer than ordinarily resulting from moderate overloads that would trip the main circuit breaker.

In 1919 a line of high reluctance commutating pole 60-cycle railway converters was developed and also a new type of protected brush rigging was introduced to give greater clear distance between brush holders of opposite polarity. The high reluctance poles increased decidedly the amount of disturbance that the machines would stand without flashing and the new type of brush rigging gave much less opportunity for the arc to spread and do damage. These improvements made the 60-cycle railway converter much better for average service when protected with the usual devices.

The next year, 1920, Mr. M. W. Smith presented a paper on "Suggested Remedies for Flashing of 60-Cycle Converters" which reviewed some of the phenomena involved and described tests made on the so-called flash suppressor and protected brush rigging. Tests indicate that under very delicately adjusted conditions some protection would be afforded but at that time the scheme was not considered commercially useful. I assume that this is still the status of this line of investigation.

Regarding Mr. Shand's conclusions suggesting main lines of progress: No 1 is well recognized and I believe has been followed by most designing engineers for a number of years past if for no other reasons than lower costs.

2. High reluctance commutating poles were investigated about 5 years ago and a complete line of 60-cycle, 600-volt converters was developed and standardized in 1919.

3. Experimental work on flash barriers was done 5 to 6 years ago and results were described in a paper presented at the annual convention in 1918 and have since been used for certain difficult service, but principally for automatically controlled machines.

4. The high-speed breaker investigation started about six years ago. At that time there was no information to determine what speed would be required of a d-c. circuit breaker to prevent

flashing on short circuit. I recommended that it be made to open the circuit within ½ cycle for 60 cycles or 1/120 of second, the time in which a commutator bar passes from brushes of one polarity to those of opposite polarity. This was about 20 times faster than existing breakers and seemed a most difficult problem but this speed was attained in some breakers built about 5 years ago, and a new design, much simpler, stronger and cheaper has since been built to give the same high speeds.

To give a better idea of the form of protected rigging and flash barriers, and the performance of machine under short circuit, I wish to show some pictures:

Fig. 1 shows short circuit on a 25-cycle, 1200-volt converter built in 1910. This is the machine on which experiments with large air gaps for the commutating pole were made and which permitted 4 times load to be thrown on and off without any serious disturbance. However, when short-circuited this machine arced over between adjacent sets of brush holders, from brush holders to bearings and even to projecting field connection strips. The amount of damage to the machine was remarkably

Fig. 1—Short Circuit on Type H C 6-750-500-1200 Volt Synchronous Converter

small, compared to the pyrotechnics and effect on the operators nerves.

Fig. 2 shows a more modern form of brush rigging assembled on a 500-kw., 60-cycle standard railway machine.

To show more detail of a brush holder bracket, the next picture (Fig. 3) is an end view with the insulating end cover removed. It will be seen that the rigging is completely enclosed by insulating material and that the spring is radially in line with the brush. This type of rigging covers a very narrow portion of the commutator and g'ves maximum clear space on the commutator over which an arc may be established. This increased the load disturbances that a machine will stand without flashing over but it is not entirely effective in preventing a flashover when short-circuited.

Fig. 4 shows flashover with this sort of rigging, the curretn being interrupted by a breaker of ordinary speed. Such a flash will generally clear itself, as short circuits in service are generally limited by feeder resistance, but occasionally will hang on long enough to trip the a-c. circuit.

Fig. 5 is a 750-volt, 60-cycle converter having the radial type brush rigging and latest type flash barrier.

Fig. 6 is a perspective and cross section of the flash barrier, the action of which is explained as follows: when short circuit occurs the arc is formed between the brushes and the leaving commutator segments, being drawn out in direction of rotation as shown by the arrow and expanding outward. The arc is mechanically scooped from the commutator by the pointed barrier which has metal inserted in its face. This metal and the barrier

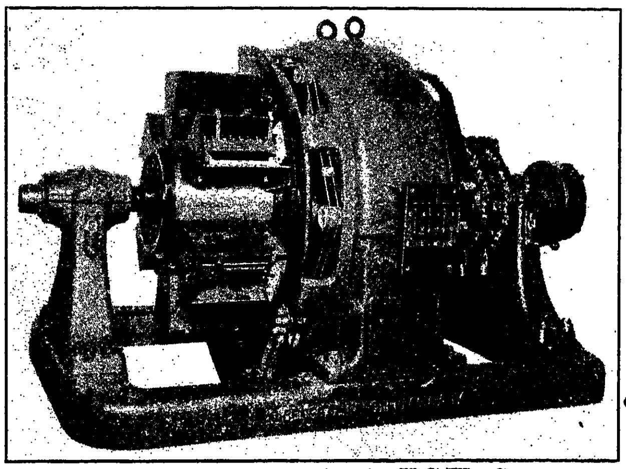

Fig. 2—Type H C C-6-500-1200-600 V C W Synchronous Converter

as a whole has a cooling effect, reducing the arc in volume and directing where it can do no harm by completing any further short-circuit paths. A second and third scoop shaped barrier are also provided as additional factors of safety in case of poor adjustment or defect of the first barrier. It is seldom that the second barrier is ever required to move any of the arc

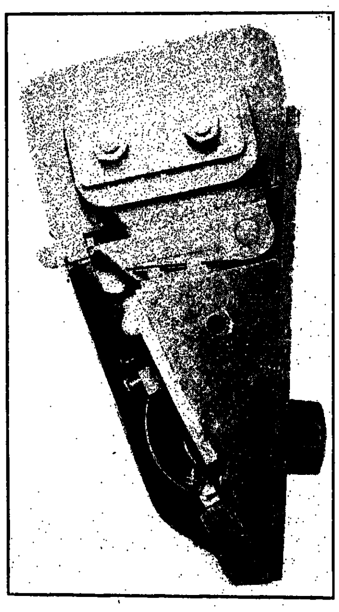

Fig. 3—Radial Brush Holder Unit Outer End Insulation Removed

from the commutator. The member at right angles and in front of the first barrier shown more clearly in the perspective splits the arc and confines that portion developed in the front of the two sections in their respective sections so they do not pile up at one corner, thus avoiding the escape of conducting gases under the side member. This form of barrier allows free expansion of gases, by proportioning the expansion chambers with increasing area at increasing distances from the commu-

tator. Furthermore, it being low, releases the gases quickly after changing their course and allows free dissipation in the open air.

As has been previously shown for the radial type of protected brush rigging, it is not sufficient to have the brushes and holders surrounded with the insulating materials. It has been demonstrated that the arc, when formed must be quickly lifted from the commutator or otherwise quickly and definitely disposed of to insure against interruption to service.

Fig. 7 shows a short circuit on two 750-volt, 60-cycle converters in series for 1500 volts, protected by flash barriers and circuit breaker of ordinary speed. The current was approximately 20 times full load. The exposure of the negative was throughout the short-circuit period. It will be seen that the arc is scooped

Fig. 4

from the commutator by the first barrier and thrown out almost radially where it can do no harm. Sixty-six of these short circuits were applied in succession and no appreciable burning or damage done that would prevent the machine from carrying its usual loads. The photograph is the 46th short circuit and is representative of all. This is probably the most severe short-circuit test ever applied to a commutating machine, the current in each of the 66 tests being about 20 times full load.

Fig. 8 is a side view looking down into the barrier, showing how the arc is confined to the first expansion chamber following the brushes. It is evident how the arc splitter holds the arc from moving sidewise.

As a-c. disturbances may also cause flashing, barriers are equally useful in such emergencies.

Fig. 9 is a short circuit of the same machine protected with barrier and high-speed breaker, two machines being operated in series at 1500 volts. It will be noticed that the high-speed breaker has so reduced the sparking unit that it is only slightly visible.

Fig. 10 shows the 750-volt, 60-cycle converter with flash guard removed after it had been subjected to 50 high-speed short circuits. The commutator, brushes, and barriers were unburned. The only mark indicating that short circuits had occurred were slight soot deposits.

Fig. 5—Radial Unit Type Rigging with Flash Barriers, 300 Kw., 60-Cycle Synchronous Converter

It will be noticed that the barriers have three point supports and may be quickly removed by unscrewing three nuts.

Fig. 11 is a view of 1500-kilowatt, 600-volt, 50-cycle machine with a different type of brush rigging undergoing short circuit with barrier and high-speed breaker protection. The total amount of sparking is completely visible and will be noticed as

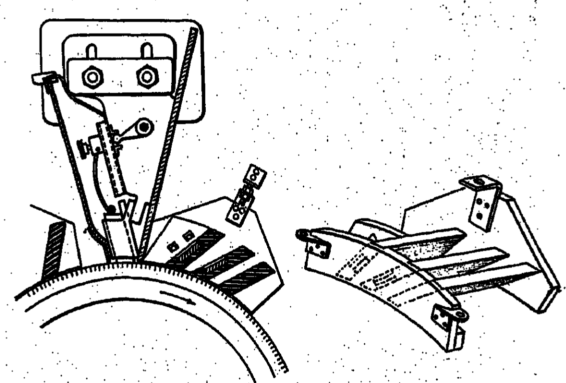

Fig. 6

a small triangular point of light. The barrier was not needed for protection in this case but is presented as a good view to show the construction.

J. J. Linebaugh: The conditions existing in d-c. generators and synchronous converters under load and short-circuit conditions are radically different, due to the interconnection of the a-c. and d-c. circuits so that commutating conditions are vitally

FIG. 7

affected and different remedies have to be used to produce a good commercial machine.

Figs. 9 and 10 in the paper show very clearly the reason for the flashing of a synchronous converter under rapidly decreasing load, due to opening of the circuit breaker and the great benefit obtained by the use of a high-speed circuit breaker. It is evident that the high-speed breaker removes the cause of the high voltage generated between bars as shown in Fig. 9, due to the fact that the short circuit is prevented from reaching a high value and reduced in a very short interval of time. The resulting ampere second load is so small and of such short duration that it does not cause great enough armature displacement to give sufficient voltage difference to hold an arc when the commutator bars move from one brush holder to the next.

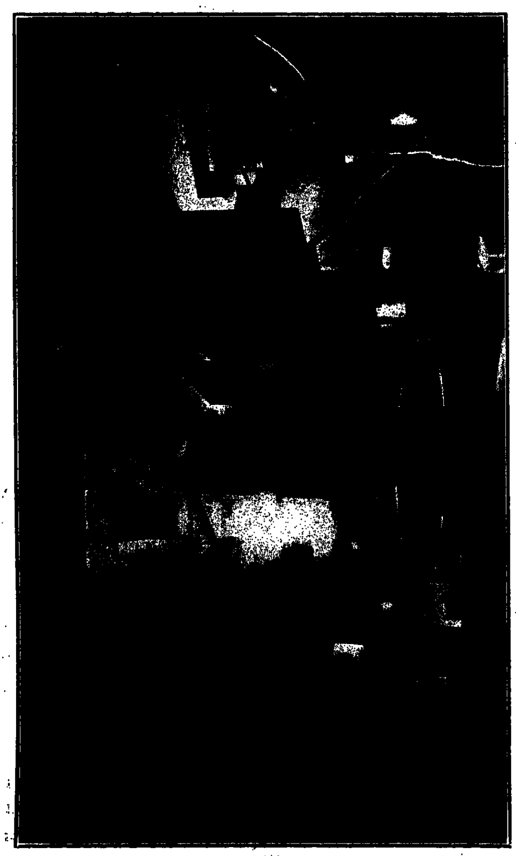

FIG. 8

FIG. 9—SHORT CIRCUIT ON TWO H C C 6-300-1200-750 VOLTS —TWO MACHINES IN SERIES 1500 VOLTS—EQUIPPED WITH FLASH BARRIERS. HIGH SPEED BREAKER SET TO TRIP AT 1400 AMPERES. MACHINES CARRYING NORMAL LOAD WHEN SHORT-CIRCUITED

The flash barriers described by Mr. Burnham are designed to take care of just such phenomena as described by Mr. Shand in Figs. 5 and 9, as the resulting arc is wiped off and raised above the commutator and cooled and dissipated so that the continued growth of the arc is suppressed. The long thin path between the barrier and commutator also tends to baffle the arc and the heat is extracted due to the cooling obtained from the barrier. If the arc should persist after the first barrier or hurdle, it has a chance to expand and the operation is repeated. Actual experience indicates that two of these hurdles are sufficient to stop practically any arcing which has been experienced. Tests indicate that a form of barrier such as described, designed to remove the arc quickly fr..m the commu-

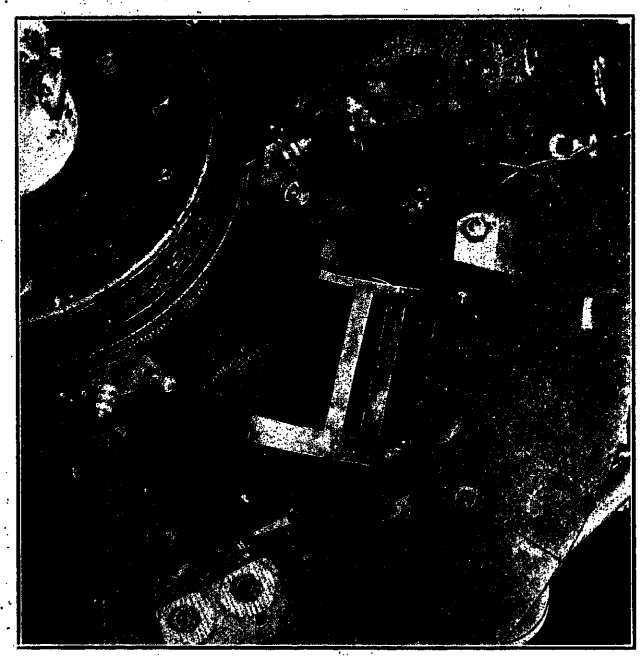

FIG. 10—TYPE H C C-6-300-1200-750 VOLT SYNCHRONOUS CONVERTERS WITH ONE BARRIER REMOVED AFTER 50 SHORT CIRCUITS, PROTECTED BY HIGH SPEED BREAKER

tator, is superior to the narrow barrier described by Mr. Shand. These barriers are applied to all machines above 750 volts, as standard practise, in addition to automatic substation machines, and have been very successful in actual operation for several years.

The 60-cyle 750/1500-volt machines shown by Mr. Burnham, have all the improvements in design developed during the last

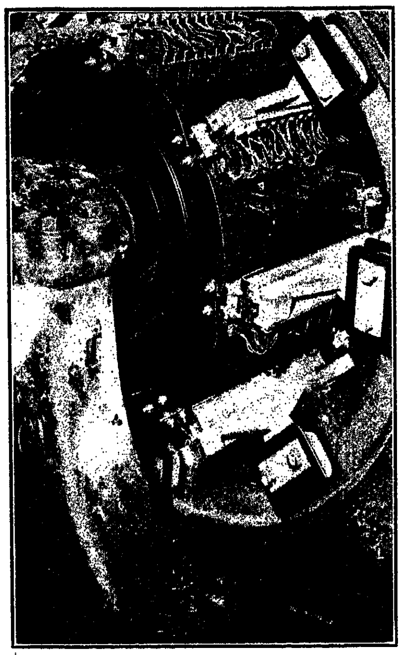

Fig. 11

few years and their behavior under test indicates that they are practically equal to the 25-cycle converter in every way.

Mr. Shand has not covered the effect of operating the rotary converter at poor power factor due to weak or strong shunt fields, and oscillograms similar to Figs. 5 and 9 would be of interest.

One advantage of the barrier, not brought out, is its ability to take care of flashing caused by a-c. disturbances of any kind. The high-speed breaker does not take care of this trouble, but the barrier prevents flashing over from such causes and the combination of the two types of protection as stated in the 1918 paper by Mr. Burnham and the writer, gives absolute protection under all short-circuit conditions.

E. B. Shand: The intention in writing this paper was not so much to set forth any new principles or any radical conclusions as to present the problem of converter flashing from a standpoint which has been in the past, it is felt, somewhat neglected. It has not been entirely neglected, for as Mr. Burnham has stated, most of the facts of the case have been stated at one time or another, but usually without proper correlation and seldom with any adequate experimental substantiation. The author, however, wishes to acknowledge a debt to the results of some unpublished work done by Mr. C. E. Wilson in 1910 under the direction of Mr. B. G. Lamme. This comprised tests and calculations on a converter in short circuit with reference to the inertia energy involved.

With respect to Mr. Burnham's references to the conclusions of my paper, these are not intended to be regarded as being a departure from present practise. All of the principles involved have been well recognized and to find the first developments of any one of them, it would be necessary to go back at least a decade.

The performance of the 750-volt, 60-cycle converters as shown in Fig. 7 of the paper is indeed striking. It is a demonstration of machines immune from destructive flashing under extreme, severe conditions. The result of a dead short-circuit test on the 500-kw. converter referred to in the paper is shown herewith, in Fig. 12. A circuit breaker of the ordinary type was used on this test, but the flash guards used were considerably simpler in form than those described by Mr. Burnham. The condition of the machine was, in fact, practically the same as for Fig. 9 of the paper except that it was completely short-circuited. The current rose to 22 times its normal value, at which point a flash of limited proportions occurred. The machine dropped out of step and later dropped back a second pole into step again. Spitting occurred in both instances, as

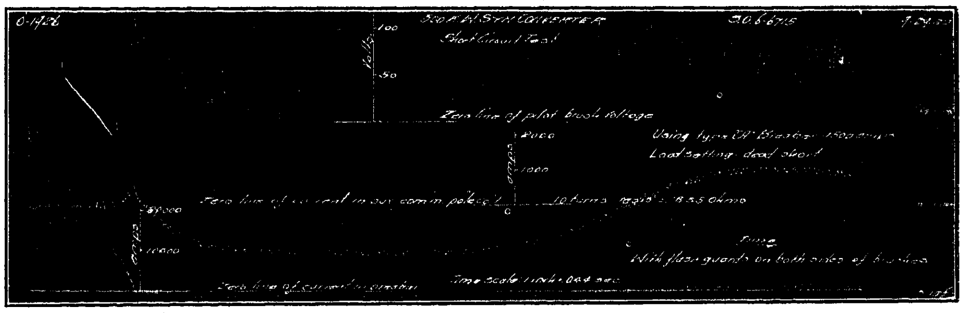

Fig. 12

would be expected, for the condition would be the same as synchronizing with the brushes down after starting. As may be seen from the oscillogram, the flashing was never destructive, and there was no injury done to the machine beyond a slight blackening of the commutator so that there was no reason why the machine might not have been put directly back into service.

In reference to the function of flash guards, I do not thoroughly agree with their principle of operation as given by Messrs. Burnham and Linebaugh. It is stated that the flash guard accomplishes its results by scooping the flash from the commu-

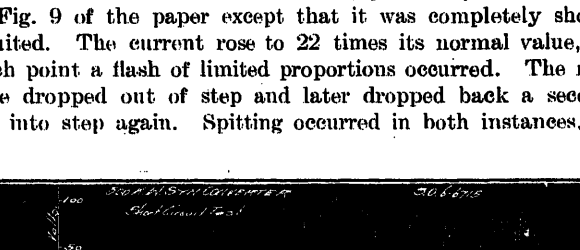

Fig. 13

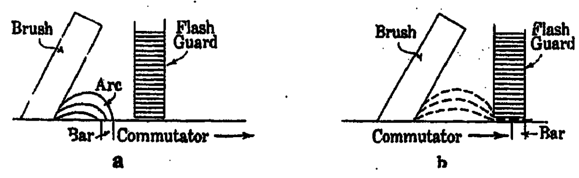

Fig. 14

tator; this may be true to a certain extent but to a greater extent it is the effect of choking off the core of the arc which makes it unstable and breaks it. For instance, Fig. 13, take the case of an arc struck between two electrodes, one electrode projecting through a plate of insulating material. If this electrode be now withdrawn, the arc is confined at one point to the dimensions of the hole, and if this be small enough the attenuation of the arc will quickly break it. When as one of these electrodes a bar passes under a guard, the arc is attenuated in the same manner and broken. (Fig. 14).

The Use of Superimposed Imaginary E. M. Fs. Currents, and Fluxes in the Solution of Alternating-Current Problems

BY VLADIMIR KARAPETOFF
Fellow A. I. E. E.
Professor of Electrical Engineering, Cornell University.

Review of the Subject.—*The solution of some advanced problems on alternating currents leads to rather complicated trigonometric transformations. Let now, in addition to the real sinusoidal currents and voltages, certain imaginary currents and voltages be assumed to exist in the same circuit. These imaginary quantities may be selected of such a magnitude and phase that together with the real quantities they will give simpler mathematical expressions than the real quantities alone. In the final results the real and the imaginary terms can be readily separated, because an imaginary voltage cannot produce a real current, and vice versa.*

This method is based on some remarkably simple properties of certain mathematical functions which contain a real and an imaginary term, as compared to the properties of similar functions containing real variables only.

The following two analogs may make this method clearer.

A. In order to make extremely fine platinum wire, a piece of heavier platinum wire is coated with silver and then passed successively through several dies until it is reduced to the smallest practicable size. Then the tubular coating of silver is dissolved in nitric acid. It would not be possible to draw platinum alone to the same size. Here the use of silver is analogous to that of imaginary quantities in alternating currents. Silver is carried along in the operations and separated in the end.

B. In the manufacture of common ether, sulphuric acid is combined with alcohol and carried through certain operations. In the end this sulphuric acid is separated and used over and over again. Sulphuric acid in this case may be likened to imaginary currents and voltages which are added to real quantities at the beginning of the problem and separated in the end.

The immediate occasion for the writing of this article was a paper by Mr. Gilman referred to under (2) in the article. Had Mr. Gilman used superimposed imaginary currents, several pages of tedious mathematical transformations could be saved.

A more general reason for writing this article was a desire to bring this method to the attention of American engineers. It is hardly mentioned in American text-books, while it is quite well-known in England and on the Continent of Europe. As is stated in the introductory paragraph to the article, the method is not new, and the examples quoted are too self-evident to claim any originality. A brief introduction to the method will be found in the author's "Electric Circuit," p. 97.

The importance of the method lies in the possibility of solving certain electrical problems in a shorter and more direct way, and possibly in making the solution of certain problems feasible which in the ordinary way lead to too complicated expressions. It is a mathematical tool, and as such should find its place among other useful mathematical methods used in the solution of physical and engineering problems.

CONTENTS

Object of Paper

The object of the following remarks is to show the advantage of using exponential expressions of an imaginary variable in the solution of various problems involving alternating currents. While the method is not new, and has been used by writers like J. J. Thomson for a number of years, it does not seem to be sufficiently well-known to American electrical engineers, who continue to use more cumbersome methods involving long trigonometric expressions. In order to show the wide scope of application of this method, three entirely different problems are solved below, namely:

(1) To find the current in a circuit containing a resistance, a reactance and a capacity in series. The solution is based on the superposition of an imaginary e. m .f. upon the given terminal voltage.

(2) To find the distribution of eddy currents in a rectangular conductor in an armature slot. The problem is solved by superimposing imaginary eddy currents upon the real ones.

(2) To find an expression for a gliding m. m. f. or flux due to a symmetrical n-phase system. A simple expression is found by adding imaginary m. m. fs. to the real ones.

General Considerations

Let an alternating voltage $E \cos w t$ be applied to an electric circuit and produce in it certain currents and fluxes (magnetic or electrostatic, or both). The usual theoretical investigation of such a circuit, even without the transient part, is somewhat unwieldy because some terms in the equations contain $\sin w t$ while others contain $\cos w t$. We shall assume therefore that an addition to the real voltage, $E \cos w t$, an imaginary voltage $j E \sin w t$, acts upon the same cir cuits, where $j = \sqrt{-1}$. The total "complex" voltage is

$$e = E \cos w t + j E \sin w t = E \exp. j w t \qquad (1)$$

where

Presented at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

$$\exp. j\, w\, t = \epsilon^{jw\cdot} \qquad (2)^1$$

The real part of the voltage $E \exp. j\, w\, t$ reaches its positive maximum at the instants $w\, t = 0$, $w\, t = 2\, ,\pi$ etc. The real part of the voltage

$$e = \exp. j\, (w\, t + \gamma) \qquad (1a)$$

reaches its positive maximum at $w\, t = -\, \gamma$, that is, it leads the first voltage by the angle γ. In practical applications it is sometimes convenient to write the second voltage also in the form $E \exp. j\, w\, t$, only in this case E is no more a real quantity but a complex constan tof the form $E \exp. j\, \gamma$, where angle γ must be given separately. Thus if in equation (1), E is understood to be a complex quantity, then the equation represents a system of two equal sinusoidal voltages of the same frequency, a real and an imaginary one, in quadrature with one another. The exponential part of the factor E gives the angle by which this system of two voltages leads a reference system in which the real part reaches its maximum at $t = 0$.

This simplification is of extreme importance because in many cases it allows us to dispense with the longer notation (**1a**) and to use the shorter notation (**1**), no matter what the phase of an alternating quantity might be. The proper phase is included in the complex expression for the amplitude.

A complex voltage (1) produces in the circuit a complex current, the real voltage giving rise to a real current, and the imaginary voltage to an imaginary current. We thus can express the total complex current as

$$i = I \exp. j\, w\, t \qquad (3)$$

where, generally speaking, I is a complex quantity out of phase with the complex voltage E. Expressions (1) and (3), when used in the equations of a circuit, give simple relationships among its constants *because any derivative or integral of the exponential function, exp. j w t, with respect to t, is equal to the function itself multiplied by a certain constant, and thus the exponential factors drop out of the result.*

1. *A Circuit Containing Resistance r, Inductance L, and Capacity C in Series.* The well-known differential equation of state is

$$L \frac{d\, i}{d\, t} + r\, i + \frac{q}{C} = e \qquad (4)$$

where q is the condenser charge. Differentiating with respect to the time we get

$$L \frac{d^2\, i}{d\, t^2} + r \frac{d\, i}{d\, t} + \frac{i}{C} = \frac{d\, e}{d\, t} \qquad (5)$$

Substituting the values of e and i from equations (1) and (3) in equation (5), gives

$$L\, j^2\, w^2\, I \exp. j\, w\, t + r\, j\, w\, I \exp. j\, w\, t + (I/C) \exp. j\, w\, t = E\, j\, w \exp. j\, w\, t.$$

The factor $\exp. j\, w\, t$ may be canceled on both sides of the equation, and we get

$$I\, [-\, L\, w^2 + j\, r\, w + I/C] = E\, j\, w.$$

Multiplying both sides by $-\, j$ and dividing by w this expression is brought to the usual form

$$I\, [r + j\, (L\, w - 1/C\, w)] = E \qquad (6)$$

from which the well-known expressions for the impedance, z, and the phase displacement, ϕ, of the circuit may be derived. Namely, put

$$\left.\begin{aligned} r &= z \cos \phi \\ L\, w - \frac{1}{(Cw)} &= z \sin \phi. \end{aligned}\right\} \qquad (7)$$

Equation (6) then becomes

$$I\, z \exp. j\, \phi = E \qquad (8)$$

which means that numerically the voltage is equal to the current multiplied by z, and leads the current by the angle ϕ. The whole treatment does not involve the use of the expressions $\sin w\, t$ and $\cos w\, t$ at all.

2. *The non-uniform alternating-current density* Δ *in an embedded armature conductor of rectangular cross-section* is expressed by the partial differential equation

$$\tfrac{1}{2}\, w \frac{d^2\, \Delta}{d\, x^2} = \alpha^2 \frac{d\, \Delta}{d\, t} \qquad (9)$$

in which $w = 2\, \pi\, f$ has the same meaning as before, α is a physical constant, t is time and x is the distance from a reference plane. For a derivation of this expression see for example R. E. Gilman, "Eddy Currents in Armature Conductors," A. I. E. E. TRANSACTIONS, 1920. We are not concerned here with the proof of this equation but merely with its solution using imaginary currents. With a sinusoidal applied voltage, the current density in each layer $d\, x$ varies according to the sine law with the time, but is different in amplitude and in phase from layer to layer. Superimposing in each layer a quadrature imaginary current upon the real current, we may put the complex current density in the form

$$\Delta = u \exp. j\, w\, t \qquad (10)$$

where u is a complex function of x and takes into account the distribution of the current in the cross-section of the conductor. Substituting the value of Δ from equation (10) in equation (9) and cancelling the exponential term, we get

$$\frac{d^2\, u}{d\, x^2} = 2\, j\, \alpha^2\, u \qquad (11)$$

This differential equation does not contain time and is much simpler than the original equation (9). The well-known solution of equation (11) is

1. In this article the notation $\exp. j\, w\, t$ is used in place of the usual exponential notation, because the first form is better adapted to the modern mechanical typesetting. While the difference may not be of importance in a mathematical deduction in which exponential terms occur infrequently, it seems preferable to use the straight "lower case" notation in the following problems because the formulas are predominantly of the exponential type and the principal transformations occur in the exponents. We are used to the expression $\log x$ and there is no reason why the inverse function, $\exp. x$, should not be written without using superior letters.

$$u = P \exp. \beta x + Q \exp. (- \beta x) \quad (12)$$

where P and Q are complex constants of integration, and

$$\beta = (1 + j) \alpha = \alpha \sqrt{2 j} \quad (13)$$

Thus, the complex flux density is

$$\Delta = P \exp. (\beta x + j w t) + Q \exp. (- \beta x + j w t) \quad (14)$$

Separating the real part of this expression from the imaginary, a formula is obtained for the true current density in the conductor, at any instant t and at any point corresponding to the distance x. A perusal of Mr. Gilman's article will readily show the advantage of the above method as compared with the use of long trigonometric expressions which lead to simultaneous equations.

3. *Polyphase Gliding Magnetomotive Force.* It is known to students of polyphase machinery that n *alternating* sinusoidal magnetomotive forces of amplitude M each, differing in time by $2 / \pi n$ from each other and shifted in space by $2 \pi / n$, produce a uniformly *gliding* magnetomotive force of amplitude $\frac{1}{2} n M$. See, for example, E. Arnold, *Wechselstromtechnik,* Vol. III (1912), p. 241. The usual proof may be simplified by superimposing imaginary magnetomotive forces upon the real. To simplify the formulas further we select such a unit of time that one cycle of current takes place in 2π units of time. Then variations of a magnetomotive force with the time are expressed by the factor $\cos t$, because $w = 1$. Similarly we select such a unit of length that a complete wave of magnetomotive force occupies 2π units of length. The variations of the m. m. f. in space are then expressed by the factor $\cos x$. Thus, an instantaneous m. m. f. due to the first phase, at a point x and at an instant t is

$$m' = M \cos t \cos x \quad (15)$$

We now superimpose upon this m. m. f. an imaginary m. m. f in time quadrature and in space coincidence with it, that is, one of the form $j M \sin t \cos x$. We then get the following *complex* wave:

$$m = M \cos x \exp. j t \quad (16)$$

But according to a well-known formula of trigonometry of complex angles

$$\text{Cos}\, x = \tfrac{1}{2} [\exp. j x + \exp. (- j x)] \quad (17)$$

so that equation (**16**) becomes

$$m = \tfrac{1}{2} M [\exp. j (t + x) + \exp. j (t - x)] \quad (18)$$

The factor $\cos (t + x)$ corresponds to a wave gliding synchronously towards decreasing values of x (say to the left), while $\cos (t - x)$ corresponds to a wave gliding towards increasing values of x (to the right). See for example the author's "Magnetic Circuit," p. 126. Thus we obtain the well-known result that a pulsating m. m. f. or flux of amplitude M may be resolved into two oppositely gliding m. m. fs. or fluxes, each of amplitude $\frac{1}{2} M$.

We now shall consider the real m. m. f. in each phase as being supplemented by a quadrature imaginary m. m. f. wave, and the resulting complex pulsating wave resolved into two oppositely gliding waves, as before. By analogy with equation (**18**), the expressions for these waves will be as follows:

$$\left.\begin{aligned} m_1 &= \tfrac{1}{2} M \exp. j (t + O + x + O) \\ &\qquad + \tfrac{1}{2} M \exp. j (t + O) - (t + O) \\ m_2 &= \tfrac{1}{2} M \exp. j(t + \delta + x + \delta) \\ &\qquad + \tfrac{1}{2} M \exp. j [(t + \delta) - (x + \delta)] \\ m_3 &= \tfrac{1}{2} M \exp. j (t + 2 \delta + x + 2 \delta) \\ &\qquad + \tfrac{1}{2} M \exp. j [(t + 2 \delta) - (x + 2 \delta)] \\ &\text{etc.} \qquad\qquad \text{etc.} \end{aligned}\right\} \quad (19)$$

In these expressions the angle δ represents both the time and space displacement between two adjacent phases, that is,

$$\delta = 2 \pi / n \quad (20)$$

To find the resultant m. m. f. due to all the n phases, we have to form the sum of $m_1 + m_2 + m_3 +$ etc. It will be readily seen that δ disappears in all the second terms on the right-hand side of the equations (**19**). All these terms are equal to each other and their sum is equal to $\frac{1}{2} n M \exp. j (t - x)$. The sum of the first terms on the right hand side is equal to zero because

$$1 + \exp. j 2 \delta + \exp. j 4 \delta + \text{etc.} = 0 \quad (21)$$

In order to see this, think of 1 in equation (**21**) as representing a unit vector. Then $\exp. j 2 \delta = \cos 2 \delta + j \sin 2 \delta$ represents a unit vector turned with respect to the first one by the angle 2δ. See the author's "Electric Circuit," p. 94. Similarly the term $\exp. j 4 \delta$ represents a unit vector at an angle 4δ with the first, or forming the angle 2δ with the second, etc. Thus, equation (**21**) represents a geometric addition of n unit vectors, each turned with respect to the preceding one by the same angle $2 \delta = 4 \pi / n$. Graphically such a sum corresponds to a regular closed polygon, that is, the sum of the vectors is equal to zero, whether n is an odd or even number.

Having proved equation (**21**) we apply it to the sum of the first terms on the right hand side of equations (**19**) by factoring out $\frac{1}{2} M \exp. (t + x)$, and thus show that the result is equal to zero. Consequently, the whole polyphase m. m. f. is due to the second terms and we may write:

$$\text{total complex m. m. f.} = \tfrac{1}{2} n M \exp. j (t - x) \quad (22)$$

The imaginary part may now be dropped, and we obtain the following final result:

$$\text{total real m. m. f.} = \tfrac{1}{2} n M \cos (t - x) \quad (23)$$

The resultant m. m. f. in this case is gliding to the right because the exciting currents have been assumed to lag in the consecutive phases from left to right. With an opposite assumption the resultant m. m. f. would glide to the left.

Discussion

R. E. Doherty: The scheme presented in this paper is highly useful, not only to electrical engineers, but also to mechanical engineers—indeed, useful in any problem which involves sine functions of time and in which the transient term is not of importance. And even if the transient is important, the particular solution of the permanent condition can be written down easily by this method. Making this possible, it certainly must be regarded, as the author says, a useful engineering "tool."

The paper does not emphasize sufficiently either the utility or the limitations of the scheme. For it is merely a scheme like other mathematical schemes, such as Heaviside's Operator, which works in some cases and not in others.

Of the three types of problems illustrated in the paper, the first is, I think, the most important in respect of the number of problems encountered in engineering, although of course its value in the rarer types 2 and 3, is also shown. And it is the former type to which the application of the method is the simplest. The author reviews how the addition of an imaginary term of equal magnitude to the real term, that is by the addition say of

$$j\, E \sin (\omega\, t + \gamma)$$

to

$$E \cos (\omega\, t + \gamma)$$

gives the vector identity,

$$E\, [\cos (\omega\, t + \gamma) + j \sin (\omega\, t + \gamma)\,] = E\ \epsilon^{j(\omega t + \gamma)}$$

that is, a vector of constant magnitude and rotating by the time angle $\omega\, t$. Making a similar addition to each sinusoidal time variable in the problem, and substituting in the differential equation gives,[1] as each term, the product of a scalar quantity and a unit vector of the exponential form

$$\epsilon^{j(\omega t + \gamma)}$$

But $\epsilon^{j(\omega t + \gamma)} \equiv \epsilon^{j\gamma}\ \epsilon^{j\omega t}$

By thus separating out the time angle unit vector $\epsilon^{j\omega t}$ in each term, the vector may be canceled out of the equation, leaving only the product of a scalar, say E or I, and a stationary unit vector $\epsilon^{j\gamma}$ or $\epsilon^{j\alpha}$, where γ and α are phase angles of these vectors with respect to a common reference. The process therefore starts with the problem expressed as trigonometric functions of time, and ends with the problem represented as a system of staionary vectors.

Following out the process as applied to equation (5), gives

$$j^2\, \omega^2\, L\, I\ \epsilon^{j\alpha} + j\ \omega\, r\, I\ \epsilon^{j\alpha} + I/C\ \epsilon^{j\alpha} = j\ \omega\, E\ \epsilon^{j\alpha}$$

Taking voltage as zero vector, and substituting $j^2 = -1$,

$$-\ \omega^2\, L\, I\ \epsilon^{j\phi} + j\ \omega\, r\, I\ \epsilon^{j\phi} + I/C\ \epsilon^{j\phi} = j\ \omega\, E\ \epsilon^{j\phi}$$

where ϕ = phase angle between voltage and current.

Using vector notation,

$$\dot{E} = E\ \epsilon^{j\phi}$$

$$\dot{I} = I\ \epsilon^{j\phi}$$

and solving

$$\dot{I} = \frac{\dot{E}}{r + j\,(\omega\, L - I/\omega\, C)}$$

which is equation (6). But it should be remembered that E in (6), although the same notation as in (1), is nevertheless a vector in (6), but scalar in (1).

From the foregoing equations, it is obvious that *the process is equivalent to the substitution, directly in the differential equation, of*

$$\frac{d}{d\,t} = j\ \omega$$

and writing the variables as vectors.

That is, representing $\frac{d}{d\,t}$ by the usual notation p,

$$p = j\ \omega$$

$$p^2 = -\ \omega^2$$

$$p^3 = -j\ \omega^3 \quad \text{etc.}^2$$

1. Since either the differential or integral of an exponential is again the exponential.

2. This was proposed in 1917 by Mr. A. Press in discussion of paper by V. Bush on "Oscillating Current Circuits," A. I. E. E., Vol. 36, p. 207.

In other words, the solution is immediately written down without, in each case, going through the process of substituting the imaginary term: which process, I fear, may appear to be necessary both from the text and the analogs given. The possibility of the above direct substitution would not, I think, be obvious from the paper to most engineers unfamiliar with these forms.

As to the limitations of the method: none is stated except that the variables against time shall be sinusoidal; but there are limitations which I believe are not obvious. A mathematical equation is applicable only under the assumptions it contains. In the present case, the fundamental assumption is that imaginary terms shall remain imaginary, and real terms, remain real. Thus no products must appear, since two imaginary terms multiplied together give a real product. I would therefore ask the Author: since in the method, each variable contains an imaginary component, does it not follow that, unless new definitions are added, the method is applicable only to *linear differential equations involving sinusoidal functions of time*; that is, it is *not* applicable, without new definitions, to equations involving products of variables, or products of a variable with the differential coefficient.

I mentioned at the outset thatthe method is useful in mechanical engineering problem. An illustration is the design of flywheels for reciprocating engines or compressors connected to synchronous machines. The equation[3] of the system of forces is

$$I\ \frac{d^2\ \theta}{d\ t^2} + T_d\, \frac{d\ \theta}{d\ t} + T_s\ \theta = f\,(t)$$

where

I = moment of inertia of rotating masses.

θ = mechanical angular displacement from a reference, rotating at the average, or synchronous, speed.

T_d = damping torque, corresponding to a phase shift at the rate of 1 mechanical radian per sec.

T_s = synchronizing torque, corresponding to one mechanical radian displacement.[4]

$f\,(t)$ = applied force as function of time. It is the fluctuating component of the crank effort; that is, the difference between the total impressed torque and that which is consumed as load and friction. Although of complicated form, it is resolved into a Fourier's Series, and each sinusoidal component considered separately.

Thus applying the method proposed in the paper,

$$-\,I\ \gamma_n^2\ \dot{\theta} + j\ \omega_n\, T_d\ \dot{\theta}_n + T_s\ \dot{\theta}_n = \dot{T}_n$$

where $\dot{T}_n$ and $\dot{\theta}_n$ are respectively the vector force, and vector displacement angle of the nth harmonic. Thus

$$\dot{\theta}_n = \frac{\dot{T}_n}{j\ \omega_n\, T_d + (T_s - I\ \omega_n^2)}$$

the phase angle between the force and displacement being

$$\phi = \tan\ \frac{\omega_n\, T_d}{T_s - I\ \omega_n^2}$$

Each component is thus computed, and plotted as waves to determine maximum.

I therefore consider the method proposed in the paper as a very important mathematical device, and have hoped by this discussion to encourage its greater use.

J. B. Whitehead: Methods of solution of differential equations are of especial interest in two connections, one when a new type of equation presents itself for solution, and the other when teaching the phenomena whose sequence is expressed by the form of the equation.

The complete solution of the simple a-c. circuit, the first example used by Professor Karapetoff in calling attention to the

3. Equation (1) in paper on Flywheels, A. S. M. E. December 1920, by R. E. Doherty and R. F. Franklin.

4. Obviously no such displacement could occur within operating limits. It is simply a proportionality factor which holds approximately in the limits considered.

method of superposed imaginaries as an aid to solution, has been known for years. Consequently its chief value here must be only as an illustration of a mathematical method. However, there is an element of danger in the use of the method in this case, since it does not lead to the complete solution of the equation of the simple a-c. circuit. The transient term on closing the circuit does not appear and is neglected. As is well known, there are many instances in practise when this term is of great importance. Professor Karapetoff clearly recognizes this, and will doubtless reply that the exponential form may also be used for the complete solution, but in this case, as he well knows, all the simplicity of method to which he calls attention disappears. Therefore, for the purposes of teaching, in this case the method appears to me to have little value and, in fact, to be open to criticism. Its brevity and simplicity make a powerful appeal, but it does not completely cover the problem. While I have had the method in my notes for a number of years, as have many other teachers of this subject, I have avoided using it, feeling that in doing so I would shirk a measure of responsibility in not giving the complete solution.

In the second example the author is on very much surer ground. He presents an apparently new equation which demands solution. Here the simplicity of the method has apparently facilitated the solution, leading to conclusions which it was possible to check in practise. I have not read the original paper describing the experiments and I think it would be of interest if Professor Karapetoff would say a further word as to the agreement between the results to be expected by the solution of the equation and those noted in actual observation.

In the third case we have again a problem whose solution has been known for some time. The method therefore should be considered from the point of view of its usefulness in explaining the phenomenon involved. I confess that I do not see its value for obtaining the intensity of a gliding or rotating magnetic field due to a polyphase system of electromotive forces. The various transformations through which the author has to proceed in order to obtain the result, seem to me to confuse the comparative simplicity of the physical relations underlying the type of field in question as related to the circuits setting it up. By use of the ordinary complex expressions for the several electromotive forces, and their successive resolution into two directions in space, lead to simple series for the two sets of components which can be immediately evaluated in single terms. This method described by Steinmetz in one of his early works has the advantage of keeping clearly before us the simple elements of the exciting circuits and the resulting magnetic intensity.

Thus, while recognizing the simplicity and beauty of the method as applied to new unrecognized problems, I question its value for the purposes of explaining the phenomena represented by the equations.

P. Trombetta: The fundamental principle upon which all calculations of electric circuits are based, is that the constants of the circuit remain unchanged after an e. m. f. is applied to it. In Prof. Karapetoff's exposition it is tacitly assumed that the constants of the circuit remain also unchanged if we apply, instead of a real e. m. f., a complex one and since the application of a complex e. m. f. yields an easier solution, it is better to study the circuit by the application of a complex e. m. f. rather than a real e. m. f. If we replace the word e. m. f. by the word force, which may mean any kind of force whatsoever, and if we replace the word circuit by the word system, we have the generalized theorem that: the study of a system, which by the application of a force gives rise to oscillations and losses of energy, is always simpler when the force applied is sinusoidal and can be expressed as an exponential function of time.

W. V. Lyon: If I understand Prof. Karapetoff correctly he is, in effect, making a plea for the vector method of solving alternating-current problems rather than that method in which the instantaneous values of the quantities are represented by trigonometrical expressions. As a mechanism for solving problems in which the electromotive forces and currents vary sinusoidally a comparison of the methods soon convinces one of the superiority of the vector method. Unfortunately, as Prof. Karapetoff says, it is not widely appreciated to what extent the vector method may be used. We are all familiar with its application to the steady conditions in simple electric circuits and in a-c. machinery, and perhaps to a lesser degree, in long transmission lines. Moreover, it is exceedingly useful in the solution of the current distribution in round wires or in rectangular armature conductors, and of the flux distribution in transformer laminations. In these cases the angular velocity of the vectors is a real number. The letter "ω" is usually used. Rather recently it has been appreciated that the vector method can also be applied to the solution of the transient conditions that are obtained in transformers, synchronous and induction machines. This latest application gives an exceedingly powerful and simple method of attack. In the problem of the transient condition the angular velocities of the vectors are not real, but may be represented by complex numbers of the form $(-\alpha + j\,\omega)$. The ω gives the real angular velocity of the vector and the α determines the rate at which it shrinks exponentially.

While Prof. Karapetoff has made no direct plea for the vector method the writer has so chosen to interpret his argument. The symbolism $E\,\epsilon^{j\omega t}$ has been used to represent a rotating vector by mathematicians for many years, long before the notation was introduced into electrical engineering. There are, moreover, other simpler and just as powerful vector notations. The solution for the current density in rectangular armature conductors is very simply expressed in terms of hyperbolic functions, more simply the writer believes than in the manner Prof. Karapetoff suggests.

If we assume that the applied e. m. f's. vary sinusoidally, with either constant or damped amplitudes, and the circuit constants do not vary, all resulting currents will vary sinusoidally as do the applied pressures. In such a case we might well agree that it was superfluous to indicate this obvious variation. There can be no doubt but that this apparent lack of any convention to represent sinusoidally varying currents and pressures is extremely simple.

The writer looks upon it as fortunate that we have a variety of symbolisms that may be used in the solution of problems inasmuch as the student may choose for himself the method that best suits his understanding. Those who are not familiar with the notation that Prof. Karapetoff presents are thus indebted to him for bringing to their attention so powerful a method. After all, the best mechanism for the individual student to use in solving problems is that which is not only simple to manipulate but which keeps before him most clearly the physical reactions involved.

V. Karapetoff: Mr. Doherty is right in saying that in practical applications, in linear differential equations, is it perfectly safe to use $j\,\omega$ in place of $d/d\,t$ and $-\omega^2$ in place of $d^2/d\,t^2$.

This is, however, not a substitute method but a direct result of expressing the current as an exponential function. In equations involving products of complex quantities, if one of the quantities is simply an exponential impedance operator which does not contain time, the method is still applicable. But if an equation contains a product of an exponential current and an exponential voltage, the result is a double frequency power and a constant average power. A new convention is then necessary as to the interpretation of the results.

Dr. Whitehead doubts the advantage of the exponential notation when the transient term is not negligible. He will find Section IV of Dr. Steinmetz's book on "Transient Phenomena" treated in the exponential form to a good advantage. As to the third illustration in my paper, E. Arnold in his Wechselstromtechnik solves the same problem by means of sine and cosine functions, and I believe that a comparison will show a decided advantage in favor of the complete notation.

Questions on the Economic Value of the Overhead Grounded Wire

BY E. E. F. CREIGHTON

Associate A. I. E. E.

General Electric Company, Schenectady, New York

Review of the Subject.—*Overhead grounded wires have been in extensive use since the construction of the earliest transmission circuits. The fundamental theory of their protective value is based on Faraday's ice-pail experiment. As the resulting law goes, there is no electrostatic field emanating from the inner surface of a charged hollow conductor. The parallel grounded wires do not surround the power wires. Consequently the protection of these grounded wires against induced electric charges by thunder-clouds, is only partial—usually of the order of 25 to 40 per cent.*

It might be erroneously inferred that several decades of use of the overhead grounded wire had established by practise its value. The several factors involved in its use do not lend themselves easily to experimental observations. For example, power lines extend over hundreds of miles, while any particular induced charge is localized at some point in these vast distances. Taking into account the brief period of a lightning stroke, the unwilling observer stands a small chance of being near the point of discharge. Furthermore, thunder-clouds differ from one another. Still further, at the instant the lightning bolt takes place the distance from the thunder-cloud to the power wires varies quite indefinitely. In fact, there is a long list of difficulties involved in experimental observation of the effect of cloud lightning on power wires. As a result, except for a few small-scale experiments performed in the laboratory, knowledge of the subject is confined almost entirely to theoretical analyses. This paper is an addition to the theory but it is not of a mathematical nature.

Conditions of protection have changed in recent times. Therefore, in this paper the definite conclusion is drawn that the expense of overhead grounded wires on wooden pole lines is, in general, an economic waste. In particular cases it may be justified. On metal tower construction the use of the overhead grounded wire is, in general, fully justifiable.

The analyses in this paper were made for presentation to a Public Service Commission. This Commission, on reconsideration, reversed its order that an overhead grounded wire should be installed on a 13-kv. transmission circuit supported on a wooden structure.

Review of New Material. — *References to the technical literature on the subject of overhead grounded wires are given in the bibliography which follows the paper. For those familiar with the subject there is given below a brief review of several parts of the paper which emphasize the recent additions to the knowledge of the subject.*

1. Analysis of the functions of the overhead grounded wire under nine distinct parts, where previously only three functions were classified.

2. Recognition that the requirements of the overhead grounded wire are less than formerly. In the early days the overhead grounded wire was needed to assist lightning arresters, but today the arresters have sufficient discharge rate not to require the assistance of the grounded wire.

3. Analysis which points out that the overhead grounded wire protects only for a specifically limited range of voltage. It is no protection for induced voltage below the normal arc-over value of the insulator, and no protection when the induced lightning voltage is sufficient to arc-over the insulator in spite of the presence of the grounded wire.

4. Appraisal of the weight to be given to each of the nine functions of the overhead grounded wire and considerations of its cost lead to the conclusion that, barring exceptional cases, it is an actual detriment when placed on semi-insulating structures, such as wooden pole lines. Used here the overhead grounded wire lowers the arc-over voltage of lightning.

5. The overhead grounded wire with considerable sag cannot be considered as a mechanical support to rigid tower structures.

6. Analysis is given to show that the overhead grounded wire on a metal tower line loses its function in protecting arc-over of insulators in proportion to the earth resistance at the legs of the tower. Experimental proof is not available at present. Also the values of ohmic resistance at tower legs which will destroy the protective value of the grounded wire to prevent arcing over insulators are not available. Metallic connections of a tower of high earth resistance to an adjacent tower of low earth resistance have little if any beneficial effect in protecting the insulator from lightning. The horizontal distance is too great.

7. On a grounded neutral system experimental tests of a short circuit of a single phase showed the necessity of connecting the overhead grounded wire to the station earth connection to reduce the earth resistance to a safe value. Otherwise the neutral rose so high in voltage during short circuit as to jump-spark into the low-voltage wiring of the station, blowing fuses and affecting the switch control.

8. Looking to the future, the overhead grounded wire, by lowering the general resistance to earth of all towers to the passage of accidental short-circuit current (of the generator, not lightning) will have a valuable function in connection with arc-suppressors. This function is really the one already recognized as an aid to proper operation of relays.

A General Conclusion.—As applied to metal structures the analyses do not bring out any detrimental function of the overhead grounded wire. It is not condemned in this use but attention is directed to some of its limitations. Further study is desirable. The cost of the overhead grounded wire is a considerable factor. At maximum it now seems that for many or most cases one grounded wire only may be needed. Exceptional cases and conditions must be decided by detailed considerations.

CONTENTS

Presented at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

Definitions

The term "overhead grounded wire" is currently used to mean the extra wire, grounded at many or all of the supports, that is strung parallel to the power wires on an overhead transmission. The "aerial grounded wire" has also come into use to mean the same.

"Overhead" is a term more commonly used by electrical engineers of transmission lines than "aerial" as applied to grounded wires. Aerial, perhaps, is the more general term. "Overhead" usually carries the idea to most people as being above the power wires although it means literally above the head. Overhead may, therefore, mean literally underhung or overhung relative to the power wires.

The vertical grounded wire—the connection between the overhead wire and the earth contact—is used on wooden poles or other types of semi-insulators. As such it is sometimes referred to as the pole wire.

Earth connections are the metallic parts extending into the earth. The earth connection may be in the usual forms of tower legs, driven pipes, or coiled wire around the base of a wooden pole.

The lightning rod is any projection of conductor in the vertical plane above the horizontal grounded wire.

In review, the four parts are: 1, horizontal overhead grounded wire; 2, vertical grounded wire; 3, earth connections; and 4, lightning rod (seldom used).

Historical

It is not the object here to trace the growth of use of the overhead grounded wire but simply to bring out some salient points and to give a bibliography of the scientific discussions of this subject. The earliest overhead grounded wires were barbed wires, such as used by farmers. The Bessemer steel used in this wire (when used in the relatively long spans between poles) was so unreliable in mechanical strength that the wire gave much trouble from breaking and short-circuiting the power wires. It was early recognized that *the barbs on the wire had no practical value in giving protection against lightning strokes*. There was erroneous theory advanced by lightning rod experts that point discharge by corona materially lessened the danger of direct stroke. The theory seems unreasonable.

There have been few attempts to prove practically the value or uselessness of the overhead grounded wire but none of these has been convincing unless perhaps one instance given in a recent N. E. L. A. report, because of the variableness in the lightning storms and the impossibility of getting an exact comparison by any of the data collected. The reasonable basis of the good effects of the overhead grounded wire has resided mostly in the theoretical consideration. It is a comparatively simple matter, although laborious, to calculate the quantity of electricity induced on a transmission wire with and without a parallel grounded wire. These figures are quite definite. The theory has been substantiated by electrostatic measurement. While it was formerly the opinion of the majority of leading electrical engineers that the overhead grounded wire fully warranted its cost under certain conditions of installation and for a definite range of voltage, it is well, nevertheless, to make note of the fact that the practise is not founded on definite experimental knowledge of the actual installations. There are many doubters of its value nowadays.

Introductory—Mechanical vs. Electrical Factors

The primary requisite of an aerial electrical line is to be ready to supply electrical power continuously. To do this two natural and fundamental conditions must exist, namely that the line must be suitably insulated to withstand all impressed voltages and, second, that it must be mechanically durable. The mechanical durability involves the mechanics of material, their strength, characteristics, etc. While the factors involved in the mechanical side of the line construction are of prime importance, it is not the object in the present discussion to treat of them except as the type of mechanical construction influences directly the dielectric strength of the insulation. To confine the discussion as much as possible to the electrical side, it is assumed initially that due weight has been given to all the engineering factors and the choice has been made of construction with porcelain, glass, wood, cement, concrete (with or without reenforcing), or steel, together with such impregnating or painting treatment as the conditions demand. The mechanical structure may then be analyzed into types according to the insulation it affords against electrical failure. Steel structures represent one type, wooden poles represent the other.

The prime object of the present discussion is to treat the electrical side, especially in the matter of insulating against lightning and the line potentials. The specific subject to be treated is indicated by the title, "Overhead Grounded Wires." It is of course, impossible to treat of the aerial wire by itself, as the whole aerial system of electric wires and supports must be taken into account as in any engineering structure. The first question we must ask ourselves, then, is: What is the object in using an overhead grounded wire?

The answer to this question differs now from what it was in earlier days of transmission. This fact is one of the excuses for this paper. In early days lightning arresters were uncertain and of low discharge rate. Insulation was weak and not wisely distributed. As a result, the overhead grounded wire was desirable to lessen the duty on lightning arresters. This necessity has disappeared. While it is not claimed that the proper value of discharge rate for an arrester is

exactly known for every application, each arrester of the valve type is capable of adjustment to a much higher value than used at present which, in the limitations of present knowledge, seems to be sufficient.

Speaking from the electrical standpoint solely, a partial answer sometimes made is: To lessen the electrostatic induction on the power wires caused by thunder-clouds. Faraday in his "ice pail" experiment showed that no electrostatic lines of force extend into a closed conductor. The earliest writers on protection of lines state that if an aerial transmission line could be entirely surrounded by a metallic sheath, such as is done with the lead encasing sheath of an electric cable, no electrostatic induction from the clouds on the power wires could take place. Such a construction has not been found economically feasible. An amelioration only of the induced voltage has been gained by the use of one to three aerial grounded wires. Lead-encased aerial cables are common practise in telephone construction. In power transmission such practise is limited by the cost of electric cables and the difficulties of obtaining suitable insulation material for very high voltages.

A more complete analysis than has previously been given of what can be expected of overhead grounded wires follows. It is not the ultimate of the possible detail analysis but is made from the viewpoint of the engineer in the process of determining the need, the value, and the desirability of this protective device.

Functions of the Overhead Grounded Wire

The functions of the overhead grounded wire may be put into nine main divisions, as follows:

1. *To reduce the quantity of electricity and the energy induced on the power wires by a lightning cloud and to reduce the voltage of a traveling wave* (with its energy located between lines and ground) which was previously the "bound" charge held by the electric induction from the overhanging thunder-cloud. This function reduces the charge and energy that reach the apparatus and arresters. In the usual location of the overhead grounded wire it gives no appreciable protection against those internal surges which have their energy located between power wires.

2. *As a protection of insulators against flash-over.* This second category is to be distinguished from the first, especially in such a respect as involves the time. If flash-over takes place it should happen while the surge energy is crowded toward a point on the line, a time presumably coincident with the movement of charges in the cloud, and not after the charge splits into two parts and travels away from this point. This theoretical matter will be taken up again under the heading "Steel Structure."

3. In some cases the use of the *overhead grounded wire as a mechanical support between towers* is of greater value than its electrical protective functions. Occasionally, however, during sleet storms accompanied by transverse winds it is a disadvantage in throwing an extra side pressure onto the towers. Even its value as a longitudinal mechanical support for rigid towers is questioned later.

4. The overhead grounded wire has in some cases a very useful function in *forming a low-resistance earth connection.* There are four aspects to this factor: (a) As a uniform earth connection the parallel grounded wire may be used in *localizing faulty insulators.* (b) Where the neutrals of the power circuits are grounded the lesser resistance of earth connection is an aid *during accidental single-phase short circuits in preventing a rise in voltage of the station ground* and consequent damage to the low-voltage wiring of the stations, including circuit-breaker control, lights, excitation, etc. This is an important function only recently recognized. Some experimental experiences will be described at some future time. (c) Where towers are set in dry earth or rock and thereby partially insulated, the overhead grounded wire may become valuable in *connection with the arc suppressor.* The multiple earth connections supply good conduction to earth in spite of those towers that are practically too insulated to give proper operation of selective relays used in conjunction with the suppressor. (d) There is also a probable, remote value, in cases of dry or rocky foundation at towers, relating to the question of *danger to human life* for anyone standing on the ground and in contact with the tower when an insulator on the same tower is accidentally short-circuited.

5. *The overhead grounded wire absorbs a part of the energy of a traveling wave on the power wires.* It thus lessens the discharge current through lightning arresters when the lightning cloud is at a distance from the station.

6. When used *near a station* and when a *direct stroke* occurs near the station, it is possible that the overhead grounded wire lessens the chance of high voltage entering the station.

7. In the type of distribution circuit known as the *three-phase, four-wire* system the fourth wire is usually grounded at one or more places. The primary object in the use of this parallel grounded wire is not for protection against lightning. The use is economic in origin. Standard 2300-volt transformers Y-connected give a line voltage of 4000 volts. The higher voltage of transmission permits a saving in copper of the wires, if the power delivered is greater than can be carried on the minimum size of wire chosen by reason of mechanical strength. There is also a saving in lightning arresters at single-phase installations. Only one main arrester is used at the transformer of a four-wire system where two main arresters are needed for a single transformer on the three-wire system.

Incidentally the presence of the fourth wire decreases the lightning voltage induced on the remaining power wires.

8. *On single-phase short circuits,* with neutral grounded, the overhead wire acting as a partial return wire *reduces somewhat the inductance.* This reduction may be somewhat beneficial or detrimental, according to conditions and requirements of circuit breakers and relays.

The overhead grounded wire lessens the stray electric field which would extend to a parallel telephone or other low-voltage line and thereby lessens somewhat the inductive interference which must be neutralized by transpositions in both circuits.

Comments Before Noting the Ninth Factor. The eight foregoing functions of the overhead grounded conductor, in so far as they are performed, are preponderatingly beneficial in their general effect on an electrical transmission (not to say economically desirable). The ninth and last tabulated function may, in some types of construction, become very detrimental.

9. *The overhead grounded wire brings the zero potential of the earth from its surface to the height of the overhead grounded conductor in the near meighborhood of the power wires.* This lowering of the potential of lightning induction in the neighborhood of the power wires is the fundamental reason for the decrease in the quantity of induced charge as described in the first enumeration.

The nearer the grounded wire to the power wire, the less the induced static charge and voltage by thunder-clouds on the power wires. *But the reduction of this lightning potential is not the ultimate desideratum in using the aerial grounded wire. The real aim is to lessen the number of flash-overs at the insulators.* For purposes of illustration the effect of different distances between power wires and conductors at zero potential will be discussed. In the extreme minimum, if the grounded wire is placed too close to the power wire its presence increases the number of flash-overs, due, not to lightning, but to the power potential itself. From this consideration alone then a mechanical clearance throughout the spans between supports must be maintained sufficient to give a suitable spark voltage to the power wires. The spark potential between the power wire and the parallel grounded wire should, in general, be greater than between the power wires and their conducting support at the insulator. The object of this ruling is to avoid damage to the grounded wire by the tendency of the craters of accidental arcs to melt the wires in two. Such safe spacing is easily obtained for grounded wires used on metal towers. It is seldom attained on wooden-pole construction and other means are necessary to avoid damage by craters. A discussion of these means will be deferred.

Relation of Overhead Grounded Wires to Cloud Lightning

Erroneous functions have sometimes been attributed to the overhead grounded wire. To counteract these speculations, occasionally heard, some statements will follow of what the overhead grounded wire does not do.

It has no effect in lessening the formation of electric charges in the clouds.

It does not increase or decrease the number of lightning flashes from the clouds.

It is not known to have any effect in either dissipating or producing appreciable charges in its neighborhood. Even the ionization produced by corona at the surface of a wire must be rapidly lost at a small distance from the wire. Otherwise, the power potentials would spark from wire to wire. If very high potentials in the future, by some unknown, incipient effect, are going to ionize or deionize the atmosphere to a radial distance sufficient to have an effect on a lightning stroke, it is a matter to be determined by future research. Even if some new very high potential power circuit gave evidence of gradually discharging atmospheric charges in its neighborhood, rapidly traveling thunder-storms (the most common form) would still be blown over the power lines.

The electrostatic potential rise in a thunder-cloud usually precedes a discharge by only about one minute. This is a short period in which to expect any relief of strain in the atmosphere around a transmission line by any known corona effect produced by the thunder-cloud.

So far as known at the present time, the value of the overhead grounded wire is entirely in relation to the power wires which it parallels.

It is presumed that the overhead grounded wire parallel to the power wires probably exerts slight effect in reducing the voltage induced electromagnetically by those little-known rare discharges which parallel the transmission line but take place from cloud to cloud.

Pertinent to what the overhead ground wire cannot do is an effect sometimes attributed to iron deposits in the neighborhood of storms. In a court-room the statement was made that iron deposits increased the frequency and severity of electrical storms. This statement is erroneous although it has enough element of fact in it to resemble the truth. The electrical charges gather in the atmosphere independently of any formation under the surface of the earth. However, any condition of electrical conduction which lowers the resistance in the path of the lightning bolt increases its current and prolongs the duration of the discharge. The conduction of bonded rails of railways produces burning effect in lightning arresters, having spark gaps, notably more severe than when there are no rails to gather in the radially traveling charge on the earth's surface. Salt swamps it might be argued would have the same effect. The writer has no data on the path the lightning might take either along the surface or (by leaving the static pull) spreading to better conducting layers at more or less depth beneath the surface. Incidental to this subject,

a study of earth pipes showed that the whole earth became a good conductor at short distances from the contact with the pipe, due not to high conductivity, but to vast cross-sections. There are, in fact, several unknown relations in the discharge path of lightning that form a field for speculation, such for example as the ohmic resistance of the feeding arteries in the cloud, the main artery, the earth contact, and the unknown path of the gathering currents on and in the earth under the discharging cloud.

Detrimental Effect of Grounded Wires on a Semi-Insulated Structure

The very presence of an overhead grounded wire anywhere on a well-designed wooden-pole structure reduces the spark potential to lightning stroke. Its presence must therefore, in this particular respect, be considered detrimental. It is detrimental somewhat in proportion to the decrease it causes in the spark voltage between the power wires and ground. For example, a normally insulated wooden-pole line, without overhead grounded wires, has a spark voltage to lightning proportional to its height above the surface of the earth. It is of the order of magnitude of 10 to 20 meters (33 to 66 feet). The distance from the power wire to the grounded wire is usually of the order of magnitude of 1 to 2 meters (3 to 6 feet). Thus the presence of the grounded wire on a wooden-pole line reduces the spark potential of induced lightning stroke to one-fifth or one-tenth. The result of this decrease is shown in a greater number of insulator flash-overs due to lightning.

To summarize this discussion crudely in a single sentence: Placing an overhead grounded wire on a well-designed wooden-pole line lowers its spark potential 80 to 90 per cent in order to lower the induced potential of lightning by a value of the order of 25 per cent.

Relation of Grounded Wire to Direct Stroke

So far as the aerial grounded wire carries zero potential above the surface of the earth it increases the possibility of direct strokes on the line. As a matter of judgment this increased probability of direct stroke is entirely negligible if not absent where metal towers are used as a support. The tower will naturally take the discharge of the direct stroke, other things being equal. The presence of the grounded wire between towers slightly increases the possibility of a stroke finding a path to the circuit.

In the case of wooden or other insulated supports the presence of the vertical wire actually decreases the distance from the earth to the lightning stroke by 10 to 20 meters in a vertical direction. If the direct stroke comes so near the line that this decrease in distance shortens down appreciably the path of lightning stroke to earth it will, in proportion, invite the discharge to strike the grounded pole rather than some other object in the neighborhood. For example, a metal mast of a ship at sea in a thunder-storm will "draw" a lightning stroke to it from a considerable radius because it is the only high point on a smooth surface. Analogously a wooden pole having a vertical grounded wire and located in a flat country should slightly "draw" a lightning stroke that happens to come in the near neighborhood. Direct strokes on transmission lines are relatively rare. This being so how are we to give weight to the factor which has a possible slight effect on increasing the rare event?

In cases of direct stroke on a wooden pole the vertical wire on the pole prevents splitting of the pole by the explosion coming from the sudden vaporization of the moisture in the wood by I^2R of the lightning current and ohmic resistance of the wood. The writer has never heard of but one case where the pole was destroyed as a support. Many cases of slight and serious

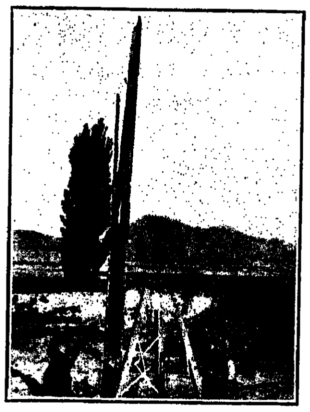

Fig. 1—Newly Erected Pole Struck by Lightning, August 7, 1916, Newton, Utah.
By courtesy of the Power Company.

damage to a pole are known. Fig. 1 shows severe damage to a pole by lightning. This experience brings up the question, important to the best type of construction, for power lines, is it worth while to invest in vertical grounded wires on poles, and thereby decrease the insulation of the line against lightning, to save that apparently rare case of complete destruction of a pole? Those who may add information, either in discussion to the present paper or in those valuable reports of committees such as in the N. E. L. A. now gathering information, should make a distinction between poles burned by dynamic current and poles destroyed by lightning. Lightning does not carbonize the wood—it explodes the moisture. The distinction is desirable because the cure is different. The vertical grounded wire, while preventing the damage by a direct stroke of lightning, increases the accidental burning effect on crossarms by the power voltage by increasing the potential gradient along the crossarms. When the vertical grounded wire short-circuits the high resistance of the wooden pole it throws the line-

to-ground potential on the part of the crossarm which is situated between the wire in accidental connection with the crossarm, and the bolt at the junction of pole and crossarm. This distance is of the order of one meter. On the other hand, if no vertical grounded wire is used the same potential is distributed over the sum of the distance along the pole and crossarm. The greater resistance to earth decreases the leakage current and lessens the risk. This distance is of the order of 4 to 7 meters.

Overhead Grounded Wires on Wooden-Pole Structures

Attempts to induce public service commission to specify the use of overhead grounded wires on wooden structures has raised the serious question whether the overhead grounded wire so used is not an economic waste. On comparatively low voltages on wooden poles it surely is a loss unless it is installed for a purpose other than lightning protection. When the question is raised, at what higher voltage on wooden-pole lines should overhead grounded wires be used? it requires to answer it a review of what useful functions it may perform.

However, before questioning in detail, distinction must be drawn between mechanical and electrical consideration. Wooden poles carrying grounded insulator-pins constitute admittedly a wooden structure from a mechanical standpoint, but it is a metallic structure from an electrical standpoint. Electrical protection of overhead grounded wires is under discussion. To discuss these questions logically the four grades of insulation below the porcelain insulators must be included as factors and each given its proper weight in the appraisal. These grades are:

(a) Nonmetallic pins, crossarms, and poles.
(b) Metal pins, nonmetallic crossarms, and poles.
(c) Metal pins, metal crossarms, nonmetallic poles.
(d) Grounded metal pins

Even the foregoing analysis is not definite enough unless by the two mechanical designations, metallic and nonmetallic, the idea of conduction and a degree of high resistance respectively are understood. For conditions attending the use of suspension insulators the distinction should likewise be made, but with different words because it is the cap and not the pin of the suspension insulator that is mechanically connected to the crossarm.

Grounded metal pins fall in a class with the metal towers and are not under analysis at present. The first three classifications, viz., (a), (b), and (c), are near enough alike to be treated with approximation in one class for the following analysis.

An attempt will now be made to apply in detail the general analysis, already given in nine functions, to the particular use of an overhead grounded wire on a wooden-pole structure.

First Function. On nonmetallic structures the overhead grounded wire is not needed as an aid to lightning arrester.

Second Function. Instead of protecting, it actually lowers the arc-over of insulators subjected to a lightning voltage.

Third Function. The overhead grounded wire is not needed for mechanical strength where pin-type insulators are used. It is detrimental in increasing the wind and sleet load.

Fourth Function. It may find some use as a low-resistance earth connection. Is it needed to localize faulty insulators? Not where wooden pins are used; and is of possible but doubtful economic use where metal pins are used. The vertical grounded wire makes a grounded pin where metal crossarms are used and therefore falls in the other classification. As making a better ground connection for a system using the grounded neutral the overhead grounded wire may be valuable, but for it to act in this capacity it is not necessary to install it for the full length of the power line but only near stations. Furthermore, as such, it is better to hang it under, rather than over the power wires. So located it cannot, after corroding with age, fall on the power wires. As an auxiliary to the arc suppressor (now under development) it seems of no particular use. It does not safeguard human life — the wooden pole is safer.

Fifth Function. In the fifth function as an absorber of traveling waves the overhead grounded wire is useful but not necessary. It is not needed to aid distant arresters. It is not necessary for isolated installations of transformers along the line which has no arresters. There are other and cheaper ways of getting protection.

Sixth Function. The overhead grounded wire may be used if desired near a station, with special precautions in construction, for use against direct stroke and yet save the expense for the rest of the lines.

Seventh Function. At present the three-phase, four-wire economics are not under discussion.

Eighth Function. As a return wire and a parallel conductor to lessen the scattered electrostatic field, the overhead grounded wire has its normal useful function. Except for very high voltage, prominent harmonics, and near parallel telephone lines this factor will seldom justify the expense.

During accidental grounds the value of the overhead grounded wire in decreasing interference with parallel telephone systems is reduced to a small, but unknown value by the predominant electromagnetic induction of the return currents in the earth.

Ninth Function. In bringing the zero potential of the earth from its surface to the height of the power lines the installation of an overhead grounded wire on an insulated structure is very detrimental. It reduces the arc-over voltage from the power wire to ground. This is the factor which seems sufficiently prominent to condemn the use of the overhead grounded wire on wooden structures.

Conclusion. Having considered briefly each of the separate items, the conclusion is reached that the overhead grounded wire is, in general, a detriment rather than an asset to a semi-insulated or high-resistance pole-line structure. It is impractical to consider here every possible detail but the endeavor has been made to mention or indicate all the factors, so that for any particular installation, engineering basis for the installation or taking down of an overhead grounded wire may be determined.

Steel Structures and the Overhead Grounded Wire

The ninth function enumerated for the overhead grounded wire which is so objectionable to wooden pole construction is not so for steel structures. The metal tower or pole brings the zero of earth potential to the height of the line in the neighborhood of the insulators. The overhead grounded wire adds nothing more to this detrimental condition. All of the first eight functions enumerated for the overhead grounded wire are more or less beneficial and none is detrimental. Specifying the use for metal structures will depend on figuring enough intrinsic value to pay for its cost. A review of some of the crucial factors follows:

Such effective protective apparatus can be installed at the stations as to make the use of the overhead grounded wire all along the line of no particular need to help the arresters.

Suppose the overhead grounded wire is considered as a mechanical support in the accidental emergency of a broken power wire. How much good can it do? Can the overhead grounded wire prevent mechanical damage to the tower sufficient to maintain service on other parallel circuits? Considerations of the flexible structure support are set aside. The overhead grounded wire is an intrinsic part of it. The usual four-legged tower is a relatively rigid support. The overhead grounded wire itself is a flexible horizontal support. It sags loosely between towers. Can a tower top move, without damage to itself, far enough in the longitudinal direction to utilize the increase in tension of the overhead grounded wire? If not, the overhead grounded wire loses its value in this function. Will enough mechanical damage be saved to the local structure and other parallel circuit or circuits on the towers to warrant the cost and depreciation of the overhead grounded wire in its entire length along the tower line?

Will the overhead grounded wire decrease the number of flash-overs of the insulators? According to the theory given by the writer in 1916 (TRANSACTIONS A. I. E. E., p. 945) it may not have much value. This theory has not been refuted, nor even questioned. It states that the voltage of the induced charge on each power wire by thunder-clouds is decreased by the presence of a parallel grounded wire only by the passage to earth of the initial charge on the grounded wire and its replacement by an induced charge of the opposite sign by the lightning charge on the power wire. Under some conditions it is questionable whether this "increased capacitance" by the grounded wire becomes active in reducing the induced potential in time to save the over-stressed insulator from arc-over. This matter will be discussed further.

Among the factors which determine the efficiency of the grounded wire in preventing arc-over of insulators are some which are obscure, due to lack of both theoretical and experimental data. The time involved in the movement of the charges in the clouds is unknown. De Blois in 1914 gave some oscillograms which showed that some of the effects of potential changes in the cloud were very slow as compared to spark lag of insulators and gaps. So far as this slow movement obtains it is favorable to effective action of the overhead grounded wire. It is understood, however, that the final stroke to earth takes place with great rapidity but no one knows that this velocity in any way approaches the velocity of light which is the approximate velocity of travel of a free charge along a transmission line. It is hoped that some of Prof. Harris J. Ryan's unpublished work on discharges will add useful information to this subject.

At any rate, we know that the circuit of the cloud lightning is long as compared to the circuit of the grounded wire. This much information would lead us to infer that, in so much as affected by distance of travel, the charge on the grounded wire would have plenty of time to pass to the earth while the main bolt is taking place from cloud to earth.

There is a factor, however, in the grounded wire circuit which has not been given practical attention, namely the resistance of each tower to earth. There are many dry localities and even rocky localities in wet countries where the ohmic resistance of the earth connections of particular tower legs is extremely high. This resistance limits the rate of discharge of the freed charge on the grounded wire. In so doing it decreases the effect of the grounded wire in preventing arc-overs of insulators. While a calculation of the theoretical value of the overhead grounded wire with well grounded legs gives a potential ratio with and without this protection of about 70 per cent (a protection of 30 per cent) for a circuit of approximately the same dimensions as the Mississippi River Power Company's 110-volt line, a high resistance of earth connections would reduce this protection from 30 per cent to an unknown smaller value.

A proof of the small value of the overhead grounded wire to prevent arc-overs of insulators can be given by a simple arithmetical example.

Suppose the insulators in use on a line can be arced over by a lightning potential of 200 kilovolts. Suppose furthermore, that the tower legs have a high earth resistance and therefore the presence of a grounded wire would reduce the induced potential on insulators

by only 12 per cent. It would then require an induction equivalent to 227 kilovolts to arc-over an insulator where the grounded wire is in use ($200 \div 88$ per cent = 227). If the induced voltage is less than equivalent to 200 kilovolts the presence of the overhead grounded wire has no value in preventing an arc-over. In fact, there would not be an arc-over if the protective wire were absent because the induced voltage is below the arc-over voltage of the insulator.

On the other hand, if the induced voltage is equivalent to 227 kilovolts the presence of the overhead grounded wire gives no useful results, because an insulator will arc-over in spite of the presence of the overhead grounded wire.

For all induced voltages below 200 kv. and above 227 kv. the parallel grounded wire, with a 12 per cent protection, has no value in preventing arc-overs. It is only over the small range between 200 kv. and 227 kv. that it would be effective. The chosen percentage of protection may actually be higher or lower according to the earth resistance of the particular tower where the maximum lightning voltage concentrates. A distinction is made in passing—while the overhead grounded wire decreases the general resistance to earth for power currents, it does not do so for lightning. Theoretically there is not sufficient time for the charge to flow to adjacent towers before the strain on the insulators produces its effect.

If this proof is sound it shows why observations made on transmission lines with and without overhead grounded wires have given so few useful data.

There is another useful viewpoint. If, instead of assuming the pessimistic conditions of protection, it is assumed that the tower legs are connected to earth with high conductance and other attendant conditions are such as to give the overhead grounded wire its maximum calculated value of 30 per cent protection, it may be considered as a very economical equivalent of an increase in dielectric strength of the insulators by somewhat less than 30 per cent; in other words, that the grounded wire is equivalent to putting extra disks on every line on the tower. The use is limited to lightning voltages. Protection is not given by the grounded wire against internal surges or, obviously, against failure of individual disks in a string.

On some general measurements made between two tower lines, the writer was led to believe that the usual resistance of earth connections of towers was high rather than low. Estimates made from related data and laboratory experiences indicate a restricted if not doubtful protection of insulators from arc-over by the overhead grounded wire when the insulators are on towers of high earth resistance. There are not enough data at the present time to give definite solutions to this problem. It would seem, however, that the problem is solvable.

To summarize the points gained so far in the analysis of metal support structures, the overhead grounded wire is not detrimental but is unnecessary as an aid to lightning arresters and it may have a small average useful range of protection for flash-overs of insulators.

On the other hand, for one purpose it seems there is going to be an incontestable use for the overhead wire on metal structures. This use is in connection with the arc suppressor which seems destined to become a standard device where aerial wires are used. As matters of development stand today the conditions needed are either very high resistance to earth, such as found on wooden-pole lines, or very low resistance to neutral such as can be obtained on metal tower lines linked in metallic contact by the overhead wire.

If the conditions are such as to make its use solely to lower the earth resistance in general, why not use it near the telephone line and even as a messenger wire? Induction on the telephone can be modified thereby. It will surely lower the voltage to earth induced on the telephone lines and make them safer to handle.

The work of this paper represents several days of concentrated effort. This is not enough for the complexity of the problem. The analysis is incomplete. More and specific experimental data are needed—data both from the laboratory and from the field.

The reasoning should be carefully scrutinized, and criticised especially in regard to its applicability to special cases.

Significance of the Analysis

The course of reasoning brings the conclusion that overhead grounded wires and vertical grounded wires on semi-insulating structures, such as wooden poles, are in general detrimental. On metal structures no technical function is found detrimental. If protection against arc-over of insulators is, as it appears, affected by the ohmic resistance between tower legs and earth either the effectiveness of the overhead grounded wire may be increased by attention to earth connections or this function of the grounded wire is sufficiently decreased to allow the grounded wire to be used lower down on the tower in another function. The relation between the earth resistance and the decrease in protection to insulators is yet to be determined.

Bibliography

Transactions of A. I. E. E., 1903-1921

Note. The principal papers in the following list involving the theory of the overhead grounded wire are: 1 by R. D. Mershon (1903) with its discussions; 3 and 4, discussion by Dr. Steinmetz (1905) and (1906); 5, by R. P. Jackson (1907); and 12, by E. E. F. Creighton (1916).

1. Mershon, R. D. The Grounded Wire as a Protection against Lightning. Vol. 22, 1903, p. 331, 2000 words.
Discussion (5800 words) by Messrs. Scott, Perrine, Mailloux, Wurts, Thomas, Kennelly, Lincoln, Woodward, Rushmore, Kelsch, Kelly, Hayward, Waters, Curtis, Jackson, D. C., Hammer, Blanck, and Mershon.

2. Report of Committee on High-Tension Transmission. Questionnaire on Lightning Protection. Vol. 23, p. 592. (500 words on overhead grounded wire, practise but no theory).
Discussion largely overhead grounded wire (1400 words) by

Messrs. Finney, Mershon, Junkersfeld, Arnold, Schuler, Storer, Perrine, Clark, E., Jackson, W. B., Neall, and Lyman.

3. Discussion by Dr. Steinmetz, Vol. 24, 1905, p. 995. (400 words).

4. Discussion by Dr. Steinmetz, Vol. 25, 1906, p. 428. (600 words.)

5. Jackson, R. P. Potential Stresses as Affected by Overhead Grounded Conductors. 1907, Vol. 26, p. 873. (2800 words, 7 diagrams of equipotential curves).

Discussion (2600 words) by P. M. Lincoln, D. C. Jackson, D. R. Scholes, H. C. Hoagland, R. P. Jackson, J. Lyman, P. B. Woodworth, W. L. Abbott, W. B. Jackson, George Hayles.

6. Vaughan, J. F. Comparative Tests of Lightning Protection. Devices on the Taylors Falls Transmission System. Vol. 27, 1908. Subhead: Overhead Grounded Wire, 1 page, (400 words).

7. Neall, N. J. Studies in Lightning Performance (1907). Vol. 27, (1908) Subhead: Overhead Grounded Wires, p. 429, (400 words).

Discussion of both the above papers, only part of which is on overhead grounded wire (3600 words) by Messrs. Buch, Lincoln, Vaughan, Thomas, Creighton, Scott, and Moody.

8. Rowe, Norman. Lightning Rods and Grounded Cables as a Means of Protecting Transmission Lines Against Lightning. (2500 words, 4 photographs, 3 of line towers, 1 of broken insulator). An installation in practise.

Discussion, much of which is on Overhead Grounded Wires, by W. Hoopes, P. H. Thomas, W. S. Lee, F. B. H. Paine, C. W. Ricker, G. T. Fielding, N. J. Neall, R. D. Mershon, D. R. Scholes, F. G. Baum, F. Osgood.

9. Lincoln, P. M. Protection of Electrical Equipment. (4200 words). Contains a little on overhead grounded wire, 1909, Vol. 28, p. 1157.

Discussion

W. W. Lewis: In this paper Mr. Creighton draws the conclusion that the overhead grounded wire is in general a detriment to a semi-insulated or high resistance pole line structure. By this I understand that he means not only the horizontal continuous grounded wire but also the vertical grounded wire that is applied to individual poles.

I believe that the experience of operating companies in general will not bear out this conclusion. While it is true that there has been considerable trouble on some systems due to the overhead grounded wire, this has been mainly on account of the fact that the ground wire was not put up with the same care and idea of permanency as the power conductors, with the result of breakage, and interference with the conductors. Also in some cases the insulators were small for the voltage and the presence of the ground wire further reduced the factor of safety. Where the ground wire is adequately installed and the insulators have a reasonable factor of safety, I believe that the ground wire is of great benefit in protecting the insulators and poles. The testimony of a few power companies in this respect will be interesting.

The Southern Power Company has overhead ground wires on practically all of its 2200 miles of 100,-44-and 13-kv. lines. It is its belief, based on experience, that ground wires afford considerable protection from lightning disturbances. The ground wires increase the mechanical stability of both pole and tower circuits and in case of pole lines prevents splitting of the poles by lightning.

The Idaho Power Company has had considerable trouble with overhead ground wires due to mechanical difficulties and is not putting them up on new circuits, in fact has removed them in some cases. However, it has had considerable pole shattering where lines were not protected by ground wire and has cured this by grounded bayonets at the individual poles. Its experience has led it to favor this class of construction.

The Utah Power and Light Company makes a practise of placing a metal band around the tops of its wooden poles and grounding this band. The conductors are in general arranged in a triangle with the top wire supported by a pin carried at the top of the pole. Wooden pins are used. Its experience with this construction has led it to believe that it has averted numerous cases of shattered poles and broken insulators. Operation without the metal band grounded, led to many cases of shattered poles. This construction cannot be used if the insulators are inadequate, as it will lead to shattering of insulators. Practically all of its 475 miles of 44-kv. line is equipped with the grounded metal bands, which its experience has led the company to favor.

Other companies have reported similar experiences which is contrary to that predicted by Mr. Creighton. A questionnaire directed to these operating companies would no doubt elicit a great deal of valuable information along this line.

C. L. Fortescue: On my trip last year to the Pacific Coast, I had some questions asked me about the grounded wire for protection, and I also elicited a good deal of information about it. A questionnaire was sent out recently by the N. E. L. A. in which experience with the grounded wire was asked. A number of people told me that the questionnaire was not always treated seriously, that the replies could not be depended upon, and that a lot of the companies that were questioned about the use of grounded wires had never installed grounded wires properly.

This seems to agree with the statements of Mr. Lewis. Where grounded wires have been properly installed, they have given a good deal of protection, I believe.

Mr. Creighton's theoretical explanation of the grounded wire, I think is not quite adequate. The grounded wire is used to increase the capacity of the transmission system as a whole to ground, so that if there is a charge induced on the system, when the charge is released as for instance by the discharge of a thunder cloud, the potential of the surge will be limited in value in

inverse proportion to the capacity. Any means which increases the capacity of the system as a whole to ground, will give correspondingly lower potentials, due to lightning effects. I was talking to the engineer of the Byllesby Company some time ago about the use of grounded wires, and he told me that his company was going to continue their use, and he thought they did good. He said that according to the general method of putting up a grounded wire it was considered as something that could be stuck up in any way at all. According to his ideas the same class of construction should be used for installing a grounded wire as in the case of the transmission lines themselves, and that if this practise were carried through, with proper maintenance, the protection obtained was good.

E. P. Peck: Mr. Creighton referred to a case which came up recently regarding the use of an overhead ground wire in a small system in New York State. The president of the Company operating that system had been ordered to install an overhead ground wire in connection with a 13,200-volt circuit which had been reported as giving adequate service without the overhead ground wire. The president objected to installing the overhead ground wire, and he wrote a large number of letters to most of the representative companies in New York State, and also to a number of large transmission companies and management corporations throughout the country. The gentleman was kind enough to send me a copy of all of the letters, which I very carefully reviewed. Of the 78 replies to his questionnaire, 72 were against the use of overhead ground wires, 2 were non-commital, and 4 were in favor of overhead ground wires on transmission lines. I was very much pleased to find that the consensus of opinion as shown in these letters were so overwhelmingly against the overhead ground wire, because they confirmed my operating experience. Had the questionnaire been sent out ten years ago, I dare say the majority of the opinions would have been favorable to the overhead ground wire, as a good many theoretical considerations would indicate that the overhead ground wire is of considerable value. My operating experience, however, has caused me to very definitely decide that the overhead ground wire is a source of trouble.

On one line in the South, which was equipped with an overhead ground wire, we had a large amount of trouble. The line was re-insulated and at the same time the ground wire was removed. After the re-insulation the line gave practically no trouble, and we concluded that the ground wire had not done any good, in fact indications showed that the presence of the ground wire caused considerable additional burning to the cross-arms and pins. Since that time, and in connection with a number of different lines, the same experience has been repeated to a greater or less extent. We do not now put an overhead ground wire on wood pole lines under any conditions, and probably never will unless some new evidence comes up.

Our results indicate that the overhead ground wire does more harm than good, not due to its falling or breaking, but due to the fact that it puts ground potential close to the conductors and reduces the insulating value of the wood pins, cross-arms and poles.

In Utica we put up several transmission lines of intermediate voltages without overhead ground wires. On these lines we have had only one pole shattered, that I recall, in two years. The insulators were not damaged and the pins and cross-arms were not burned. We have not lost a single insulator on these lines. On the other hand we have lost something like 15 insulators, due to flash-over, on our steel tower lines equipped with overhead ground wire, in about the same period, though the steel tower line is insulated with excessively large insulators which had not been in service as long as a year at the time of the failure.

It is my definite opinion that the overhead ground wire on wood poles does more harm than it does good.

C. P. Steinmetz: The great value of Mr. Creighton's paper, in my opinion, consists in the very complete review and discussion of the function of the overhead ground-wire. While I thoroughly agree with all the facts brought out by him, I am sorry to say that I must somewhat disagree with the conclusions drawn therefrom.

I am fully convinced that the overhead ground-wire, when properly installed in a transmission system, is a most effective and a most valuable protective device.

I believe it is necessary to protect a station by adequate lightning arresters, and the failure to install lightning protection at the station is economically inexcusable. Nevertheless, if I were given the choice between the use of the overhead ground-wire, or the use of lightning arresters in the station without the overhead ground-wire, I would rather take my chances with the overhead ground-wire and no lightning protection in the station than to attempt to run without overhead ground-wire with all the lightning protection of the station that it would be possible to give, although neither of these plans is economically defensible, but both, ground-wire and lightning arresters, in my opinion, are necessary and are supplementary to each other.

The advantage of the ground-wire is that its function is preventive, while that of the lightning arrester is merely curative. The ground-wire keeps the high-voltage disturbances out of the system, those disturbances which might enter from the outside, by lightning, etc., or originate in the system, while the lightning arrester discharges such disturbances as have entered the system. Theoretically, therefore, either should be sufficient by itself to protect the system. Unfortunately however, neither of the two is complete in its action. The overhead ground-wire does not completely keep out abnormal voltages, but the best we can expect is that it reduces the over voltage of the disturbance, which, entering the station has to be discharged by the lightning arrester.

Unfortunately, the lightning arrester must have a spark gap in series with the discharge circuit, which must be set for a voltage materially in excess of the line voltage, so as not to interfere with normal line operation, and this is a limitation of the protective value of the lightning arrester, and every discharge of the lightning arrester, to some extent, means a shock to the system, and therefore it is desirable to reduce the work put on the lightning arrester as much as possible by the overhead ground-wire, and so getting the higher safety resulting therefrom.

In my opinion the two most important functions of the overhead ground-wire are, first, that it reduces the voltage electrostatically induced in the transmission line as the result of the bound charge on the line, produced by the charge of the thundercloud, or electro-magnetically as direct induction from a lightning flash overhead. When calculating this effect we invariably get rather disappointing results, that is the total effect is not more than 20 to 40 per cent voltage reduction at the most, and my conclusion and that of other observers is rather that the protective value of the overhead ground-wire is materially more than would be indicated by the reduction of the voltage due to its use.

The explanation therefore seems to me the following: For some years I have studied the phenomenon of the thundercloud, and from whatever data I gathered, to get an idea of the actual voltage of the thundercloud and the lightning flash, its current value, etc., my conclusion rather is that in the average the voltages induced by the thundercloud in transmission circuits are not very materially above those which the transmission line insulation would stand momentarily. With many of the induced lightning disturbances not much above the disruptive strength of the line, the result would be that a moderate reduction of the lightning voltages such as given by the ground-wires, would very much increase the safety of the system, out of proportion to the percentage of reduction, especially as not only the voltage, but also its duration is reduced by the ground-wire.

Thus it may be that a reduction of the lightning voltage by 30 or 40 per cent would, in view of the time lag of the circuit

insulation, reduce the number of failures perhaps by 80 or 90 per cent, depending on conditions.

The second protective action of the ground-wire is its damping effect on any wave or other disturbance traveling along the line, by its action as a short-circuited secondary. The ground-wire must consume considerable of the energy of a traveling wave in the transmission line, and thus greatly increase the energy dissipation of the traveling wave, especially when it is considered that most of these ground-wires are steel cables, which have a large high-frequency resistance.

The result hereof would be that when using a ground-wire, only those disturbances, atmospheric and otherwise, which originated near the station, would reach the station with serious amplitude and dangerous voltage, but anything happening further out on the line would be sufficiently dissipated, or reduced in intensity, that when it reaches the station it is of negligible magnitude. I believe in this consists one of the main protective values of the overhead ground-wire, that it practically frees the station from any serious disturbance which occurs in the line at a considerable distance from the station, and requires the consideration only of those disturbances which occur nearer to the station, which are of a rather lesser number.

There also would be a certain action resulting from the energy dissipation which protects against the line building up standing waves or cumulative oscillation by arcing grounds, etc., in the transmission wires. That, however, is probably not of such great value, because the resistance of the transmission wire, is usually sufficiently high to limit the building up of a stationary wave. It is only in very high-power circuits where the line resistance is very low that there may be some danger of the building up of destructive oscillations. The two main features, in my opinion, are the screening effect tending to keep disturbances out, and the energy consumption rapidly dissipating disturbances, and these fully justify a properly installed overhead ground-wire in long distance transmission circuits.

W. S. Jones: In a paper presented at the meeting of the Institute at Washington, D. C. in 1914, Mr. L. A. DeBlois stated certain conclusions which were determined as a result of tests made by him in connection with the investigation of lightning protection for buildings. These conclusions appear to be pertinent to the subject under discussion and are quoted as follows:

"(a) All conducting surfaces not thoroughly grounded, when exposed to the influence of a charged cloud immediately overhead, acquire a potential against ground which increases with the height of the conducting surface above ground.

(b) A difference of potential will exist between all conducting surfaces not bearing the same average spacial relation in the electrostatic field to ground or to nearby grounded objects. Such average spacial relation is determined by their shape and size as well as distance from ground or grounded objects.

(c) Conducting surfaces in a vertical plane which would acquire practically no potential from their position in the electrostatic field may acquire a charge from the influence of adjacent objects.

(d) The grounding of a conducting surface generally increases the danger of sparks from adjacent non-grounded surfaces.

(e) Interconnecting adjacent conducting surfaces can prevent differences of potential between them but may increase the tendency of the lowest surface (relative to ground) to arc to ground.

(f) Discharges tend to take the shortest path, and large surfaces in the horizontal plane should be interconnected or grounded at more than one point.

(g) A grounded roof acts as shield for objects beneath it and even when poorly grounded diminishes the potential between them, but potentials can be introduced below it by conductors which extend inward from the outside, provided they are of sufficient capacity.

(h) Secondary discharges may occur from the sudden charge of an overhead cloud or from its discharge. The discharge in any case follows the natural frequency of the circuit and consequently may become oscillatory, though this condition is improbable in the ordinary interior apparatus, excepting only electrical equipment.

(i) The effect of adjacent lightning rods is to diminish the intensity of secondary effects, though for outside rods of reasonable height and spacing, the 'secondary static protective-ratio' is practically inconsiderable."

If these conclusions still hold true, and I believe that they do, the overhead grounded wire does not adequately safeguard the line against lightning on account of the induced secondary effects and the reluctance, on the part of a lightning discharge, to follow horizontally along an aerial conductor.

I believe that in such cases, where overhead grounded wires are used, a much more effective and satisfactory arrangement would be to provide a grounded aerial point at each pole were it practicable to extend the point to its proper height. This, however, appears to be a problem from a mechanical standpoint.

It is my opinion that the only effective means of protection against lightning and surge disturbances is the use of electrolytic arresters, or others equally as sensitive and as efficient, at frequent points along the line.

R. H. Marvin: This paper performs a valuable purpose in pointing out that before deciding either for or against the ground wire, that consideration must be given to the functions it is supposed to perform and the need for so doing.

There are few subjects on which experimental data are so scanty, difficult to obtain and to interpret when found.

In the case of wood pole lines it would appear that not enough importance had been attached to the effect of the high resistance of the pole. It is generally admitted, that with the possible exception of a direct stroke, the actual lightning discharge over the surface of an insulator is harmless. The damage is done by the dynamic or power arc which follows it. It is common practise in the laboratory to use high resistances in series with sphere gaps. The resistance does not effect the break-down voltage but does prevent a heavy current and injury to the spheres. Another good illustration is the horn gap arrester with high resistance. The value of such arresters is debatable, but its strongest enemies will admit that it does protect itself. This is well brought out in the recent "Questionnaire on Lightning Arresters" where one reply after describing the destruction of a modern type of arrester states, "I am positive that a water barrel horn gap style of arrester, as above suggested, would not have been injured."

The wooden pole gives this important feature of a high resistance between each insulator and the ground. There is not much known about high-voltage arcs, but it is probable that they follow the same general principles as the shorter low-voltage arcs. If this is so it can be shown that for any given arc length and pole resistance there is a definite minimum voltage necessary to maintain an arc. If the voltage is below this value, the arc cannot hold. It is probable that in many cases insulators on wood pole lines without ground wires flash-over from lightning, but owing to the high resistance of the pole no arc forms and no damage results. The particular point I would bring out is that it is not so much the induced lightning discharge we wish to prevent or avoid, but the destructive effects of the dynamic power arc.

This action is confirmed by several cases which have come under my observation. In the first instance, a 33,000-volt line with wood poles, metal arms and overhead ground wire gave excessive trouble from flash-overs. By mounting the ground wire on insulators and bringing the ground connection off in such a way as not to ground the metal arms, the trouble disappeared. Another 33,000-volt system having also metal arms on wood poles experienced numerous flash-overs and shut-downs

on the parts having a ground wire, but none on a short section where the ground wire had been omitted.

E. E. F. Creighton: Engineers of transmission systems will note, with respect, the foregoing comments of the able discussers of this incomplete presentation on overhead grounded wires. There are convincing opinions expressed both for and against the use of the grounded wire. We must, for the present, let the situation stand. Briefly summarized, there are places where the use of the overhead grounded wire is good practise. On the contrary, there are other conditions of line construction where the expense of the overhead grounded wire is an economic waste. This is the particular point the author wishes to stress. In between these extremes there is a range of middle ground where the use or absence of the grounded wire becomes a special problem.

The present state of knowledge of this problem is admirably brought to mind by choosing an expression from Mr. Lewis's and Mr. Marvin's discussions respectively, and placing these expressions in juxtaposition. "It is their (the operators') *belief*, based on experience, that overhead grounded wires afford considerable protection from lightning disturbances." "There are few subjects on which *experimental data* are so scanty, difficult to obtain, and, when found, to interpret."

There are developments now under way which, when available, will help to crystallize more definitely the practise in the use of overhead grounded wires.

Wave Form and Amplification of Corona Discharge

BY J. B. WHITEHEAD AND N. INOUYE
Fellow, A. I. E. E. Associate, A. I. E. E.
Both of Johns Hopkins University

Review of the Subject. *Corona forms on a round wire or cable when the voltage is raised to such a point that the voltage gradient near the wire is sufficiently high to break down the insulating properties of the air. The larger the wire the higher the voltage to cause corona. The corona is luminous and ionizes the air, giving it electrical conductivity; thus corona has the effect of giving the conductor a larger diameter; and since a higher voltage is required for corona on a larger wire, a state of equilibrium is reached and corona is an equilibrium phenomenon not necessarily attended by spark-over.*

Since corona causes conductivity it is a cause of leakage and consequently of loss of power. It also increases temperature and decomposes the air into chemical constituents which are harmful to insulation. Engineers therefore have usually regarded corona as a dangerous phenomenon and one to be avoided by proper design. Transmission lines, for example, for the most part are designed so that their operating voltage is well below that at which corona would be formed on the conductors.

Two suggestions have been made to make use of the properties of corona. The first is as a protective device for transmission lines. Since the corona is conducting and dissipates energy, it has been proposed to operate transmission lines relatively close to the corona-forming voltage. When abnormal rises of voltage due to lightning or other causes occur, corona begins, the air becomes conducting, and the high voltage is relieved. The exact value of corona in this connection is not known, although there is some evidence that it acts in the manner described.

A second use of the corona, suggested by one of the authors of the present paper, is that it be used as a method for measurement of the crest values of high alternating voltages. The corona begins at a sharply marked definite value of voltage, and the laws governing the value are now well-known. The corona voltmeter is an instrument for detecting, either by the sound or by the conductivity of the air occasioned by corona, the exact voltage at which corona begins. The value of the voltage is given in terms of the dimensions of the instrument and the pressure and temperature of the air. The instrument has been described in two earlier papers, in which it is shown that the measurements of voltage with the corona voltmeter are more accurate than by any other method and that the instrument has several other advantages over methods at present in use. The present paper deals with methods for increasing the sensitivity of the corona voltmeter and for adapting the ordinary telephone receiver and standard portable instruments as indicators of the first appearance of corona. The corona discharge current is rectified and also amplified by means of hot cathode tubes. Incidentally the experiments on rectification included a study of the wave form of the discharge due to the alternating corona. It was also found that the sound due to the corona could be amplified so that the first appearance of corona would be indicated on a loud-speaking telephone.

CONTENTS

I. INTRODUCTION

THE high-voltgage corona appears at a sharply marked definite value of voltage of a clean round wire. This fact is made use of in the corona voltmeter, the law of corona as affected also by temperature and pressure being now known to a high degree of accuracy. The instrument appears to offer the most accurate method for determining crest values of high alternating voltages.

Presented at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

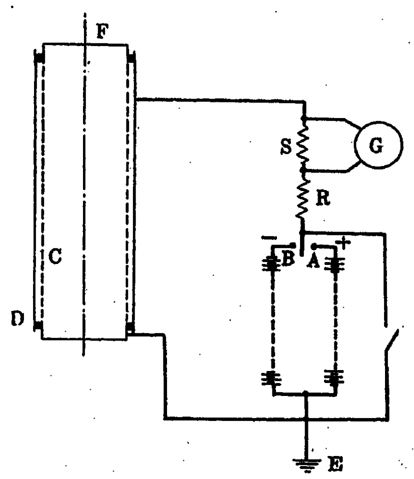
In addition to the method of visual observation, which is relatively inconvenient, two methods have been used in the corona voltmeter for detecting the first appearance of corona, (a) the telephone, and (b) the continuous-current galvanometer. Both of these devices indicated the first appearance of corona with a high degree of accuracy. Under laboratory conditions either may be used with satisfaction, the telephone being somewhat simpler, and useful for detecting occasional local sparking due to surface imperfections of the corona wire. However, the total volume of

· discharge produces a relatively small current, ensitive galvanometer is necessary, more sensi·ian can be had in a readily portable type, and ng usually a telescope and scale. Consequently nconvenience is occasioned if the voltmeter is noved from place to place. Moreover the sound corona in the telephone, while clear and sharp iiet room, is easily masked by other extraneous

It is desirable therefore to develop methods erving the first appearance of corona on the usual f portable instrument with direct-reading scale, o by means of a loud-speaking telephone. Both hings have been accomplished in the experi-described below, thanks to the rectifying and ring properties of the three-electrode vacuum In addition some interesting curves showing ve form of corona discharge have been obtained.

II. Apparatus and Method

essential elements of the galvanometer method cting corona are shown in Fig. 1, in which C, forated cylinder in the corona voltmeter, is



1—The Galvanometer as Detector of Corona

ed to ground, and the corona wire F is placed center of the cylinder. D is a surrounding only slightly larger in diameter than C, from ; is carefully insulated. When corona appears central rod F the surrounding air is copiously and this ionization extends through the per-s to the space between the cylinders C and D, hus becomes highly conducting, resulting in a n of the galvanometer G.

resent experiments were all conducted with the lischarge on a nickel-plated steel rod 0.289 cm. in.) in diameter. The sensitive d'Arsonval neter used is of wall type and has an undamped ty of 1280 megohms; when critically damped hunt of 3400 ohms the sensitivity is 428 meg-The resistance R, Fig. 1, of 50,000 ohms was ries to protect the galvanometer from possible cuit in the corona voltmeter. The potential attery between galvanometer and ground was ninus 115 volts.

The length of the cylinder D was 60.95 cm., its diameter 24.67 cm., and its space separation from the cylinder C 0.317 cm.

The curves in Fig. 2 were taken with the corona rod, 0.289 cm. diameter and plotted with galvanometer deflections in centimeters as ordinates, and transformer tertiary coil volts as abscissa. (See Fig. 3). The

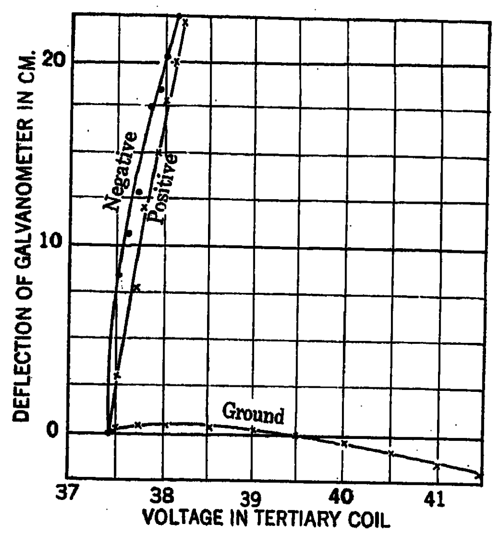


Fig. 2—Galvanometer as Detector of Corona

Atmospheric pressure.

ratio of transformation of the high-tension transformer was such that 120 volts on the tertiary coil corresponded to 100,000 volts at the high-voltage terminals. Three curves were taken at atmospheric pressure, one with the electrode D of Fig. 1 at 115 volts positive, one at 115 volts negative, and one at ground potential as shown in Fig. 2.

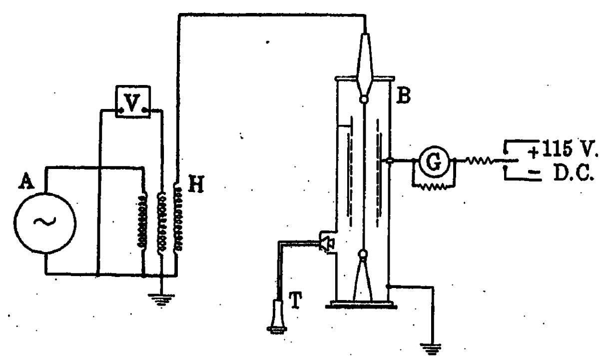

Fig. 3—Principal Connections

T—Telephone receiver.

It is to be noted that negative potential on the electrode D is best for the detection of the first presence of corona, in that the curve rises most sharply. The greater sensitivity of the negative electrode is obviously due to the fact that corona formation or ionization of the air occurs first due to the motion of the negative electron. The acceleration of the electron is greatest

when it is moving toward the positively charged corona conductor. Under these circumstances the positive ions, as products of the process of ionization, are repelled and therefore give maximum current in the galvanometer circuit of Fig. 1 when the electrode D is negative.

III. Galvanometer with Rectifying Valve

a. Wave Form of Corona Discharge. While the curves of Fig. 2 are readily obtainable on sensitive galvano-

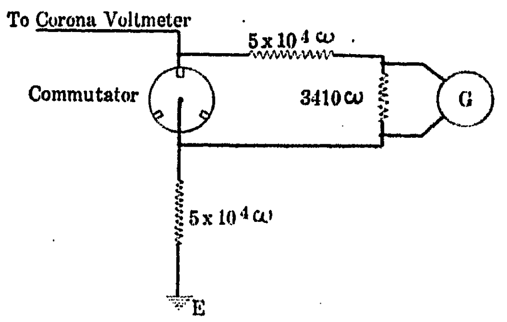

Fig. 4—Connections to Study Wave Form of Corona Discharge

meters, they cannot be taken with even the most sensitive types of direct-reading portable instrument. In considering possible ways of using the discharge with satisfaction on a less sensitive type of instrument it is to be noted at once that in the arrangement of Fig. 1 the deflection of the d'Arsonval galvanometer is proportional to the difference of the mean values of the corona discharge on the positive and negative sides

Thickness of copper disk: ¼ inch.

of the wave form. The deflection due to the discharge must therefore be largely due to some difference in the heights of the peaks in the positive and negative sides of the discharge current. It is evident therefore that elimination of one-half of the discharge current curve will greatly increase the net unidirectional current in the galvanometer circuit. This can be accomplished either with a synchronous commutator used as suppressor, or more conveniently still, by means of a rectifying vacuum tube. The whole question of the difference between the volume of discharge on the positive and negative sides of the voltage waves is one of great interest. It therefore seemed desirable, from the standpoint of the purpose of the experiments and also from that of the interest of the phenomenon itself, to take a series of wave forms of the corona discharge current.

For this purpose a special synchronous commutator was mounted on the shaft of the alternator furnishing the high voltage. In Fig. 4 the commutator was put in shunt to the galvanometer and the discharge current was short-circuited through each full cycle, except for one very short interval. The commutator, Fig. 5, was made of a copper disk, 4¼ in. diameter, with three slots of ¼-in. width filled with hard rubbed placed at intervals of 120 deg., corresponding to half the number of poles of the alternator, and so each giving open circuit at the same position on the wave form. The

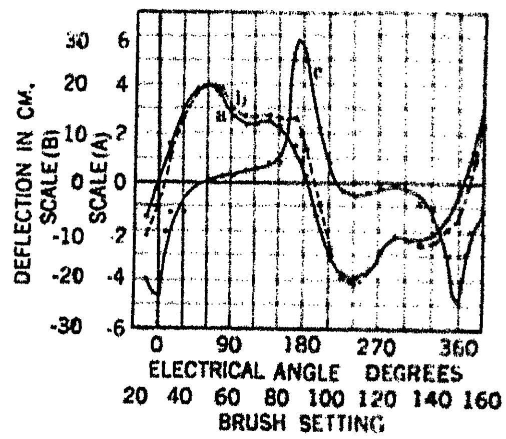

Fig. 6—Wave Form of Corona Discharge Current on 0.188-in. Corona Rod
(Corona starts at 30.6 volts)

Curve *b*—Deformed current (Scale A) at 30.6 volts.
Curve *c*—Corona discharge current (Scale B)

commutator was insulated from the shaft. Three copper brushes were attached at intervals of 30 deg. on the movable wooden disk; the two outer brushes were connected together to keep continuous contact to the copper disk, and under the middle one the open circuit was given by the three slots on the commutator.

First, the brush setting was observed corresponding to the maximum value of voltage on the corona wire by shifting the brush to find the point of no charging current in the galvanometer, and it was found to be 30 deg. on the fixed disk, calibrated 360 deg. on the whole circle.

Two wave forms of the currents through the galvanometer circuit were observed for voltages below and above corona formation; the difference of these wave forms must be the wave form of corona discharge. The wave form observed just before the start of corona is the charging current through electrode D and the wave form observed just after the start of corona is

the superposition of charging current and corona discharge current.

The observations were taken at atmospheric pressure of 74.77 cm. and room temperature of 18.2 deg. cent. on the corona wire of 0.289-cm. diameter. Readings are shown in Table I; the curves in Fig. 6 are plotted from the same observations; the positive direction of current was from the electrode D to ground (Fig. 1.).

From the curves it may be seen that the corona discharge current is of alternating form with a rather peaked shape for each half cycle, but the value of the positive peak is a little higher than that of the negative and this is the reason why the negative electrode is more effective for detecting corona.

TABLE I.
Wave Form of Corona Discharge

Brush setting in degrees	Galvanometer deflections in cm. Before corona	After corona	Corona discharge
25	−6.5	−10.5	−4.0

b. Rectifying Valve in Detecting Circuit. If we choke off one of the half waves shown in curve C of Fig. 6 we have at once a great increase of unidirectional current in the detecting galvanometer circuit. As stated above, the most convenient way of accomplishing this is the rectifying tube or valve of "kenotron" or similar type, which as is well-known passes current from a plate electrode to a heated filament, but completely chokes current from the filament to the plate.

Placing the valve between the galvanometer and the electrode in the corona voltmeter, Fig. 1, we observe at once a great difference in the sensitivities as between the two methods of connecting the valve in the circuit, *i. e.*, (1) the filament of the valve connected to the electrode and the plate to the galvanometer, and (2) the filament to the galvanometer and the plate to the electrode.

In Fig. 7 three curves correspond to the three cases,

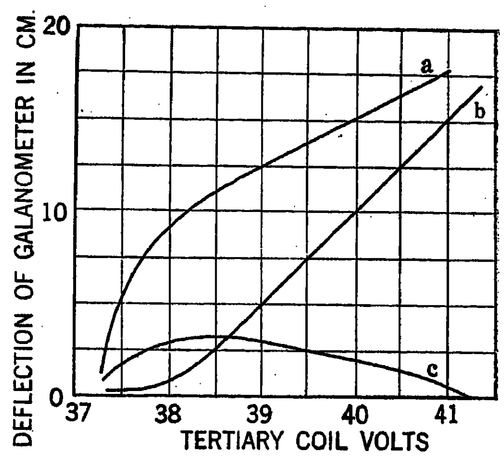

FIG. 7—GALVANOMETER WITH KENOTRON WITHOUT ANY POTENTIAL ON THE CIRCUIT

Curve *a*—Filament of kenotron being connected to the galvanometer.
Curve *b*—Filament to the electrode in the corona voltmeter.
Curve *c*—No kenotron used.

(a) filament connected to the galvanometer, (b) filament to the electrode, and (c) no valve being used. In each case no continuous potential was used, the galvanometer being connected directly to ground through the high resistance R, Fig. 1.

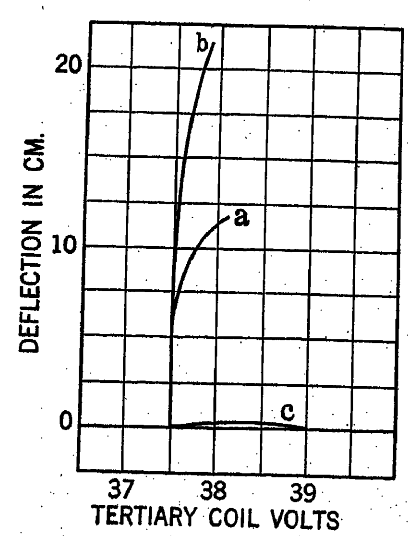

FIG. 8—GALVANOMETER WITH RECTIFYING VALVE POTENTIAL APPLIED ON THE FILAMENT

(Plate of valve connected to the electrode in the corona voltmeter)
Curve *a*—No potential on the filament, this corresponds to the curve (a) in Fig. 7.
Curve *b*—Negative potential on the filament.
Curve *c*—Positive potential on the filament.

From these results it may be said that the valve with its plate connected to the electrode gives the maximum volume of corona discharge current. This is in agreement with the condition of greatest sensitivity when the valve is not used, namely, negative electrode

D, or current from electrode to ground. For greater sensitivity we add negative potential of 115 volts on the filament through galvanometer and high resistance by means of a battery of cells. With positive potential on the filament no current was detected, as is to be expected.

Using the same galvanometer with shunt resistance and other conditions unchanged, observations were taken of galvanometer deflections corresponding to (a) no potential on valve filament, (b) negative potential 115 volts on valve filament, and (c) positive potential 115 volts on filament, the plate of the valve being connected to the electrode in the corona voltmeter in each case and the voltage being gradually raised through the corona forming value. Voltages are given throughout in terms of values at the terminals of the tertiary coils. The results of these tests are given in Fig. 8. The influence of negative potential on the filament in increasing the sensitivity is very noticeable. The positive potential chokes off the discharge almost completely. From these results it is obvious that the rectifying valve may be used with great satisfaction for increasing the volume of corona discharge as a means of detecting the first presence of corona and that it should be so connected that the plate of the valve is connected to the electrode in the corona voltmeter.

In connection Fig. 10 we found no charging current on the wave form of corona discharge current.

c. Portable Instrument in Place of d'Arsonval Galvanometer. Although the volume of the discharge current is greatly increased by the methods described above, it was found to be not yet sufficient to give satisfactory indications on a portable type of instrument. Tests of this question were made using a Siemens and Halske needle galvanometer having 25 divisions of scale on each side of a central zero, and each division corresponding to 10^{-6} ampere. The resistance of the instrument is 100 ohms.

Using this needle galvanometer with shunt of 9000 ohms in place of the d'Arsonval galvanometer of the earliest experiments, we found a deflection of only $1\frac{1}{2}$ divisions for a voltage 6 per cent above corona-forming value. Ordinarily this excess voltage would give deflections well off the scale using the most sensitive wall-type instrument. In these experiments the filament of the valve was connected through the instrument to the negative terminal of a 115-volt instrument, this being the most sensitive method of connection, as described above.

In view of these results it will be seen that while the rectifying valve has given a great increase in the volume of discharge, this increase is not yet sufficient to permit the use of the common type of portable instrument. If this type of instrument is to be used, some form of amplification of the discharge current must be used. This amplification was accomplished by the use of three-electrode amplifying tubes in the experiments described below.

d. Wave Form of the Rectified Corona Discharge Current. Before applying the usual methods of amplification to the corona discharge current it is important that the rectified corona discharge shall have no reverse current, that is that it shall be strictly unidirectional. Elimination of reverse currents is necessary since the rectifying valve and also the amplifying tube may be overloaded by them and so prevent the amplification of the unidirectional component. For these reasons we investigated the wave form of the rectified current by means of the synchronous commutator, as described above. At first we found large values of charging current in the wave form, these being induced currents arising in the circuit between the galvanometer and ground, and due to the alternating static field. In these measurements the galvanometer was connected directly to the electrode in the corona voltmeter and the valve between the galvanometer and ground, as shown in Fig. 9. After shortening the connections between all parts and changing the positions of the valve and the galvanometer to those shown in Fig. 10, we finally obtained strictly unidirectional current of very irregular wave forms.

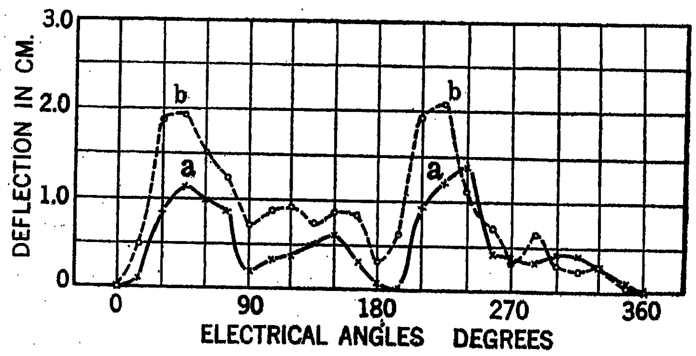

FIG. 11—WAVE FORMS OF RECTIFIED CORONA DISCHARGE CURRENTS BY THE KENOTRON

Curve a—No potential applied on the filament of the kenotron.
Curve b—Negative potential applied on the filament of the kenotron through the galvanometer and the high resistance.

The two curves in Fig. 11 were measured by the

commutator method described above, the plate of the valve being connected directly to the electrode in the corona voltmeter. First one side of the galvanometer was grounded through the high resistance R, and next negative potential of 115 volts was applied to the filament through the galvanometer and high resistance.

The irregularity of the wave forms shown in Fig. 11

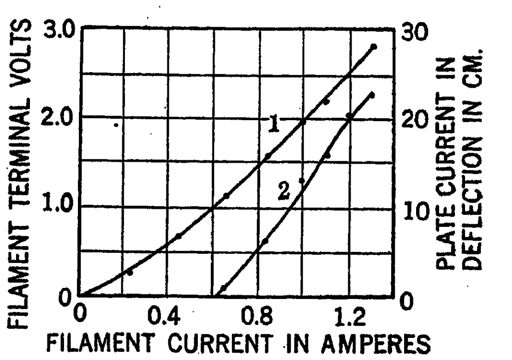

Fig. 12

Curve 1—Filament terminal volts,
Curve 2—Plate current.

is in some measure due to the continuously changing thermoelectric electromotive force at the brush contacts which is not sufficiently eliminated by the high resistance in series in the galvanometer circuit. (See Fig. 4.) This thermal electromotive force was further eliminated in its effect on the current to be measured by taking the difference of right and left galvanometer deflections both before and after starting corona. It

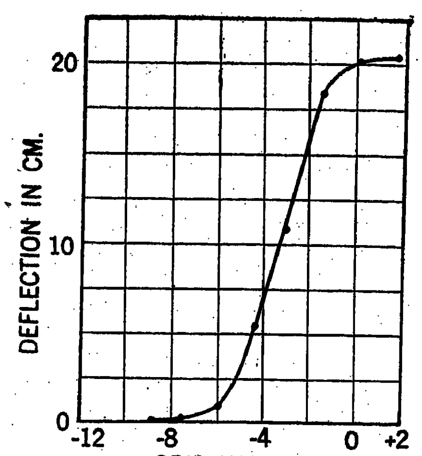

Fig. 13—Plate Current

is probable that the elimination of this effect is not complete and that therefore the curves shown in Fig. 11 are not an exact reproduction of the shape of the corona discharge. They must however approximate it very closely and they show clearly that there is no reverse element in the rectified current. It is sufficient for amplification that there be no reverse current and consequently these experiments were next undertaken.

IV. Amplification of Corona Discharge Current

a. Characteristic Curves of the Electron Tube. The problem presented is to amplify the unidirectional pulsating current from electrode D with an average value of about 10^{-7} ampere to a value which may be read on a conveniently portable instrument, such as the Siemens and Halske needle galvanometer, described above. After experiments with several different

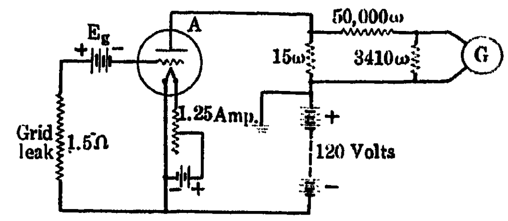

Fig. 14—Connection for Measurements of Characteristic Curves of the Electron Tube

methods of connection and different tubes, the connections of Fig. 15 were found to be most suitable for our purpose.

One 102-A Western electron tube was used and its characteristic curves were studied. The relation between plate current and filament current with no grid voltage and also the relation between plate current and grid voltage with constant filament current were taken. The curves of Figs. 12 and 13 were taken with

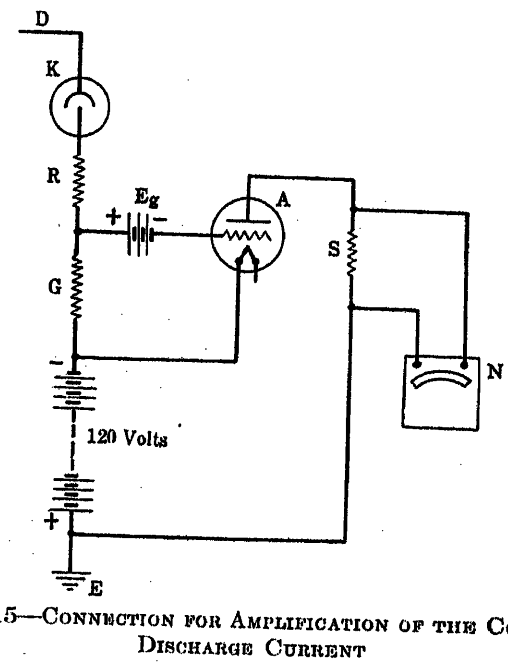

Fig. 15—Connection for Amplification of the Corona Discharge Current

a d'Arsonval galvanometer in the plate circuit and with 120 volts on the plate. Fig. 14 shows the method of measuring the relation between plate current and grid voltage. The relation of filament current and plate current is obtained with slight modifications of the connections as shown. The grid leak of 1.5 megohms and a different location of the ground connection is required for the amplification of the corona discharge current. (See Fig. 15). In these experiments, owing

to its high sensitivity the galvanometer was equipped with a shunt, as shown.

From the curve of Fig. 15 it is seen that the grid voltage must be about 8 volts in order to secure zero deflection in the connection of Fig. 15. With the start of corona and current over the resistance G, we may expect a sharp increase in plate current, that is to say, amplification.

b. Connection and Operation of the Amplifier for Increasing Corona Discharge Current. The connections for amplification of corona discharge current are shown in Fig. 15; where D is the electrode in the corona voltmeter; K the rectifying valve already described, with plate connected to electrode D; R, protective resistance of 50,000 ohms; G, grid leak of 1.5 megohms; E_g, grid voltage (series of small cells); A, electrode tube No. 102-A; S, shunt resistance for detecting instrument; N, Siemens and Halske portable needle galvanometer; E, ground connection and positive side of plate battery.

TABLE II.

Relations between the Grid Voltage and the Shunt Resistance of the Galvanometer.

Grid Voltage,	0.0	1.48	2.97	4.47	5.94	5.94	7.43	7.43	8.85	8.85
Shunt Resist. in ohms,	1.0	1.0	1.0	1.0	1.0	10.	10.	100.	100.	1000.
Tertiary Coil Volts,	Deflections in mm.									
22.0	7.8	7.7	5.5	2.0	0.8	5.0	1.0	2.8	0.5	0.7
38.1	7.8	7.7	5.5	2.0	0.8	5.0	1.0	3.2	0.5	0.7
38.2	No change	No change	No change	2.8	2.0	18.7	10.5	Off scale	24.5	Off scale
38.5				2.9	2.2	20.7	12.8		Off scale	
39.0				3.0	2.4	23.0	14.0			
39.5				3.1	2.6	Off scale	16.8			
40.0				3.2	2.7		20.0			

*Full scale of the instrument used was 25 mm.

In the above in all cases the galvanometer shunt resistance was made as high as possible. Higher values than those given result in large deflections at voltages below that of the start of corona. Corona at 38.2 volts on tertiary coil.

It is desirable that the needle of the galvanometer stand at zero position before the starting of corona discharge and that we have as large a deflection as possible on the start of corona, that is, we should have the same or better accuracy than is possible in using the d'Arsonval galvanometer without amplification or discharge. We were able to obtain this condition very closely after many trials by changing the value of the shunt resistance R and the value of the grid voltage E_g. We were able to obtain such conditions that the initial deflection of the galvanometer was less than one millimeter before the starting of corona, and immediately off the scale when corona begins. The process of obtaining this condition is clearly seen in Table II, where the relations between the shunt resistance, values of grid voltage, and initial deflection are given. The value of the grid leak was also varied from 50,000 ohms to 2 megohms, and it was found that 1.5 megohms grid leak gives most satisfactory results in amplification.

From the above results the following are the best values for amplification: Grid voltage, 8 to 9 volts; shunt resistance, 100 to 1000 ohms; grid leak, 1.5 to 2 megohms. Obviously the value of shunt resistance pertains only to the instrument used in these experiments, but the values of grid voltage and grid leak are always suitable for the type of tube described.

The importance of the rectifying valve for amplification should be emphasized. If no valve is used, alternating voltage is applied to the grid of the electron tube and will be so amplified that it will be impossible to secure zero deflection of the detecting instrument before the start of corona.

V. FURTHER STUDY OF WAVE FORM OF CORONA DISCHARGE

A further study of the wave form of corona discharge has been made and in this the value of the discharge current has been carried far above that in the immediate neighborhood of the starting of corona.

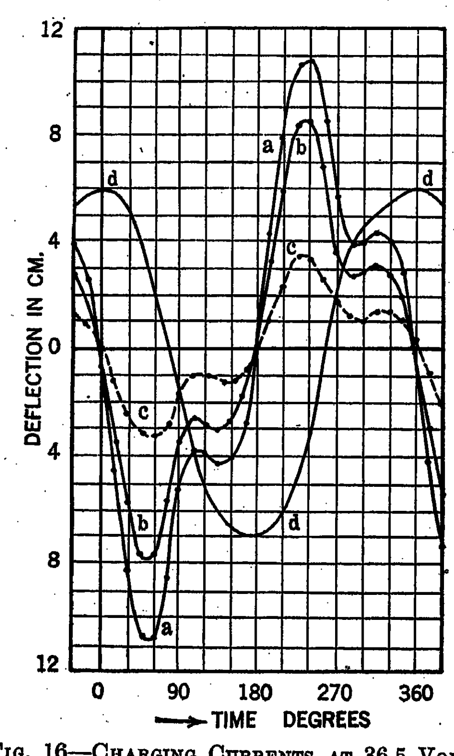

FIG. 16—CHARGING CURRENTS AT 36.5 VOLTS
(Corona starts at 37.2 volts)
Curve *a*—Charging current of electrode and lead wire together.
Curve *b*—Charging current of lead wire alone.
Curve *c*—Difference of curves (a) and (b).
Curve *d*—Wave form of voltage.

a. Improvement of Synchronous Commutator. As shown in Fig. 5, the width of each slot filled with hard rubber corresponds to 20.2 electric degrees. If the middle brush, under which the open circuit is given by each slot, has no thickness, then the duration of open circuit must correspond to the interval of 20.2 electrical degrees and the deflection of the galvanometer is proportional

to the mean value of the wave form during that interval. But obviously it has a certain contact area which will shorten the duration of open circuit, and the amount of this shortened period must correspond to the width of the brush contact area.

In the case of the observation of the curves shown in Figs. 6 and 11, two 0.005-in. copper strips were used as the middle brush. The effect of the wearing of contact surface and different pressures on the brush was noted in the difference of deflections in two measurements of wave form of the same current. As a consequence we used one sheet of 0.016-in. thickness because it is easier to keep the same wearing surface and the same pressure of contact with one thickness. After sufficient wearing the width of contact area was measured as about 1/32-in. This contact width of brush makes the duration of open circuit about 16 electrical degrees, and the point on the wave form obtained by shifting this brush corresponds to the mean value of the wave form of width of 16 electrical degrees, thus the wave form as obtained by us is not an exact representation of corona discharge current, but is approximate only, each point on the curves representing a width of about 4.5 per cent of the entire period. With this commutator Figs. 16 to 19 were taken.

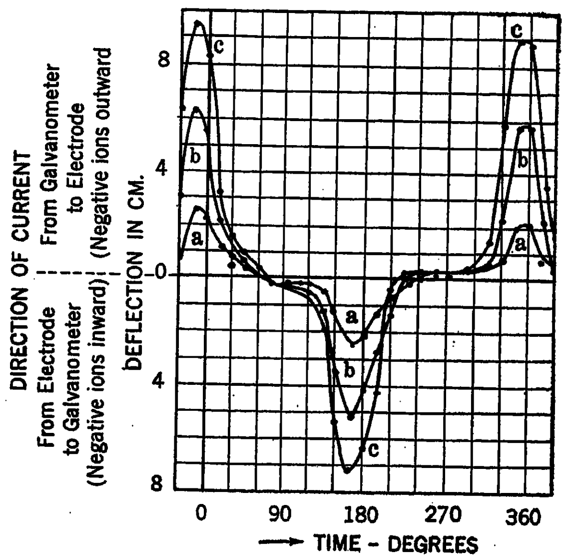

FIG. 17—NO VOLTAGE ON ELECTRODE

Atm. press. 75.77 cm.
Temperature, 20.8 deg. cent.
Curve *a*—37 volts,
Curve *b*—41 volts,
Curve *c*—45 volts.

b. Galvanometer used. In order to obtain rapid readings of the two deflections on the two sides of zero, for the elimination of the thermoelectric electromotive forces on the commutator, a galvanometer of short period was used, sensitivity 1085 megohms undamped, and a period of 13.8 seconds. When critically damped with 1900 ohms the time required for the deflection to fall to zero from 12 cm. was 13.6 seconds.

c. Shielding of Lead Wire between Electrode D and the Galvanometer. Careful electrostatic screening of all connections and instruments is necessary in measurements of the small values of current in the connection to electrode *D*. At first electrostatic induction between the high-tension conductor of the voltmeter and the lead wire from the electrode to the screened observation room was found to be comparatively large. Working below the starting voltage of corona we measured the charging currents, (a) of electrode inside and lead wire outside together, and (b) lead wire alone by disconnecting at the outlet of the corona voltmeter. The wave forms in these two cases are shown in (a) and (b) of Fig. 16 respectively. The difference between these two curves is the charging current of the electrode itself. All have the same typical form, and the wave form of voltage is also shown in curve (d).

After completely shielding the lead wire by enclosing in metal tube, the charging current for both electrode *D* and lead wire when connected together is practically coincident with the curve (c) of Fig. 16, showing the elimination of exterior electrostatic induction.

It is not possible to eliminate completely the charging current of the electrode *D*, owing to the holes in the grounded cylinder of the voltmeter. These holes are essential to its principle of operation. Thus the wave form at voltage just above the start of corona is the superposition of the electrode charging current and the corona discharge.

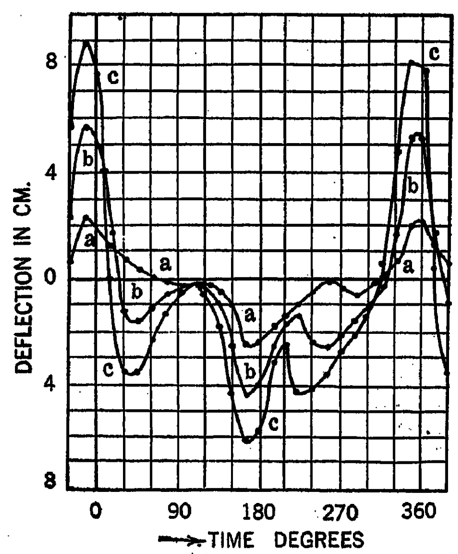

FIG. 18—NEGATIVE ELECTRODE

Corona starts at 36.5 volts.

Direction of current:—same as Fig. 17.
Curve *a*—37 volts,
Curve *b*—41 volts,
Curve *c*—45 volts.

d. Wave Forms of Corona Discharge Current with 0.289-Cm. Nickel Steel Rod. With the speed of the alternator maintained constant by a tuning-fork speed-control device and by shifting the commutator brush in the direction of rotation of the alternator, wave forms were taken for various conditions of corona discharge. Twelve points were taken on each half wave. We

record three sets of wave forms as follows: (1) For no continuous potential between electrode and ground, (2) for negative electrode, and (3) for positive electrode. Each set consists of three curves, one taken just above the corona starting voltage, and two at values considerably higher. They are shown in Figs. 16 to 19.

It was possible to take only one set of curves in any one day and consequently different values of starting voltages of corona are shown. The charging current of the electrode for a voltage just below the starting of corona was taken in each case. The fact that the values of this charging current were equal in all three cases is a check on the satisfactory condition of the commutator and brushes.

In all of the curves (Figs. 16 to 19) 0 deg. and 180 deg. of electrical angle on the commutator scale were fixed by the position of zero charging current, corresponding to the maximum points on the voltage wave. The wave form of the voltage of the high-tension side

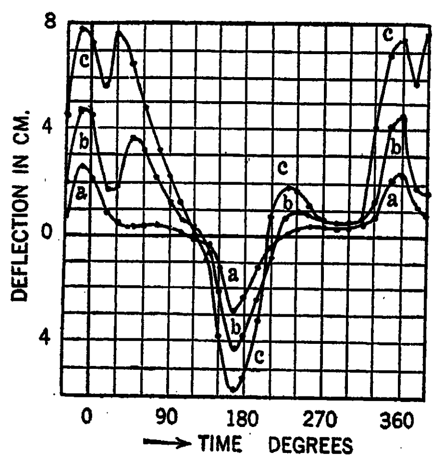

FIG. 19—POSITIVE ELECTRODE
Corona starts at 37.7 volts.

Curve *a*—38 volts.
Curve *b*—41 volts.
Curve *c*—45 volts.

of the transformer was measured by means of an air condenser, and is shown in Fig. 16. As the true wave form of corona discharge measured by the present method is the difference of the two wave forms below and above the critical value of voltage, it appears to be quite accurate only for voltage a small value above the corona starting value. For higher voltages, however, it is not correct to take the difference between the total current and the charging current as measured since the charging current itself becomes larger. This charging current is approximately proportional to the voltage except insofar as the capacity of the voltmeter may alter, due to the presence of corona. In the absence of definite knowledge on the magnitude of this alteration of capacity, the curves in Figs. 17, 18 and 19 were based on corrected values of the charging current for each voltage, assuming this charging current to be proportional to the voltage. All that may be said on this point at this time is that the shapes of the resulting curves indicate that a possible error on this account does not manifest itself in any serious change in the shapes of the curves. In Fig. 20, three curves are shown giving the net discharge currents under the conditions of Fig. 1. These curves are comparable with those of Fig. 2, except that they are taken with the d'Arsonval galvanometer used in the wave form ex-

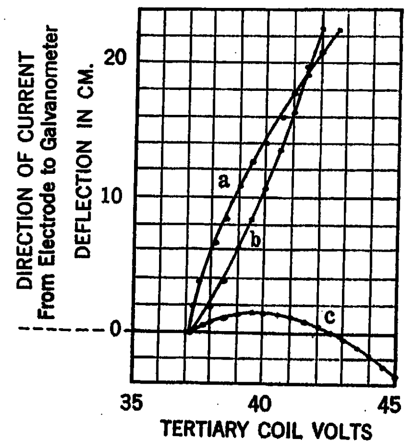

FIG. 20—DEFLECTIONS OF GALVANOMETER

Curve *b*—Positive electrode. (Reverse direction)
Curve *c*—No potential.

periments. The current read in these curves therefore is the algebraic sum of the positive and negative half waves of the discharge current. It is interesting to compare these curves with the wave forms of the currents under the corresponding conditions as shown in Figs. 17, 18 and 19. The deflection of the galvanometer in Fig. 20 without the use of commutator is proportional to the difference of the mean values of each half wave, and in the case of no potential on the

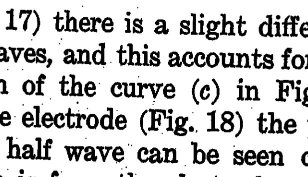

FIG. 21—STRAIGHT TELEPHONE CIRCUIT AS DETECTOR OF CORONA FORMATION

R—Telephone repeating coil
D—Two dry batteries in series
E—Ordinal telephone receiver.

electrode (Fig. 17) there is a slight difference between the two half waves, and this accounts for the relatively small deflection of the curve (*c*) in Fig. 20. In the case of negative electrode (Fig. 18) the predominating mean value of half wave can be seen clearly as that whose direction is from the electrode to the galvanometer. A similar predominating mean value with direction reversed can be seen as pertaining to the curve (*b*) of Fig. 20, and the curves of Fig. 19.

We can offer no explanation of the very irregular shapes of the waves of discharge current when negative and positive potentials are used on the electrode. It is noticeable that one-half wave in each case has the characteristic single peaked form as given by Fig. 17. It is the reverse wave which has the broken shape. We can only point to the complicated condition of ionization between the rod and outer cylinders, as influenced by the varying time above ionizing voltage, the rate of recombination of the ions, and the varying potential gradient. It is noticeable however that in the case of no potential on the electrode only one peak was found for each half cycle of alternating current and this peak corresponds to the maximum point of voltage wave.

VI. Loud-Speaking Telephone for Corona Detection

As already mentioned, the telephone is an excellent detector of corona formation under laboratory conditions. The sound of corona transmitted by the ordinary transmitter and receiver is however rather too weak for use in the presence of other noises. The connections using an ordinary transmitter, repeater, and receiver for use as detection are shown in Fig. 21. In order to obviate the disadvantage mentioned we have tried a loud-speaking telephone and have succeeded in greatly amplifying the sound of corona discharge. Many experiments and different types of connection were tried before a substantial amplification was obtained, but for brevity we give only the results and final method of connection. The greatest difficulty was found in separating the pure corona note from other noises which were also picked up and amplified in the loud speaker. The connections of Fig. 22 g ivea very satisfactory amplification, so that observations on the beginning of corona are readily possible at some distance from the loud speaker and in the presence of normal noises of a large laboratory, such as the operation of several other machines and the talking of individuals. One stage of amplification with a Weston 102-A tube was used, and other details are given in connection with Fig. 22.

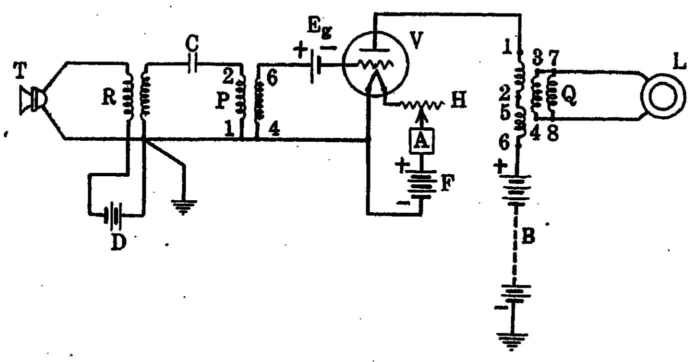

Fig. 22—Amplifier of the Sound of Corona Formation

D—Two dry batteries in series,
T—Telephone transmitter,
R—Ordinal telephone repeating coil,
C—Two condensers 2 μ. f. each in parallel,
P—Input transformer,
E_g—Grid voltage (1.5 volts),
V—Vacuum tube,
H—Wire resistance,
F—Filament battery (filament current:—about 1 ampere),
A—d-c. ammeter,
B—Plate battery 115 volts,
Q—Output transformer,
L—Loud-speaking telephone receiver.

While the results with the loud speaker are interesting, assuring the possibility of detecting corona formation and announcing it to several people at a distance, we believe that quite the same degree of accuracy of determination, if not better, can be obtained by a close-fitting head-piece, shutting out other noises, equipped with the ordinary telephone receiver. Under these circumstances extremely accurate indications of the first appearance of corona are possible.

Detailed description of the rectifying valves, speed-control device, commutators, and other equipment mentioned in this paper will be found in a paper entitled "The Corona Voltmeter, the Electric Strength of Air," by J. B. Whitehead and T. Isshiki, A. I. E. E. Transactions 39, May 1920.

Discussion

J. H. Morecroft: There is only one point on which I can add anything and that is on the use of the vacuum tube as a voltage rectifier. It is an experimental instrument not used very much as yet by electrical engineers, but as Dr. Hull told us some time ago, it will be used by every engineer very soon. There are certain cases where voltages are to be measured where it is impossible to get the measurement without the use of the vacuum tube.

Sometimes we want measurements in a circuit having but a few millivolts of power, of the order of one, two, three, four or five volts, and a frequency of perhaps a million cycles per second. If you have to measure that kind of a circuit with the ordinary engineering apparatus, you throw up your hands and say it is impossible to do it, there is no indicating instrument which will respond, even if it used up all the millivolts there are in the circuit, and if it did respond, you would not know what the reading

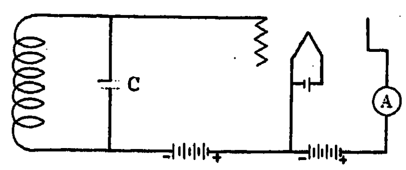

Fig. 1—Scheme for Measuring Maximum Voltage Across Condenser C

meant, because the errors at a million cycles would be excessive, and it would be necessary for you to have recourse to the newer devices, of which the vacuum tube is the most important.

Take an oscillating circuit with an unknown voltage across the condenser, and a frequency of, let us say, a million cycles. and measure the voltage. We might try to put a voltmeter across the condenser. If we did, the voltmeter would short-circuit the current, and we would have no voltage at all, so that evidently will not work. A scheme like this, however, will work. Put the grid of a vacuum tube as in Fig. 1, insert

a biasing battery which makes the grid of the vacuum tube negative, and if the grid of the vacuum tube is made sufficiently negative, there will be no current going through the plate circuit. When this circuit is not excited, put on sufficient negative voltage, on the grid by means of the biasing battery so that the plate current is cut off, and then, if you start to excite the circuit, the grid will go up and down in potential, and as soon as it goes positive, a little bit more than the critical amount, as previously adjusted, then the grid, going positive, will allow a little bit of current to go through the plate circuit, and if the plate circuit instrument is sensitive enough, you can read it. The biasing battery must now have its voltage increased to reduce the plate current again to zero; the amount of increase in biasing voltage is the maximum value of the high-frequency voltage across C. In the case of corona you ordinarily have much more power available than in the high-frequency oscillating circuits used in radio.

In looking over the curves, I notice that Dr. Whitehead gives the curve for a certain type of Western Electric tube in Fig. 13, and uses the diagram shown in Fig. 14. If that is so, there is an error in the curve, an error due to the 1.5 meghoms, which is connected in the circuit. If in taking a curve we make the grid at all positive, of course the grid will draw current, and this current will have to flow through the 1.5 megohm resistance, and the drop in this resistance will be very high compared to

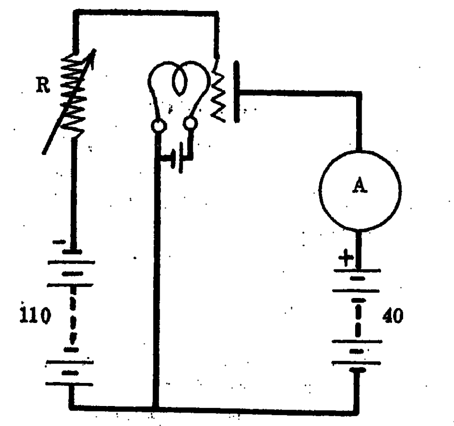

FIG. 2

the voltage being used. For example, if we have two micro-amperes flowing in the grid circuit, which is a pretty small current, if the two micro-amperes go through 1.5 megohms, there is a drop of 3 volts in the resistance. If we have 4 volts in the grid battery, the grid will be positive only to the extent of one volt. It looks to me as if something of that kind may have taken place, because it is very seldom in the Western Electric tubes of that type that the plate current falls away so rapidly, and becomes horizontal, as indicated in Fig. 13.

G. D. Robinson: I would like to call to Dr. Whitehead's attention a circuit differing somewhat from the one that he has shown.

In the corona voltmeter we are interested in an extremely small flow of current through the more or less ionized gas between electrodes in the meter. When the gas between the electrodes is normal the resistance between them is substantially infinite, but at the moment that corona starts appreciable ionization occurs and this resistance drops to a lower, but still enormous, value. As the current which can be passed through this ionized gas is insufficient to give a deflection on a portable meter, it has become desirable to cause this small current to control a larger current which can operate the portable meter. Dr. Whitehead's circuit uses the $I\ R$ drop caused by the flow of this small current through a resistance unit to control the grid voltage and plate current of a three-element vacuum tube. The variation of this circuit which I have in mind makes use of the $I\ R$ drop *through the tube itself*, from filament to grid, to produce a similar result. The circuit will be as shown in Fig. 2. Here R represents the variable resistance of the ionized gas path between electrodes. A is a sensitive portable meter, perhaps one giving full scale deflection with one milliampere. I have found it desirable in a similar case to use more voltage in the grid circuit than in the plate circuit. The figures beside the batteries are possible values for these voltages.

In considering the effects of the grid upon currents in a circuit such as this it is customary to use curves showing the value of plate current and of grid current for various values of grid voltage. With negative grid voltages the grid current is so small that frequently it is neglected, but this current is *not* zero and in this case it is *not* negligible. When these characteristic curves have been taken with a sufficiently sensitive galvanometer it will be seen that any attempt to increase the negative grid current beyond a certain very small value will result in shutting off the plate current completely. This "very small value" will vary greatly with different tubes and different adjustments of plate and filament voltages. It is at least as small as 10^{-8} amperes in some tubes. Yesterday I obtained from Mr. Chubb of the W. E. & M. Co. the opinion that by removing the base, a three-element vacuum tube might be obtained in which a current of 10^{-12} amperes in the grid circuit would be enough to shut off the plate current. What does this mean? It means that if the ionized gas path in the corona voltmeter permits the passage of the *very small value* of current a change of current of the order of one milliampere can be obtained in the portable meter when corona starts.

This circuit does not satisfy the condition that the meter should read zero before corona starts, but obviously the meter could be shunted by a battery and resistance so that it would satisfy this condition. In the circuit shown in the figure the meter reading should be substantially constant at a large value before corona starts. At the start of corona the reading should *drop sharply.* I am of the opinion that this circuit can be made to give greater current amplification than was obtained by Dr. Whitehead.

As a-c. voltages applied to the grid of the vacuum tube will affect the reading of the d-c. meter in the plate circuit, precautions to reduce any such a-c. voltages to a small value would probably be required with this circuit.

John B. Whitehead: I wish to thank Professor Morecroft and Mr. Robinson for their suggestions in connection with the tube circuits. After a lapse of six months I can recall nothing which suggests that the connections in Fig. 14 were not used as there found. However, I understand that Professor Morecroft's comment refers particularly to the upper portion of the curve of Fig. 13, where the grid voltage becomes positive. The critical condition in which we are interested is that of zero value of the plate current when the grid has a considerable negative potential. It is quite possible, as Professor Morecroft suggests, that there may be some current in the grid circuit. If this is the case, the presence of the grid leak would undoubtedly cause the value of the grid voltage to be other than that indicated. The absence of the grid leak in Fig. 15 would therefore cause a change in condition. However, it will be noticed from Table 2 that observations were taken at various values of grid voltage, showing that the most effective were between 7.4 and 8.8.

As to Mr. Robinson's comment, I judge that he suggests that the indicating galvanometer shall carry current before corona forms, and fall to zero after corona forms, this result being accomplished by varying the current in the grid circuit. It is possible that a greater sensitivity may be obtained thereby, but I question whether the conditions will be as practicable and uniform as those well-known connections that we have used. Moreover, there is a considerable advantage in having the instrument stand permanently at zero, with deflection for the critical condition rather than the reverse. I hope that Mr. Robinson will have an opportunity to try the connection he suggests.

Prevention of Transient Voltage in Windings

BY J. MURRAY WEED
Member A. I. E. E.
Power and Mining Engineering Department, General Electric Company, Schenectady, N. Y.

Review of the Subject.—*This paper relates to windings such as are used in transformers, reactors and the like, with particular reference to the characteristics which determine internal distributions of suddenly impressed voltages or sudden voltage changes, and the resulting internal oscillations. Ordinary lightning arresters, which limit the maximum voltages reaching the winding terminals, but cause rather than prevent the occurrence of sudden voltage changes, certainly give no protection against excessive voltages between turns or between coils. After describing the production of these transient voltages in ordinary windings, and pointing out that the treatment of symptoms by the addition of extra insulation tends to defeat itself by augmenting the cause, this paper explains these phenomena as due to faulty arrangements of inherent capacitance with the inductance of the winding. A fundamental principle is evolved indicating the constitutional remedy, which, if perfectly applied, would give only uniform internal voltage distributions, however abrupt or frequent the voltage changes at the terminals might be. Methods of application are described for the ordinary windings, by supplementing the faulty arrangements of inherent capacitance with auxiliary capacitances or condensers. Methods are given, also, for the construction of windings with the ideal distribution of inherent capacitance called for by the principle.*

Two alternative statements of the fundamental principle upon which the ideal distribution of capacitance is based are emphasized in the paper, and the application of the principle is adequately illustrated in the figures, of which Fig. 2 is a simplified diagrammatic representation of the arrangement of inherent capacitance with the inductance of that certain type of ordinary windings shown in Fig. 1, Figs. 3 to 5 illustrate methods of correcting this faulty arrangement by means of supplementary condensers, Figs. 6 and 7 show two typical forms of a general method of constructing windings with the ideal distribution of inherent capacitance, and the remaining figures illustrate practical modifications of this method.

With the ideal distribution of capacitance with inductance called for by the fundamental principle here enunciated, sudden and erratic changes in voltage at the terminals of the winding, or impressed wave trains of any frequency, result only in voltage distributions which are at every instant uniform. With practical arrangements approximating the ideal one, it is only necessary to insulate between turns and between coils, with ordinary factors of safety, for the proportional part of the maximum voltage which may appear at the terminals.

CONTENTS

HOW TRANSIENT VOLTAGES ARE SET UP IN ORDINARY WINDINGS

In ordinary electrical windings, in which all of the turns link a common magnetic circuit, such as those for alternating current transformers or reactances, any fluctuating or alternating voltage existing across or in the windings, unless the fluctuations or changes within the cycle are very rapid, has at each instant of time a practically uniform distribution throughout the winding. Voltages between points in the winding at any instance are approximately proportional to the numbers of intervening turns. Practically uniform voltage distribution thus prevails throughout such windings in normal steady operation at ordinary commercial frequencies. On the other hand, the resulting voltage distribution at the instant of a sudden voltage change, as from the closing of a switch, is far from uniform, and results in an internal oscillation. Moreover, voltage distributions and oscillations due to successive sudden voltage changes will superpose, augmenting each other if in synchronism and in phase, but tending to neutralize each other if in phase opposition. The internal voltages resulting in this manner from a succession of sudden voltage changes thus depend upon the way the changes are timed with respect to each other. Similar results will be produced, if the voltage changes at the terminals are sufficiently rapid, even though they are not absolutely instantaneous. With an external oscillation or high-frequency wave train arriving at the terminals, if the frequency is the same as the frequency of the internal oscillations, internal resonance will occur, and excessive voltages may be produced between neighboring portions of the winding. A single large sudden or quick change of voltage at the terminals of a winding may, in fact, produce transient voltages between turns which are very large as compared with those corresponding to uniform distribution, and the insulation stresses resulting from a succession of voltage impulses or a high-frequency wave train may become relatively much higher than those due to a single impulse.

Presented at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

Extra Insulation Constitutes Treatment of Symptoms

Occurrences of the phenomena described above have demonstrated themselves in practise through years of painful experience, in the rupture of insulation between turns and between coils, resulting from switching, arcing grounds and lightning. As demands for reliability increased, and experience seemed to show the need of it, the insulation was increased, until its effect upon the cost and characteristics of transformers became a serious handicap. An unfortunate and for a long time mysterious phase of the situation lay in the fact that each increment in the insulation provided seemed to be followed, and as we can now understand, actually was followed, by a corresponding increment in the transient voltages which might appear to break it down. (From what follows, this will be seen to be due to the reduction of capacitance between turns caused by the increased thickness of the intervening spaces occupied by the insulation.)

Object of the Paper

While it has long been known that these results were due to capacitance within the winding, it is obviously impossible to eliminate capacitance, and the subject was not sufficiently well understood to avoid the evil effects. It is the object of this paper to enunciate a fundamental principle whereby the evil effects of capacitance in windings can be avoided, and to describe several practical methods for the application of this principle. The principle involved becomes obvious and will be stated after a brief review of the way capacitance occurs in windings and of how it affects voltage distribution.

Distribution of Capacitance

Every portion of the inductance of any winding, as represented by a turn or a coil, may be considered as having a certain amount of capacitance in parallel with it, as the capacitance between turns and the capacitance between coils. The conclusions which it is here desired to draw from these considerations will not be affected by the fact that these capacitances are distributed around the turns and through the coils. Capacitances or elements of capacitance are also found between the various parts of the winding and grounded parts of the apparatus or surrounding objects, which will be included under the general term of capacitance to ground.

Effect of Capacitance on Initial Distribution of Suddenly Impressed Voltages

Any voltage appearing suddenly at the terminals of such a combination of inductance and capacitance must be accompanied by an impulse of current necessary to charge the various elements of capacitance. The charge for each element is transmitted through other capacitance elements in series with it, since no current can flow through the inductance at the first instant. It is evident, therefore, that the voltage distribution at the first instant will be that due to the action of capacitance alone. In the ordinary winding, this distribution will be far from uniform with respect to the turns and coils of the winding, the instantaneous voltage across the end turns, for instance, being relatively very great.

Effect of Capacitance on Initial Distribution of Current Growth

The voltage across each individual turn, resulting from the initial distribution due to capacitance, constitutes the initial impressed voltage for that particular turn. This voltage must be opposed by an equal voltage magnetically induced in the turn. This induced voltage, however, is not merely that due to the self-inductance of the individual turn, but it is the summation of the voltage of self-inductance, which is due to the growth of current in this turn alone, and all the voltages of mutual inductance set up in this turn by the growths of current in other turns. The growth of current will be maximum in those turns for which the impressed voltage is maximum while in the turns of minimum impressed voltage the current growth may be minimum in the positive sense, or it may be in the negative sense with maximum negative value. A negative growth of current will occur in any turn in which the summation of voltage of mutual inductance due to current growths in other turns which is opposed to the impressed voltage for that turn is greater than this impressed voltage.

Production of Internal Oscillations

The natural tendency of this initial distribution of current growth, by redistributing the condenser charges, is toward a uniform distribution of the voltage. Unfortunately, however, as this condition is approached we find a nonuniform distribution of current. With perfect mutual inductance between all of the turns, the current would become uniform at the proper instant, and both current and voltage distribution would remain uniform, but on account of magnetic leakage between different parts of the winding, the current can be brought to uniformity only after a further redistribution of voltage, giving maximum voltages where minimum voltages were previously found, and vice versa.

Superposition of Oscillations

We have thus roughly outlined the first swing of an internal oscillation which will be gradually damped out, resulting in a condition of uniform voltage distribution provided there are no further quick voltage changes at the terminals. If a succession of such voltage changes appear, the voltage distribution and oscillations which would be caused by each change will be superposed upon the remaining effects of all previous changes.

Fundamental Principle on Which the Constitutional Remedy is Based

The fundamental principle whereby these non-uniform voltage distributions and oscillations may be eliminated from windings will now be stated as follows: *If the capacitance associated with any inductance is so disposed that the initial distribution of a suddenly impressed voltage, which is effected by the capacitance, is uniform with respect to the inductance, the growth of current within the inductance will be uniform, and the voltage distribution will therefore remain uniform, each element of capacitance receiving charge at the same rate that it loses it.*

In a winding which meets these conditions, the current in all parts will be the same at each instant of time. The action within a given turn of the mutual inductances between it and the various other turns, in this case, will be exactly like and simultaneous with that of its own self-inductance. These mutual inductances are with propriety, therefore, all included with the strictly self-inductance of the turn as the inductance referred to in the statement of the principle, although it is necessary to distinguish between the self-inductance of the turn and mutual inductances between it and other turns in considering the effects of quick voltage changes when this principle is not complied with.

Perfect Cure Would Result from Exact Application

In a winding fully complying with this principle, the voltage distribution would be uniform at all times, without regard to the abruptness or frequency of voltage changes at its terminals. The voltage which could appear across the insulation between turns or between coils would be limited to a value proportioned to the voltage at the winding terminals by the ratio of the number of intervening turns with the total number of turns in the winding. To provide the insulation necessary for safety, therefore, it would be necessary to consider only the proportional part of the maximum voltage which can appear, or would be permitted to appear, across the total winding. Moreover, for the provision of suitable external protection, it would be necessary to limit only the maximum voltage the suddenness and frequency with which voltage changes occur being of no importance.

Approximate Methods Giving Practical Results

Several methods will now be described whereby a disposition of capacitance in accordance with this principle may be obtained with sufficient approximation for practical purposes, thus reducing the insulating of windings to a rational basis wherein the internal insulation required bears a definite relation to the normal operating voltage between the parts involved, as expressed by moderate factors of safety, and at the same time removing the necessity for restrictions as to switching, eliminating the danger from arcing grounds and simplifying the duties of lightning arresters.

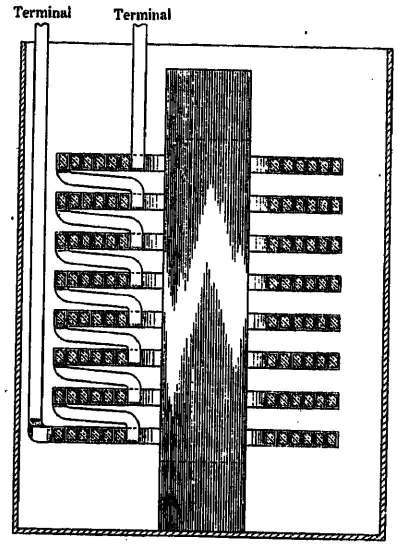

Fig. 1—Reactor Winding in Cross-Section—Case and Laminated Core Grounded

The reactor is chosen for illustration instead of a transformer on account of its more simple arrangement of inherent capacitance, which is shown diagrammatically in Fig. 2. The methods of correcting faulty arrangements of capacitance, illustrated in Figs. 3, 4 and 5 with reference to this winding, if correctly carried out, are applicable to the more complicated cases of transformers.

General Method Applicable to Ordinary Windings, Supplementing Inherent Capacitance

A general method suggests itself which is applicable to ordinary windings, by the provision of a system of supplementary capacitances or condensers, so proportioned and interconnected with the winding as to give the desired disposition of combined supplementary

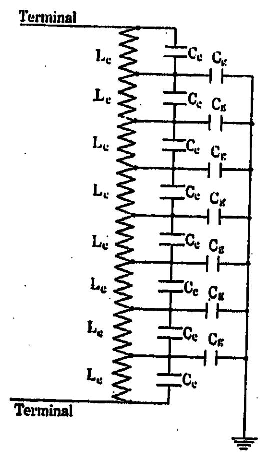

Fig. 2—Arrangement of Inherent Capacitance with Inductance in the Reactor of Fig. 1, Somewhat Simplified

Inductance elements L_c correspond to the individual coils, condenser elements C_c represent capacitances between coils and condenser elements C_g represent capacitances to grounded core and case. Without ground capacitance, the initial distribution of suddenly impressed voltages would be uniform. The ground capacitances cause greater initial voltages across coils which are nearer to the line terminals, resulting in subsequent oscillations.

and inherent capacitance. This is illustrated in connection with the very simple arrangement shown in Fig. 2, which is here chosen for simplicity of treat-

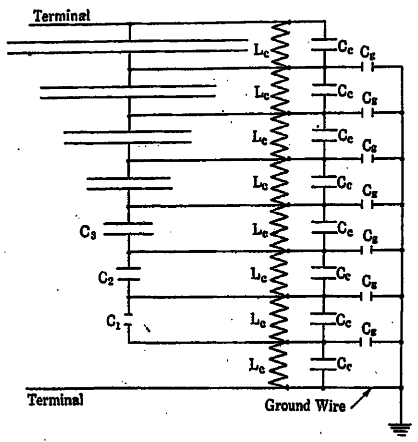

Fig. 3—A Method of Neutralizing Effects of Ground Capacitance in Arrangement Shown in Fig. 2

This method is applicable only when the winding is definitely grounded at some point. It consists in connecting condensers C_1, C_2, etc., across individual coils, the capacities of the respective condensers being given by the equation $C_n = \frac{n^2+n}{2} C_g$, where n is the number of the supplementary condenser, counting from the point of grounding.

ment. This diagram represents a simplification of the disposition of inherent capacitance in the reactor winding of Fig. 1. The capacitances between coils appear as equal condenser elements, C_c, in parallel with the equal inductance elements, L_c, which repre-

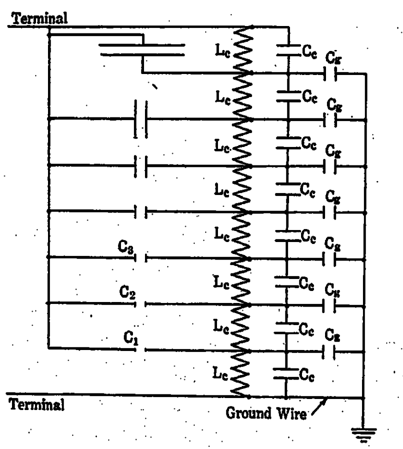

Fig. 4—A Method of Neutralizing Effects of Ground Capacitance Alternative to that Shown in Fig. 3, Applicable only when Winding is Grounded

Condensers C_1, C_2, etc., are connected between the line terminals and various points of connection between coils. The capacities of the respective condensers are given by the equation $C_n = \frac{n}{N-n} C_g$, where n is the number of the supplementary condenser, counting from the point of grounding, and N is the number of coils between this point and the line terminal.

sent the inductances of the individual coils. The condenser elements, C_g represent capacitances to ground or to neighboring conducting surfaces. If the ground capacitances could be eliminated, and if the arrangement of inherent capacitance with inductance were adequately represented by the C_c and L_c elements of Fig. 2, this would constitute an ideal arrangement in which the initial distribution of a suddenly impressed voltage would be uniform. The ground capacitances result in a condition for the various coils with respect to the suddenly impressed voltage, with which we are familiar in connection with suspension insulators, where the maximum voltage appears across the disk at the line end of the string. In the winding, the initial voltages will be greater for coils which are nearer to the line terminal, and these initial voltage distributions result in oscillations, as described above, due to reactions between the inductance elements and the capacitance elements. Specific

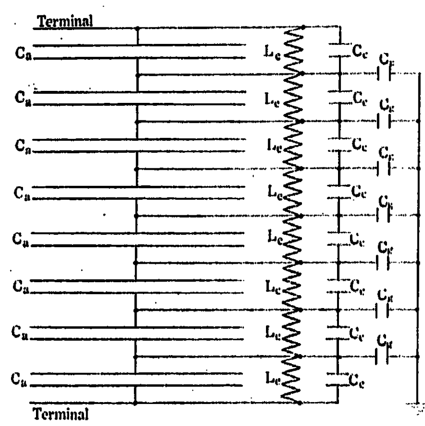

Fig. 5—A Method of Neutralizing Effects of Ground Capacitance in Arrangement Shown in Fig. 2, which does not Require Grounding

The condensers, C_a, connected across the individual coils, must be large as compared with the inherent ground capacitances or possible inequalities between intercoil capacitances. If the coil inductances are unequal, these condensers must be unequal, their capacitances being in inverse proportion with the inductances.

methods for correcting this faulty disposition of inherent capacitance by means of supplementary condensers, which, if correctly carried out, are applicable to the more complicated cases of transformers, will now be given.

Methods Limited to Grounded Winding

If the winding is definitely grounded at one end, we will be able to neutralize the effects of the C_g elements, by means of supplementary condenser elements, by either of the methods illustrated in Figs. 3 and 4. With all the capacitance elements C_g equal, the required capacitance of any supplementary condenser C_n, in Fig. 3, is

$$C_n = \frac{n^2 + n}{2} C_g$$

and the required capacitance in Fig. 4 is

$$C_n = \frac{n}{N-n} C_g,$$

where n is the number of the condenser, counting from the grounded end, and N is the total number of coils.

Method Without Ground Limitations

To carry out correctly the arrangements shown in Figs. 3 and 4 would require an indefinite number of sizes of auxiliary condenser units to fit the different cases and definite knowledge of the amounts and locations of the inherent capacitances of the winding. Moreover, they would possess the obvious disadvantage that they can be applied only in connection with a grounded winding. A method without these disadvantages is illustrated in Fig. 5, where the auxiliary condenser units, C_a, are all equal, and of sufficient size to overpower the inherent capacitances to ground. That is, the capacitance C_g is negligibly small in comparison with the capacitance of an auxiliary condenser unit. With this arrangement it makes no difference where the ground is located on the protected winding, or whether or not it is grounded at all.

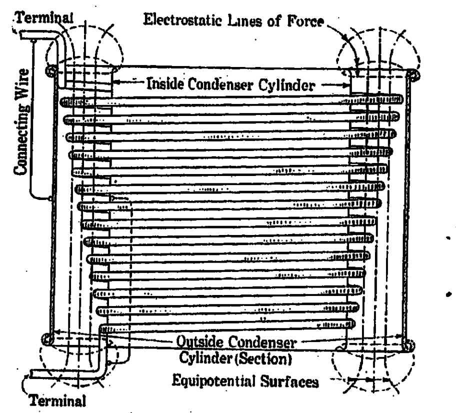

Fig. 6—Tapered Single-Layer Winding Embedded in Dielectric of a Condenser Consisting of Two Concentric Cylinders

The condensers plates (cylinders), are respectively connected to the winding terminals, and the winding progresses gradually, turn by turn, in the radial direction from one plate to the other, so that the electrostatic potential impressed upon each turn by the action of the condenser field corresponds to a uniform distribution of voltage. Nonuniform voltage distributions and internal oscillations cannot occur in windings so disposed.

More General Case and Alternative Statement of Fundamental Principle

The method illustrated in Fig. 5 has been described in connection with a winding in which the various inductance portions were assumed to be equal. It is clear, however, that the same general method is applicable to any winding in which leads for connection to condenser units are brought out at convenient intervals, breaking up the inductance into parts which may not be equal. In this case, the capacitances of the auxiliary condenser units must not be equal but must be proportioned in accordance with the fundamental principle given above. For this application the principle may be stated in a more convenient form, as follows:

To give uniform distribution, with respect to the inductance, of voltages appearing suddenly across the terminals of windings, the capacitances in parallel with all of the various portions of the inductance must be in inverse proportion with the respective portions of inductance.

Limitations of Supplemental Methods

The methods which have been described insure that the voltages which can appear across the various coils or portions into which the winding is divided by the condenser leads are proportional to the respective portions of inductance, the sum of these partial voltages at any instant being the total instantaneous voltage across the whole winding, but they do not insure uniform distributions within the individual coils or portions of the winding, since the way capacitance occurs within these portions has not been affected.

If the way the voltage appearing across any individual coil distributes itself throughout the coil were not affected it is evident that voltages which may appear between turns or across portions of the coil will be reduced in the same proportion as that across the whole coil. As a matter of fact the reduction in voltage between turns or across portions of the coil will be greater in proportion than that across the coil as a whole, and this proportional reduction will be more marked the larger the auxiliary capacitances which are used. This is on account of the relatively large amount of electricity required to charge the auxiliary condensers, and the limited current which can be supplied from the line. The change in voltage across the entire winding, and consequently, that across the individual coil, will be less rapid with the condensers than without them, and less non-uniformity of voltage distribution among the turns of the coil result naturally from the more gradual change across the coil as a whole.

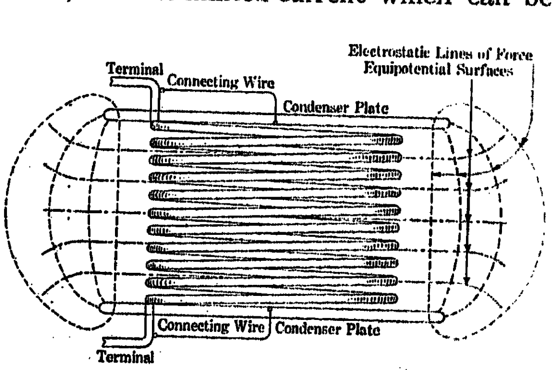

Fig. 7—Cylindrical Single-Layer Winding Embedded in Dielectric of a Condenser Consisting of Two Parallel Plates

The equivalent arrangements shown here and in Fig. 6 are typical forms of a general method for the construction of windings with the ideal distribution of inherent capacitance.

Method of Constructing Windings with Ideal Distribution of Inherent Capacitance

The methods which have thus far been described are applicable as a corrective measure in connection with ordinary windings of previous types. It is, how-

ever, possible to design and build windings in which the inherent capacitances will have the ideal distribution, so that no supplementary condensers will be needed. A general method which completely meets the conditions for uniform voltage distribution

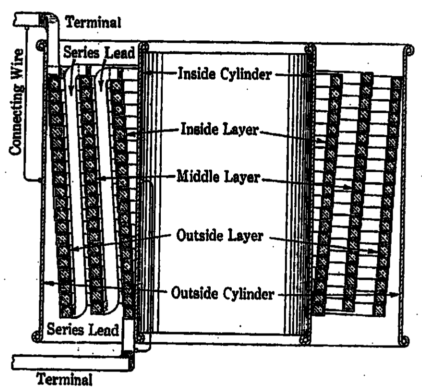

Fig. 8—Multilayer Winding, in Cross-Section of Type Shown in Fig. 6

The last turn of one layer is connected to the first turn of the next layer by a series lead passing between the layers. Except for the disturbing effect of these leads, which constitutes a departure from ideal conditions, this arrangement gives the same results as a single layer of three times the length, progressing gradually from one cylindrical plate to the other. A slight modification of this arrangement would result from making the winding layers cylindrical and tapering the plates.

with respect to the individual turns, without the use of supplementary condensers, is illustrated in typical forms in Figs. 6 and 7. This method consists in enclosing or embedding the entire winding within the dielectric of a suitably proportioned condenser, the terminal plates of the condenser being connected to the terminals of the winding, and each turn of the winding being so positioned that, with uniform voltage distribution,

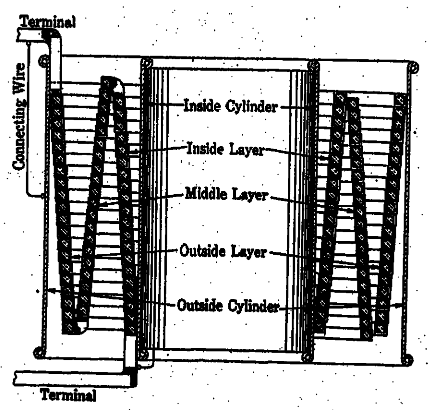

Fig. 9—Arrangement Equivalent to that Shown in Fig. 8

The series leads between layers are eliminated by inverting the middle layer.

its potential will be the same as that which would exist in the part of the dielectric where the turn is located if the winding were not present. Turn by turn or element by element, the winding traverses the dielectric of the condenser, progressing gradually from one terminal plate toward the other. Modifications of these typical forms, embodying multilayer constructions, are shown in Figs. 8 and 11.

Effect of Winding Conductor Thickness

A matter to be noted in connection with these arrangements of windings between condenser plates is

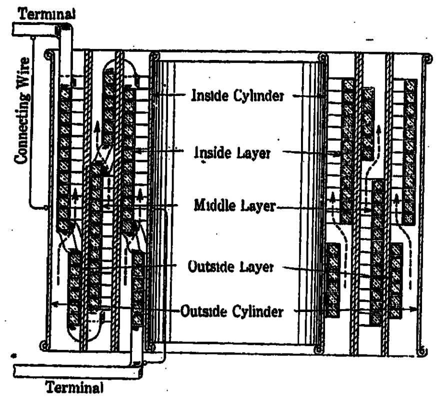

Fig. 10—Modification of Arrangement Shown in Fig. 9

Cylindrical layers or sections of layers are substituted for the tapered layers. With the mid turn of each layer section in its correct position with respect to the condenser plates, corresponding to Fig. 9, it is seen that the other turns are slightly displaced from their ideal positions. This arrangement permits the introduction between layers of insulating cylinders and of passages for the circulation of cooling fluid. These passages are offset as indicated by the curved arrows.

found in the fact that the winding conductor occupies space which otherwise would be occupied by the dielectric of the condenser. If this conductor possessed only length and breadth, lying within equipotential

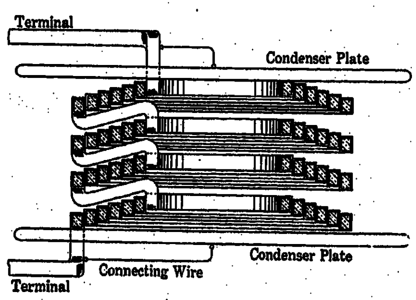

Fig. 11—Multicoil Winding of Type Similar to that Shown in Fig. 7, the Coils being Conical in Shape Instead of Cylindrical

The arrangement of this winding with respect to the disk-shaped condenser is similar to that of Fig. 8 with respect to the cylindrical condenser. A slight modification of this arrangement would result from making the coils flat and the condenser plates concial. Other practical modifications of this arrangement, similar to those shown in Figs. 9 and 10 for the arrangement of Fig. 8, are obvious.

surfaces, no effect would be felt, but due to its thickness in the direction of the field, it eliminates or short-circuits all potential drops within the space occupied. So far as the dielectric is concerned the effective distance between the plates is thus reduced by the combined thickness of the intervening conductors. In fixing the relative distances of the various turns from the respective plates, the thickness of intervening

conductors should be neglected, measuring only those portions of distance which are within the dielectric, and, of course, measuring in each case to the adjacent surface of the turn, and not to the center of its section.

Practical Modifications and Approximate Methods

As in the case of all engineering applications, practical considerations must here be taken into account. With the arrangement shown in Fig. 8, we find a disturbing element in the leads passing between the layers for connecting adjacent layers in series. These leads locally reduce the effective distance through the dielectric between layers, thus introducing extra voltage stresses. This becomes important when the normal layer voltages are high. If this were the only matter to be considered, this disturbing element might be escaped by inverting intermediate layers, giving the arrangement illustrated in Fig. 9. This would be a theoretically good arrangement, but one which may be modified further with several important practical advantages, making the arrangement only a little less good from the standpoint of voltage distribution. Thus, in the arrangement shown in Fig. 10, cylindrical insulating barriers have been introduced between adjacent layers, ducts have been opened up for the free circulation of cooling fluid, and the winding layers have become cylindrical instead of tapered. The middle point of each cylindrical layer portion of the winding occupies its ideal position in the dielectric, while turns on opposite sides of each mid-turn make slight departures from their ideal positions in opposite directions, the departure increasing gradually as we pass further from the mid-turn. This will permit corresponding departures from uniform initial distributions of suddenly impressed voltages within the individual layer sections, although the distribution of the total terminal voltage among the different sections will be in proportion with the numbers of turns between respective mid-turns.

Discussion

M. E. Skinner: I do not understand from the paper that actual transformers or even reactors have been constructed in which the inherent but rather disturbing effects of leads, connections and taps, space occupied by the conductors themselves, and of non-uniform inductance per turn, have been overcome. The paper appears to crystallize several ideas as to how these inherent difficulties may be overcome, but the structures illustrated are still a long way from anything employed at the present time in power or distribution transformer construction. It is interesting to note that the solution chosen for the problem of taps is their complete elimination. This is undoubtedly the most effective as well as the easiest way out. The fact that it has been found advisable to reinforce the insulation of the end turns of so simple a winding as that employed in an air core reactor, illustrates the difficulty of applying the principle upon which Mr. Weed's paper is based to commercial apparatus.

In this connection I should like to point out that the number of transformers which fail from overheating and from mechanical stresses is probably as great as the number which fail from voltage stresses. Of the insulation failures, relatively few occur between line turns. It would therefore appear as though the present practise of padding the insulation between the turns connected to the line was taking care of the situation admirably and this with no decrease in mechanical or thermal reliability and at very little increase in cost.

The picture drawn by Mr. Weed of the ease with which high voltages are built up in a transformer winding is rather alarming. However, it is comforting to remember that actual exhibitions of these high voltages on commercial systems are rare.

I believe that more improvement in service records will result from a reduction in the number of taps and leads, and from more thorough insulation of these exposed points in transformer windings than from such a delicately balanced winding construction as is proposed in this paper.

F. F. Brand: Mr. Weed is to be congratulated on the clear manner in which he has outlined the theory of transient voltages in windings and methods of eliminating them in simple cases.

There are unfortunately other factors than insulation to be considered in transformer design. Some of these fundamentally tend to have an opposite effect on the design.

Consider only the mechanical forces between windings. These are naturally higher in low-voltage transformers than in those for high voltages. The smaller insulating clearances necessary, the better space factor of the windings, result in increased flux densities surrounding the windings and thus result in higher forces.

For this reason the style of winding most suitable for low voltages may be radically different from that suitable for high voltages. In the former, mechanical force problems may predominate, in the latter, insulation problems.

Thus any method which makes it easier to insulate between the various parts of the structure, which enables the windings to be made more compact, increases the mechanical forces, and this must be considered in selecting the type of winding.

There is also a limit, due to variation in insulating value of the materials used, or to possible damage of the insulation, beyond which it is not safe to reduce the insulation and this, in connection with the mechanical forces produced under such conditions as short circuits, may make it uneconomical or impractical to use windings of the types illustrated which can be perfectly shielded.

Most of our present transmission systems are very complicated, there are wide variations in transformer requirements even on one system or circuit and these militate against the use of such shielding arrangement.

With the growth of extra high-voltage systems, where synchronous regulation becomes necessary, where systems assume the type of great trunk lines, the transformer requirement should become more fixed under all operating conditions. Furthermore the tendency to use solidly grounded neutral enables radical departure in transformer design to be made. These facts may and should allow the use of more perfect shielding of windings than has yet been accomplished commercially, although we must recognize that the grounded neutral system will probably increase the frequency of short circuits, because every insulator failure at once develops into a short circuit, and thus mechanical conditions may again be of increased importance even in extra high-voltage designs.

H. O. Stephens: In considering the design of transformers to withstand the transient voltages which always occur in operation the designing engineer has the choice of four methods.

1. He may disregard all means of eliminating or reducing these excess voltages and must recognize that they will be present between turns, between coils, between windings and between windings and ground. In this case it will be necessary to provide sufficient insulation at all of these points to withstand the maximum transient voltages that may occur under the most severe operating conditions.

2. He may use lightning arresters at all points of danger to prevent rises in voltage materially above the line voltage. He may use high-frequency absorbers to prevent line oscillations below the discharge voltage of the arresters. He may shunt inductances with resistors where possible in order further to absorb the energy in high-frequency oscillations. If the expedients employed to keep the abnormal transient voltages as low as possible are wholly successful, he may insulate the transformer between adjacent parts to withstand only the normal voltages with a reasonable factor of safety.

3. He may design the transformer along the lines brought out by Mr. Weed's paper so that the relation between inductances and capacitances within the transformer are such that a uniform distribution of transient voltages throughout the windings will be obtained. In this case he may also provide the transformer with only the necessary insulation to withstand the normal voltages with a reasonable factor of safety.

4. He may choose a proper balance between all of the three methods outlined above, using lightning arresters and whatever means are available for reducing the transient voltages to a minimum, designing the transformer so as to obtain as uniform a distribution of voltages throughout the windings as practicable and finally providing sufficient insulation to withstand the voltages which calculation and experience show will be developed between the adjacent parts of the windings.

Transformer design consists so largely in choosing a proper balance between diametrically opposing characteristics that it is seldom possible to carry out any single idea to its logical conclusion. If it were always possible to design transformers with the simple types of windings shown in Mr. Weed's paper it would be feasible to carry out the shielded winding construction to its full possibilities. Unfortunately however, the transformer is the connecting link in all systems between all other electrical apparatus and must therefore be adapted to all of the peculiarities and vagaries of all apparatus and systems. Even in the simplest design taps are usually necessary to compensate for variation in system conditions and a very large percentage of transformers have to be designed to operate on different parts of the same system and in some cases on different systems so that they may and very frequently do become extremely complicated. As soon as taps or series multiple connections are a necessary feature of the windings it becomes practically impossible to carry out a system of shielding the windings which will give anything like a uniform distribution of transient voltages.

In the present state of the art it would appear that the best engineering judgment would dictate that we follow the middle ground outlined under paragraph four. Experience has shown that with proper consideration given to system layout and operation, with careful disposition of the transformer windings so as to avoid groupings that will actually invite dangerous resonant conditions, and with reliable insulations so disposed as to insure ample protection against these now well-understood transient voltages, modern high-voltage transformers have proved very reliable from an insulation standpoint.

However, Mr. Weed deserves much credit for the way he has worked up this physical conception of the behavior of transients and even if it may never prove entirely practical to adopt it in its entirety, there is no doubt that consideration of this method of preventing dangerous rises in voltage has already been of considerable benefit to the transformer designer in teaching him how to avoid specially objectionable combinations of internal inductance and capacitance.

L. F. Blume: The value of Mr. Weed's paper consists in its emphasis of the fundamental principles which govern the relation between inductance and capacitance of a winding. A transformer winding, reactor or similar electrical apparatus, usually classed as possessing the property of concentrated inductance is in reality a very complex circuit consisting of a large number of inductances and capacitances in series and in parallel. For example, a typical transformer winding possesses capacitances from turn to turn, from layer to layer, from coil to coil and also from the external surfaces to other parts of the apparatus and to ground. These capacitances are so enmeshed with each other and with the various inductances of which the winding is composed that it is generally hopeless to disentangle them for purposes of analysis.

However by clearly describing an ideal principle of design Mr. Weed makes a forward step towards the understanding of the problem, and, what was heretofore a hopelessly complex mesh-work now becomes a regular pattern of inductances and capacitances the action of which is readily understood.

The principle may be crudely stated as follows:

Imagine that the conductors in a winding are broken at each turn so that no current can flow through the copper. Under this condition the voltage distribution within the windings due to an alternating source of potential is entirely governed by the capacitances possessed by the windings.

If the winding has been designed so that the voltage distribution throughout the winding under the aforementioned condition is identical with the voltage distribution under ordinary conditions, then there can never be an interchange of current between the inductance and capacitance portions of the winding and therefore under all conditions of excitation, normal and abnormal, the voltage distribution remains unchanged.

Several transformer windings built in Pittsfield in accordance with this principle were subjected to all sorts of high-frequency tests and voltage impulses. A complete verification of its theory was obtained. In attempting to apply this principle, however the designer cannot lose sight of other very practical considerations. Mechanical strength, cost of winding, reactance, cooling and insulation, all require due thought and at best a design is a compromise in order that all of these may be properly taken care of. The elimination of internal concentrations or their reduction to a minimum is one of these, and the designer has the choice of reducing the abnormal stress by skillful manipulation of the capacitances or of employing sufficient insulation to withstand them.

The various shielded windings which are described by Mr. Weed differ from ordinary windings used in transformers mainly in two respects. First, a metal shield is connected to each terminal. Second, capacitance of the winding to ground is eliminated.

From these differences it is a simple step to the conclusion that voltage concentration and internal resonance in ordinary windings is largely due to the small surface area of the winding terminals, and to the comparatively large capacitance of the coil surface to other parts and to ground; and by increasing the one and decreasing the other improvement in coil design from the standpoint of transient voltages might be expected.

Appreciable improvements can thus be secured in many transformer windings without employing the rather radical departures that are suggested by Mr. Weed, and without sacrificing other important considerations. For example the use of a metal clamping plate in close proximity to the end coils and electrically connected to the terminals in a cylindrical coil structure very effectively reduces the voltage concentration on the end turns when a surge occurs. Again by shortening the coil stack the surface capacitance to ground is decreased and by this means voltage concentration under abnormal conditions is appreciably lessened.

Whether it is desirable to proceed further toward the ideal winding depends in addition to the limitations imposed by other design considerations mentioned above, upon whether the abnormal voltages introduced are sufficiently severe or occur sufficiently often, and whether the use of more insulation may not serve just as well.

Abnormal voltage stresses due to any cause whatever occurs at most, only occasionally and then the duration is extremely brief. This, together with the fact that a given insulation is capable of withstanding for very short time a much greater stress than for longer periods, helps to reduce materially the burden on the insulation.

The above facts are presented not for the purpose of discounting in any way the value of Mr. Weed's paper, but to point out that failure of applying to practise entirely the principle in the manner described by him is due not to a lack of appreciation of the importance of the theory but to many other factors that help to determine the nature of the design.

C. L. Fortescue: This paper is very interesting to me for many reasons. One of them is that I recognize the same ideas that have been used in connection with obtaining better distribution on strings of insulators. It seems rather peculiar that transformer windings and strings of insulators should require similar methods in order to get good distribution under transient conditions, but such is the case. If you could imagine a uniform inductance which has no distributed capacity, that inductance under an impulse would divide the impulse equally throughout all parts of its windings. However, it is impossible to get an inductance without distributed capacity. and therefore we must consider what determines the distribution of the impulse through a winding which has distributed capacity.

First of all, leave out of account the inductance itself. If we have capacity, in order to determine the potential of that capacity, we must have charge. That means we must have current flowing for a finite time. The impulse of voltage across the inductance is determined by the rate of change of the impulse, and therefore we cannot pass sufficient current in a given time to charge up the connected capacity to the right potential. In order to get the proper distribution, we must take the capacity part of our system, and so design it as to give uniform distribution of voltage.

In Fig. 3, of Mr. Weed's paper we have one method which is prosposed. That method is identical with that known in insulator strings as grading the insulators, that is to say, the insulator in the line which has a greater part of the capacity current, due to distributed capacity to take care of, is made of larger capacity—its capacity admittance is increased, and as the insulators approach towards ground, the capacity is graded,—those near the ground end being of less capacity than those near the line end. This method has been found quite effective, in giving proper distribution, and of course the distribution is entirely independent of the frequency or the rate of change.

Fig. 4 corresponds to the use of shields, such as the distribution shield at the terminal of the insulator string on the high-voltage side. This shield increases the capacity of the lower insulators, the line insulators, to the line, and grades the capacity in a manner similar to that shown by Mr. Weed; that is to say the capacity to the line is of such a magnitude that it completely annuls the distortion due to capacity to ground or the distributed capacity of the insulator string.

Fig. 5 shows another method that is being considered in connection with improving the distribution of potential over strings in insulators, that is to say, by making the capacity between adjacent insulators large compared with the capacity of the hardware to ground so that the latter becomes negligible as compared to the capacity between insulators. In this way a very excellent string distribution can be obtained.

Fig. 6 illustrates another method of shielding. For example, in the case of a string of insulators, if we put on the top and bottom of the insulators, a shield sufficiently large to give a field in the neighborhood of the string corresponding to that between two infinite parallel planes, we shall have a condition such that each insulator will have a capacity to the ground shield and a capacity to the high-potential shield of such value as to maintain each at its proper potential. and we shall get a string distribution, determined simply by the capacity between adjacent insulators.

Nine years ago I called attention of the Institute in a paper to a general theorem of electrostatics on systems of conductors having potentials, which covers in a general way the principles for obtaining any desired potential distribution. It may be stated in the following way: Arrange the system so that its natural potential distribution shall correspond to the natural electric distribution due to end electrodes or terminals. If you do this, you will get a condition in which there is no discharge between the individual members and the external space and you will then have the most efficient system.

As far as the application of these ideas to tranformers is concerned, I think certain types of winding tend towards the elimination of these transient maldistributions. The tendency is to use a distributed form of winding in which the high-tension part of the winding is removed from the ground as far as possible, and therefore its capacity to ground is decreased while of course, its capacity towards the high-tension terminals is correspondingly increased. The capacity is large for such a type of winding and it has a great deal of strength against transients coming in on the line. It approximates very closely the characteristics Mr. Weed pointed out.

J. F. Peters: When one considers the enormous voltages that theoretical considerations indicate have been produced in transformers which have been operating on comparatively high-voltage systems in the past, one wonders why any of them continue to live through the service; yet transformer failures have been comparatively rare. In more recent years the neutral of most high- and moderately high-voltage systems have been grounded either directly or through resistance, thus eliminating or greatly reducing the possibility of arcing grounds—the principal cause of high-voltage disturbances. In recent years the few insulation failures in transformers to my knowledge were not in or near the end coils and were all in ungrounded-neutral delta-connected banks.

That does not prove that comparatively high voltages may not appear across the end turns of transformers, but it does indicate that the present practise in insulation is adequate for the service, and it is accomplished with reasonable cost.

The paper presented by Mr. Weed is very interesting indeed. It shows theoretically how the maximum voltages in transformers can be reduced, but to actually approach even approximately the theoretical "constitutional remedy" outlined in the paper would be extremely difficult and very expensive. The schemes discussed by the author in connection with Figs. 8, 9 and 10 are, I believe, not as simple as one may be led to believe. With the arrangements shown in these figures it is assumed, I believe, that the total inductance of each turn is the same as that of every other turn throughout the winding. That, however, is not the case. The current that flows through the winding, due to an abruptly applied voltage, appears as a magnetizing current and a uniform current throughout the winding will not produce a uniform voltage.

This is because the magnetic circuit is not symmetrical with respect to all turns. This condition can best be seen by considering a number of identical coils located side by side and all connected in parallel. When an a-c. voltage is applied to these coils the outer or end coils will take very much greater current than the inner ones and the difference between currents of outer and inner coils will be greater the higher the applied frequency. That is, the more abrupt the applied voltage the greater will be the unequal division of current. Therefore, in order to get a uniform voltage across all turns of the structures, shown in Figs. 8. 9 and 10, the rate of change in current in the end turns of all layers must be much greater than that for the inner turns. In order to produce the proper current in all turns during the initial adjustment, the coils would have to be curved in cross

section instead of straight, as indicated, which would be difficult to carry out in practise.

The schemes shown by Figs. 3, 4, and 5 and particularly that shown by 5, could be incorporated in any transformers, but it is very probable that after bringing out the additional leads and adding the cost of condensers, that the resulting transformer would be more expensive and less reliable than those built according to present practise, which are proving themselves entirely adequate.

F. W. Peek, Jr.: It was my good fortune to witness the tests and to take part to some extent in the work of which the shield described by Mr. Weed is one of the practical applications. In that investigation, made at Pittsfield, in about 1912, various types of transformers were taken and subjected to disturbances corresponding to those produced by arcing grounds. Taps were brought out from the different coils and the voltage distribution throughout the winding was measured by sphere gaps. Very high voltages may be produced in any part of the winding by varying the frequency of the disturbance.

It is surprising that a static shield can be effective in eliminating these very high local transient voltages. Yet that such is the case has been demonstrated by tests. The ideal shield described in the paper is difficult to apply in practise. However, it is approximated in practise in the way of clamping rings and considerable advantage is gained thereby.

It may be of interest to point out here that the operation of the shield is very similar to the stress distributing ring now used on high-voltage line insulators. There is this difference, however, in a transformer the voltage distribution under normal conditions is determined by the windings. The ring functions only under abnormal conditions. In the insulator the shield determines the normal distribution as well as the abnormal distribution.

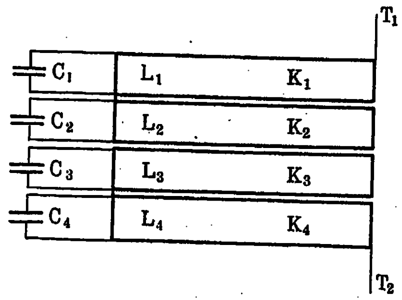

Fig. 1—Four Coils of a Transformer Connected in Series
Letter C indicates the capacity of the coil, L the inductance of the coil and K denominates the coil. T_1 and T_2 are the terminals.

P. Trombetta (communicated after adjournment): I find it very difficult to understand how the author got his conclusions, I find also that the paper contains some very specific contradictions which if taken seriously will upset either all his reasoning, his conclusions or both. Under the topic, "Object of the Paper," he states that it has long been known that the high voltage resulting at the terminal coils of transformer windings is due to the presence of capacitance and that it is obviously impossible to eliminate capacitance and that the subject was not sufficiently well understood to avoid the evil effects. On the other hand, farther on he proposes to eliminate these evil effects by introducing more capacitance. It seems quite clear to the writer that if the complete elimination of the capacitance would clear the effects certainly the nearer we get to the complete elimination the better should be the results and therefore it is impossible to see how by adding more capacitance we cure the effects.

A closer study of the phenomenon will, however, show that the burning of terminal coils in transformers is due to a phenomenon which is not at all mentioned in Mr. Weed's paper and which may be explained as follows:

In Fig. 1, K_1, K_2, K_3, K_4 represent four coils of a transformer; L_1, L_2, L_3, L_4 represent the inductance of the respective coils, C_1, C_2, C_3, C_4 represent the capacity between turns of the respective coils. Now as shown by Dr. Steinmetz, any system which contains distributed capacity and inductance has no fixed period of oscillation and any piece of such system may oscillate by itself irrespective of the rest of the system, so if we apply a voltage at the terminals T_1, T_2 of this transformer, we may have the transformer as a whole oscillating or any one of the coils

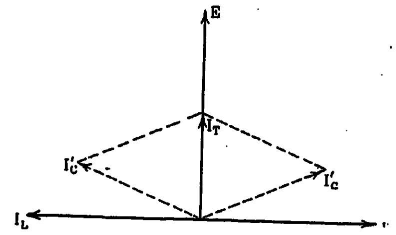

Fig. 2—Vector Diagram of a Circuit Containing Capacity and Inductance in Parallel
I_C and I_L represent the currents in the condenser and inductance respectively. I_T represents the vector sum of the two currents in phase with the e. m. f.; I_C and I_L represent the current vector of such a circuti when it is in resonance and neither the condenser nor the inductance have any resistance. I_C' and I_L' represent the same vector in case the condenser and inductance have resistances.

may oscillate by itself or in combination with any number of the rest of them. Now it is well known that if an oscillating system is made up of a capacity connected in parallel with an inductance with very low resistance, at the resonance frequency we obtain the effect known as "Effet de Bouchon," which means that the circuit in which the oscillations are taking place is stopped up and no current can pass through it. The vector diagram for such a circuit is shown in Fig. 2 in which E is the applied e. m .f., I_c the current flowing in the condenser circuit, and I_L the current flowing in the inductance circuit. It is shown in this diagram that if the resistance is zero we may get enormous currents flowing through the condenser and the inductance while no current can flow through the main circuit. Therefore, if we say coil K_1 in Fig. 1 is set in oscillation at resonance and no current can flow through the circuit, the voltage drop through all the rest of the coils would be zero and the total voltage applied to K_1 is equal to the total voltage of the line. In other words, in this case of the four coil transformer, the voltage applied to K_1 would be four times its normal voltage and hence the insulation is broken down which results in the burning of the transformer.

The conditions for the above effects are more favorable the smaller the capacity C_1 and the larger the inductance L_1 of the coil because in order to start the oscillation some current actually has to pass through all of the coils and the value of initial current depends upon the capacity C, that is, by increasing C the amount of current which must pass through the whole transformer before the system can be set in oscillation is increased on account of the fact that by increasing C the frequency of oscillations is decreased. On the other hand, it is impossible to pass within a very short time any appreciable current through the whole transformer due to its inductance and therefore by making C large enough we can prevent oscillations altogether.

J. Murray Weed: My chief effort in this paper was to give a clear conception of the causes of transient voltages and voltage oscillations in windings, with a theoretical solution of the prob-

lem of preventing them. I fully realized the difficulties involved in making general application of this solution, and the imposibility of making any application perfect, but I felt that it was not necessary to emphasize these phases of the subject. The danger is not that we will go too far in our efforts to make these applications, but rather that conservatism will unduly restrict our efforts in this direction. I feel that a thorough knowledge of the fundamental principles should enable us to make partial applications which will result in better transformers, or in transformers of equal value at less cost.

This is being done at the present time in the consideration given to the effects of various winding arrangements upon the distribution of capacitance, and in the use of metal clamping plates which are connected to the outgoing leads.

In the figures of the paper, I have suggested several methods of making approximations to the ideal arrangement, some of which may be found useful for practical application in suitable cases. I did not expect that any of the methods suggested would find general application, but I have gone as far as I have been able to go in pointing the way, and I would not be surprised to see the application of the general method here illustrated carried much further than seems to be expected by most of those who have discussed the paper.

Two or three points in the discussion require specific consideration.

In Mr. Blume's statement of the points wherein the shielded windings which I have described differ from ordinary windings, he has omitted one of prime importance. This point is brought out in the paper, but I take this occasion to emphasize it. To meet completely the conditions for uniform voltage distribution, each turn must be so positioned within the dielectric of the condenser that the potential which would be imparted to it by the electrostatic field, assuming that this field is not disturbed by the presence of the inductance is that which gives a uniform voltage distribution with respect to the inductance.

Mr. Peters has recognized a condition which no one can appreciate more keenly than I. It is practically impossible to perfectly meet the condition specified in the preceding paragraph, which constitutes the essence of the "Constitutional Remedy." The discrepancy due to variations in the inductances of different turns in a transformer winding, however, is not so serious as Mr. Peters seems to think. I presume that the results he speaks of were obtained with coils which were not linked with an iron core. That the inductances of all turns in a transformer winding are practically equal is demonstrated by the fact that transformer design is based upon this principle, primary and secondary voltages being proportional to the respective number of turns. There is, however, a tendency in the direction which Mr. Peters has spoken of, especially for high voltage windings, which are distant from the core. That I do not consider a moderate discrepancy of this sort serious is sufficiently indicated by my proposal, in the last paragraph of the paper, of the arrangement shown in Fig. 10. My conception of the effects of such discrepancies or failures to meet perfectly the conditions for uniform voltage distribution is given in the paper under the heading "Limitations of Supplemental Methods."

As for Mr. Trombetta, I feel that he may obtain a better understanding of the paper if he reads it again, together with the discussion which has been contributed by the others. His coil K_1, of course, is a part of the winding, and cannot act alone in the manner which he has described. Whatever its action, it comes within the scope of the theory which I have set forth.

Colloid Chemistry*

BY WILDER D. BANCROFT

Professor of Physical Chemistry, Cornell University

THE Chairman of your Program Committee wrote to me that he wished my talk to be a popular presentation which would interest the members who came to the meeting and also a profound discussion which could be read with profit by the eighteen thousand members who decided not to come. Either alternative is a large order and the two are mutually inconsistent, so I am not likely to satisfy anybody. Your Chairman evidently forgot that, if I were to tell you all the things which I consider interesting about the theory of colloid chemistry, I should keep going for several weeks. I give my unfortunate class at least twenty-five lectures at full speed on this very point. I am going to compromise tonight by telling you of a few things which might reasonably be of interest to electrical engineers, without making any attempt to cover the whole ground.

Speaking broadly, we can define colloid chemistry as the chemistry of bubbles, drops, grains, filaments, and films. These are things of which at least one dimension is small. In other words colloid chemistry is the chemistry of materials in which the surface is large relatively to the mass. For this reason one rather flippant person suggested calling the subject superficial chemistry; but some of us objected to the connotations.

Not so very long ago it was the fashion for the lecturer to present colloid chemistry as a succession of miracles. It was said to constitute a separate world of matter in which none of the facts of ordinary chemistry are so. Barium sulphate and metallic gold are soluble in water; metallic silver is blue, red, or yellow; globulin has a gram molecular weight of 700,000; a suspension of gamboge in water behaves like an ideal gas with a molecular weight of 200,000 tons; colloidal platinum is an inorganic ferment and is poisoned by potassium cyanide or by corrosive sublimate; all systems are in a state of flux undergoing irreversible changes.

Fortunately those days are over and we now try to make the phenomena of colloid chemistry seem the most obvious things in the world. If we start with adsorption and the Brownian movements, everything else follows fairly satisfactory; but these two concepts have not been familiar ones to the chemist and are perhaps quite unknown to the electrical engineer.

One property of every surface is that the surface tends to condense upon itself everything else with which it comes in contact in amounts which vary with the nature and structure of the surface, the nature of the substance in contact with the surface, the pressure, and the temperature. This formation of a surface film with a relatively high concentration is called adsorption. To most of us that seems a harmless name for an observed fact; but there are people who do not like it. A distinguished biological physicist from Cincinnati claims that the crime of the century is not the demonetization of silver, but the way in which colloid chemists sail under the black flag of adsorption. This metaphor seems to me a bit mixed but that is of no importance. It is possible also that I may have misrepresented my friend. It may be that the demonetization of silver was the political crime of the last century and that adsorption is the chemical crime of this century.

We know that adsorption takes place and that it is specific; but we do not know why hydrogen or carbon monoxide concentrate at, or are adsorbed by, a charcoal surface, for instance. One explanation is that the hydrogen or the carbon monoxide is attached to the surface of the charcoal either by regular chemical bonds or by contravalences, thus forming something analogous to a chemical compound. We cannot go any further than this because the carbon particles in the charcoal hold to each other more firmly than they do to the hydrogen, which would not be the case if methane, acetylene, ethylene, or ethane had been formed. For most purposes, however, it is quite sufficient to know that hydrogen concentrates at, or is adsorbed by, a charcoal surface without bothering our heads as to the mechanism of the adsorption.

While the phenomena due to adsorption constitute practically the whole thing in colloid chemistry, we cannot dispense with the Brownian movements, when we are dealing with fine particles suspended in a liquid. If we drop a very fine particle of sand in water, the sand will tend to sink because it is denser than the water. According to the kinetic theory, the water molecules are in violent motion and consequently will bombard the sand particle continuously. If the particle is large relatively to the molecule, the bombardment will have relatively little effect upon it; but if the particle is very small, it will be driven first one way and then another by the buffeting of the water molecules. This actually happens and, under the microscope, the finely-divided particles of any solid may be seen moving continuously in a zig-zag fashion. This phenomenon was first observed in 1828 by an English botanist named Brown and was named after him.

As would be expected from the theory, the Brownian movements are less marked the larger the particles. In fact, there is no perceptible motion when the particles exceed 4μ in diameter, while particles with diameters of about $10\ \mu\mu$ give apparent trajectories up to $20\ \mu$. The speed of platinum particles having a diameter of $10\text{-}50\ \mu\mu$ has been estimated by Svedberg at $200\text{-}400\ \mu\mu$ per second; but Perrin does not believe that these estimates are accurate. With increasing vis-

*Lecture presented at the A. I. E. E. Midwinter Convention, February 16, 1922.

cosity of the liquid the Brownian movements decrease, which is what one would expect on any hypothesis.

It is easy to see that the bombardment by the water molecules will give rise to irregular movements; but I should have supposed that the general effect would have been equivalent to a fairly uniform bombardment from all sides. This is not the case, however, and, for some mathematical reason which I have never understood, the statistical effect is a greater bombardment from the bottom than from the top when the suspended particle is denser than the liquid and the reverse when the particle is less dense. This is so judiciously arranged that the force of gravity is balanced and consequently this absolutely hit-or-miss bombardment results in a practically uniform distribution of the particles throughout the mass of the liquid.

This practically uniform distribution occurs only when the particles are very fine and consequently it follows that we shall get a colloidal solution whenever we have sufficiently fine particles and keep them fine. If several of the fine particles agglomerate or coalesce to form a large particle, the Brownian movements will be unable to keep this larger particle suspended and it will sink to the bottom or rise to the top as the case may be.

There are two different ways in which we can keep fine particles from coalescing or agglomerating. One is to coat them with a suitable material film. You are perfectly familiar with this on a somewhat larger scale and under other conditions. You know that you can buy a pasteboard box containing several separate doses of a liquid medicine, castor oil for instance. The separate masses of liquid do not run together because each one is enclosed in a gelatine capsule. We can do the same thing with suspended particles. We can coat them with a film of gelatin or some other substance which will keep them from coalescing. In some extreme cases a film of adsorbed water or other liquid will prevent agglomeration. Water seems to do this for tannin. When pyroxylin is carried into apparent solution by acetone, the separate particles are kept from coalescing by a film of adsorbed acetone.

We can also keep suspended particles from coalescing by charging them electrically all with the same sign, in which case they tend to repel each other. If we have suspended particles which adsorb hydrogen ions very strongly and chlorine ions very slightly, we can stabilize that colloidal solution by adding hydrochloric acid, in which case the particles will all be charged positively by the adsorbed hydrogen ions. If the particles adsorb hydroxyl ions very strongly and sodium ions only slightly, we can stabilize such a colloidal solution by adding alkali. If we add caustic soda to hydrous chromic oxide, the latter goes into apparent solution and we get an apparently clear, green solution of what used to be called sodium chromite. Nowadays we know that it is a colloidal solution of chromic oxide, the oxide particles being charged negatively by adsorbed hydroxyl ions. Of course a colloidal solution which is stabilized by the adsorption of an ion, will be precipitated if we add an electrolyte which has a readily adsorbable ion of the opposite sign from that which stabilizes the solution. You are probably quite familiar with Acheson aquadag which stays up admirably in water but flocculates when salt is added.

Precipitation occurs on a large scale when muddy rivers flow into the sea. When rain falls in a clay country, the run-off is muddy. The Mississippi river is very muddy at St. Louis; but there is a good deal of relatively coarse clay in it, most of which settles out gradually. At New Orleans the river normally has much less clay than at St. Louis; but the clay particles are very fine and show very little tendency to settle. They are charged negatively by adsorbed hydroxyl ions and that checks coalescence. When the river flows into the Gulf of Mexico, the concentration of sodium ions is so great in the salt water that it more than makes up for the relatively slight degree of adsorption of the sodium ions and the adsorption of these latter neutralizes the negative charge on the clay which therefore precipitates, forming a delta. Of course, there is some settling, due to the current becoming zero; but the chief factor in the formation of deltas is the precipitation of the suspended clay by the salts in the sea water.

At one time we used to distinguish between colloidal solutions stabilized primarily by adsorbed ions and those which were not, calling the first suspension colloids and the second emulsion colloids, the particles in the first being solid and precipitated readily by electrolytes, while the particles in the second were liquid and were relatively insensitive to electrolytes. A classification of this sort is valuable in the early days; but it emphasizes differences which are not real and consequently such terms as suspension and emulsion colloids are now practically obsolete. We can make oil suspensions which are quite as sensitive to electrolytes as colloidal gold. Colloidal sulphur, though charged negatively, withstands high concentration of hydrochloric acid. Gelatin solutions are not affected much by most salts; but recent work shows that the hydrogen ion concentration is important. In other words, we get all gradations and there is nothing to be gained by making arbitrary distinctions.

Gelatin is interesting because certain special things coagulate it and make it insoluble. Tannin is one and chromic salts are another, If we add tannin or a chromic salt to gelatin, we make it insoluble. This is utilized technically in making leather. Vegetable tanning consists in adding tannin to the hide substance, which is very similar to gelatin and becomes insoluble. In chrome tanning we make the hide substance insoluble by the addition of chromic salts. This phenomenon is also made use of in certain photographic processes. Bichromate has no effect on gelatin; but

if a bichromated gelatin is exposed to light, there is a reduction to a chromic salt and the gelatin therefore becomes insoluble where the light has struck it.

Having explained what we mean by colloidal solutions, I will take up a few cases of adsorption which may be of interest to you. A striking illustration is the gas mask in which the chief adsorbing agent is charcoal, which is very specific in its action, adsorbing certain substances much more strongly than others. If charcoal had adsorbed air in preference to poison gases it would have been useless as a protection against these latter. It was necessary that the charcoal should adsorb the toxic substances preferentially, that it should adsorb them very completely, and that it should adsorb them very rapidly. The requirements were very severe. The air may take only one-tenth of a second to pass through the canister and yet it may be necessary in that space of time to reduce the concentration of the toxic gas from, say, 1000 parts per million to 1 part per million or less. The charcoal developed by the Chemical Warfare Service met that requirement with a safe margin. In fact, in laboratory experiments, it was shown that the charcoal will reduce the very high concentration of 7000 parts per million of chloropicrin, $CCl_3 NO_2$, in a rapidly moving current of air to less than 0.5 parts per million in something under 0.3 seconds. This was, of course, a special charcoal. On the first of July, 1917, the best charcoal that we had would not stop chloropicrin for one minute under the conditions of the standard test. The charcoal, made on a small scale later, stood up at least 1200 minutes against chloropicrin under the same condition. This gives an idea of what was done in the way of improvement, though the large-scale manufacture of charcoal did not give so effective a product.

The early use of charcoal as an adsorbent was quite a different one and runs back to the end of the eighteenth century. Solutions of raw sugars are dark colored but can be decolorized by treatment with charcoal. The charcoal takes out nearly all the coloring matter and only a little of the sugar and we therefore have a very effective purification. Here too the chemist has developed much better charcoals than were used originally. It is worth noting, however, that the charcoals which are best in the gas mask are not the best for decolorizing sugar. The two sets of service conditions are quite different. Although contact catalysis involves adsorption, it does not follow that the charcoal, which is the best catalytic agent for making phosgene, $COCl_2$, from carbon monoxide and chlorine, is either the best charcoal for the gas mask or the best charcoal for decolorizing sugar.

When decolorizing sugar, we are not interested in the fact that, theoretically, the coloring matter, which is removed from the sugar solution, changes the color of the charcoal. We have other cases of adsorption in which the important thing is the fixing of the coloring matter on the adsorbing agent. If we dip a piece of cloth in a suitable colored solution, and perhaps heat the solution to boiling, the cloth will take some or all of the coloring matter out of the solution and will be dyed. We distinguish a number of different types of dyes such as basic, acid, substantive, mordant, vat, and sulphur dyes. Some of these are in true solution and some are in colloidal solution; but in all these cases we are dealing with an adsorption of the dye or of a reduction product of the dye either by the fiber itself or by the mordanted fiber, and the mordanting of a fiber is also a case of adsorption.

When discussing charcoal, a reference was made to the catalytic manufacture of phosgene. It has long been known that porous materials accelerate certain reactions and that this effect is specific. This acceleration of reaction velocity by an undissolved substance which undergoes no marked change itself, is known as contact catalysis and is of the greatest value in technical processes. The so-called contact sulphuric acid is made by passing a mixture of carefully purified sulphur dioxide and air over finely divided platinum at about 450 deg. In the synthesis of ammonia from hydrogen and the nitrogen of the air, porous iron is the chief catalyst, though other substances, known as promoters, are added to increase the action of the iron. The oxidation of ammonia to nitric acid is done in the presence of platinum as catalytic agent, while nickel is used chiefly in the hydrogenation of oils. In making ethylene from alcohol as a preliminary stage in the manufacture of mustard gas, either alumina or kaolin is used as the catalytic agent. As yet, we do not know how the catalytic agent activates the reacting substance and we cannot predict at all what substances will make the best catalyzers in any given case. If we ever get a satisfactory theory of the subject, I think that catalytic methods of making all sorts of chemical compounds will drive out pretty nearly all the regular processes. The plants act in that way now, their catalytic agents being called enzymes.

If we have electrified particles, as we do in some of our colloidal solutions, they will move under the influence of a direct current. As electrical engineers you are familiar with the particular case of electrified solid or liquid particles in air, which is known as the Cottrell process for precipitating smokes. A high-voltage, direct current passes from a point to a plate, ionizing the air and charging the suspended particles, which are carried to the plate and can there be scraped off. I have seen the statement that, in the Washoe reduction works of the Anaconda Copper Company, the Cottrell process has been introduced on so large a scale that the point electrodes consist of one hundred and eleven miles of chains. The Cottrell process removes suspended solids or liquids; but, of course, will not remove a gas, such as sulphur dioxide for instance.

In the case of a colloidal solution, the charged particles will move with the current if they are charged positively, through having adsorbed a cation, and they

will move against the current if they are charged negatively, owing to adsorption of an anion or to having emitted a cation. This transference under electrical stress consists in a motion of the particles relatively to the water. If we should in any way hold the particles stationary and leave the water free to move, we should expect an electrical stress to cause the water to flow past the particles, the water going to the anode if the particles are charged positively and to the cathode if the particles are charged negatively. This can be realized if we consolidate the particles into a porous diaphragm. Suppose we have a porous cup in a beaker with one electrode, the cathode, inside the cup and the other electrode, the anode, outside the cup. If the diaphragm is charged negatively, the liquid will flow through into the porous cup, eventually causing it to overflow. When the liquid passes through a diaphragm, the phenomenon is called electrical endosmose; when the suspended particles are carried through the liquid, the phenomenon is called cataphoresis. The word hylophoresis, or transport of matter, has been suggested as the general term covering both cases; but it has not yet been adopted.

Cataphoresis is the thing that has made electrolytic lead refining commercially feasible. Glue, or some similar material, is added to the bath and is carried to the cathode, where it modifies the structure of the lead so that it comes down as a fine-grained deposit and not as feathery crystals. The use of so-called addition agents is quite common in electro-plating and many of these are colloidal. The commercial applications of electrical endosmose have not been very successful as yet. By placing peat between two electrodes and passing a high-voltage current, the peat acts as a diaphragm and the water is squeezed out electrically. The water content of the peat can be reduced from ninety to sixty-five per cent with a reasonable expenditure of power; but the cost of getting the water content down to twenty per cent has proved excessive. The method is said to have been used successfully in drying alizarine paste and things of that sort, where the value of the product justified a greater expenditure for drying.

In addition to the adsorption of a gas or a liquid by a solid, we may also have the adsorption of a solid by solid. Several cases of this sort are of great interest to the electrical engineer. Theoretically, aluminum should be an utterly useless metal because it stands in the electrochemical series near the alkali metals and calcium, quite close to magnesium. We should expect it to corrode rapidly under almost any conditions; but that is not what happens. The reason that you can use aluminum for transmission lines, when the price of copper soars, is simply and solely because aluminum as a metal is a successful failure. Its natural duty in life is to corrode; but the oxide or hydroxide film which is formed is adsorbed so strongly by the metal that it protects the surface and thus stops further corrosion. The only reason why an aluminum wire or sauce-pan does not corrode is because the air and liquids do not come in contact with the metal. If we amalgamate aluminum, the oxide coating does not adhere and the metal corrodes rapidly, giving us the so-called fibrous alumina.

Nickel also becomes covered ordinarily with a strongly adsorbed film of oxide or hydroxide and consequently does not rust. In the case of iron the oxide film is usually not coherent and consequently the metal goes on rusting. It is possible, however, under special conditions, to give iron a coating of the magnetic oxide which protects the metal surprisingly well.

We speak of noble metals as ones that do not corrode in the air; but it is an open question in my mind how many metals can qualify under this definition. We know that platinum black is always oxidized in contact with air, which makes it probable that sheet platinum has an oxide film on it. Under ordinary conditions most of our metals do rust or corrode; but a good many of them, fortunately for us, stop corroding because of the formation of a protecting film. Zinc corrodes superficially and we all know that a copper roof turns green and then undergoes very little further change. As I see it, the corrosion problem is to treat a metal so that it will corrode to a limited extent and then stop. In other words we must study the conditions which cause the formation of a protecting film. Calorized iron is one solution of the problem, phosphatized iron is another solution, and there are doubtless many more.

A protecting film is not always a desirable thing. The difficulty in condensing zinc from zinc vapor is due to the fact that any zinc oxide which is formed is adsorbed strongly by the globules of liquid zinc as they form and we get blue powder instead of cast zinc. It is very difficult to melt aluminum scrap because of the oxide film around each piece. You are familiar with the fact that when dirty mercury is shaken, it forms globules which do not coalesce because of films of oxide or grease around each drop.

This brings us naturally to the question of emulsions, which are drops of one liquid suspended in another liquid. Since the two liquids in the ordinary emulsions are usually water and some form of oil, it has become customary to use the word oil for the non-aqueous liquid even though, as in the case of benzene, it is not strictly an oil. While we can make emulsions which are stabilized by an adsorbed ion, most actual emulsions are stabilized by the use of an emulsifying agent which forms a film around the drops of the suspended liquid. To emulsify oil in water, we are apt to use a sodium soap in the laboratory, while the pharmacist uses gum acacia a great deal. We can emulsify water in oil by using calcium soaps as in the case of some lubricating greases or we can use rosin in the case of paints in linseed oil. Whether we get water emulsified in oil or oil emulsified in water depends on the nature

of the emulsifying agent and not on the relative masses of oil and water. Speaking broadly, an emulsifying agent, which goes more readily into water than into oil, will emulsify oil in water. The converse is also true. Emulsions are very important physiologically because Clowes has shown that protoplasm behaves in many respects like oil and water emulsified by a mixture of calcium and sodium soaps, the lipoid material being considered as oil.

If we replace the oil in an emulsion by air or a gas, we have a foam. You have probably seen advertisements of Foamite as a means of putting out fire. This consists of solutions of aluminum sulphate and sodium bicarbonate to which has been added some organic material such as licorice. When the two solutions are mixed, the chemical reactions may be written,

$$Al_2(SO_4)_3 + 3NaHCO_3 = Al_2O_3 + 3Na_2SO_4 + 6CO_2 + 3H_2O.$$

The alumina and licorice form a film round the bubbles of carbon dioxide giving a very stable foam.

A more important application of foam is the ore flotation process. If we shake up water to which a little oil has been added, we get a bubble of air surrounded by an oil film. This bubble is fragile and breaks on reaching the surface. If we have present a sulphide ore with a siliceous gangue, the siliceous gangue is wetted preferentially by water and the sulphide particles by the oil. The patent of the Minerals Separation Company calls for the use of a fraction of one per cent of oil per ton of ore. An ore pulp usually runs about one ton of ore to four or five tons of water. When air is beaten into this mass, the particles of the sulphide ore go into the oil-water interface or into the oil itself, stabilizing the film because we then have practically armor-plated bubbles. The resulting froth can be scraped or shovelled off. Since most of the sulphide ore rises with the froth and since most of the siliceous gangue stays in the water, a very effective separation occurs. In most cases acidification of the solution and rise of temperature increase the effectiveness of the separation.

If the amount of air is insufficient, the oil may cause the ore particles to agglomerate and sink. This was patented by Cattermole; but it is not technically so successful as the frothing process. If the amount of air is excessive relatively to the ore, the number of bubbles will be so great that the ore particles cannot coat them sufficiently to armor-plate them and a fragile froth will be formed. This principle is made use of in the Callow process, in which air is introduced in fine bubbles at the bottom of the cell. These bubbles break as soon as they reach the surface and consequently the ore particles must be removed before they settle back. We can thus have clotted particles, armor-plated bubbles, or fragile bubbles, according to the conditions.

Coming back for a moment to emulsions, there is a wonderful chance for somebody to discuss whether the most important natural emulsion is milk or the rubber latex. Milk is necessary to life in the early stages; but pneumatic tires play a very important part later in life. Milk is an emulsion of liquefied butter fat in water which contains some other things. As obtained from the cow, milk is not very satisfactory when considered solely as an emulsion, because a more concentrated emulsion known as cream rises fairly quickly. If milk is passed through a homogenizer, the fat globules are broken up into smaller, more nearly uniform drops and we get an emulsion which remains unchanged when passed through an ordinary separator. If the cow had been more efficient mechanically, it is probable that skimmed milk would never have been discovered. When the milk emulsion is broken up by churning, the liquefied butter fat hardens into butter. The rubber latex is the milky juice from various kinds of rubber plants, chiefly trees and vines. It is an emulsion of liquid rubber in water which contains other things. The rubber emulsion can be broken down in a great many ways. On the plantations it is usually done by adding acetic acid. The liquefied rubber hardens just as did the liquefied butter fat and the product is raw rubber. One reason that we do not let milk sour in order to get butter is that the caseine comes down too. I do not know whether acid breaks the butter emulsion and whether one can get butter by adding vinegar to cream.

Raw rubber is not a satisfactory product in itself because it is too brittle when cold and too sticky when warm. It has to be vulcanized, which usually means heating with sulphur. Vulcanization is a problem of adsorption. There is only one compound of sulphur with rubber. It contains thirty-two per cent of sulphur, has the formula $C_{10}H_{16}S_2$, and is known as hard rubber or ebonite. Ordinary vulcanized rubber contains perhaps four per cent of combined sulphur and must therefore consist chiefly of raw rubber with hard rubber adsorbed on the surface of the raw rubber. Most rubber chemists dispute this conclusion because it is not possible to dissolve raw rubber out of vulcanized rubber with the solvents which will carry pure raw rubber into colloidal solution. This is not a serious objection however because we have already seen that a film of aluminum oxide keeps aluminum from being acted on by things which corrode pure aluminum.

Electrical engineers are interested of course in insulation problems. In addition to rubber we have three other well-known substances which are valuable, each in its own way: porcelain, artificial silk, and bakelite. The manufacture of all these involves colloid chemistry; but a discussion of these substances would take me far beyond any reasonable time limit. I hope, however, that I have succeeded in showing you that colloid chemistry is a subject which is of real interest to the electrical engineer.

Heating of Railway Motors in Service and on Test-Floor Runs

BY G. E. LUKE

Associate, A. I. E. E.

Westinghouse Electric & Mfg. Co., E. Pittsburgh, Pa.

Review of the Subject.—*The rating given to a motor is the manufacturer's guarantee of the motor performance under the conditions given on the name plate.*

Assuming that this rating is entirely safe, then the successful functioning of the motor depends entirely upon the application engineer's analysis of the particular duty that the motor will be required to perform.

Where the required motor output is practically constant the application is simple; however, in many cases the motor load is apt to be anything but constant, consisting of loads of all degrees of magnitude, and in such cases the economically correct application is especially difficult. The past improvements made in the motor design, mechanically and electrically, have resulted in greater importance of the motor-operating temperatures, in fact in the great majority of cases the motor rating is limited only by the motor temperature. It is obvious then that correct motor applications depend to a very great extent upon correct operating temperatures.

Ratings such as the continuous, short-time, normal, and duty-cycle ratings give the performance of the motors under some particular conditions; however, the duty required of a great number of industrial and railway motors will not agree with any of the above ratings. Thus the application of motors to cranes, hoists, steel mills, and railways must be made with the knowledge of the motor's performance under one or more arbitrary conditions.

In general the two ratings which should be known for motor application to such irregular duty are the continuous and a short-time rating. The time period of the short-time rating should not exceed one hour and in many cases a one-half hour run is preferable.

The correct application of a motor requires a knowledge of the thermal conditions inside of the motor. Thus it is evident that the motor must be able to dissipate eventually all of the heat losses generated. On a continuous load the final rate at which the heat is transferred from the motor to the air will be equal to the rate of heat generation.

The resulting temperature rise can be estimated with the physical conditions known. This is simply a problem in physics and involves the conditions of ventilation with the corresponding ventilating surfaces. To predetermine the internal temperatures requires a knowledge of the rate of heat flow along the various heat flow paths to the ventilating surfaces.

Under irregular loads the temperatures are transient and are determined not only by the conditions of ventilation and rates of heat flow, but also by the motor's ability to store heat, which is proportional to the product of the motor's mass and specific heat. Hence the temperature rise of any part of a motor under any given load for some definite time is a function of the rate of heat flow from that part to the surrounding air and its thermal capacity. Thus from the known physical conditions the temperature rise of the motor can be predetermined and with certain assumptions a simple equation can be developed which will give an approximate value of the motor temperature under any given load conditions.

When the constants of the theoretical equations are based upon tests (such as given by short-time and continuous rating) the above method of temperature predetermination will be sufficiently accurate for most practical purposes, and will make possible the calculation of the motor temperature rise under any duty cycle.

The temperatures referred to are not only those temperatures obtained by thermometers upon the surfaces of the machines, but also the maximum internal temperatures, since it is the latter temperatures which first produce insulation failure.

The temperatures obtained by thermometers bear no fixed relation to the maximum temperatures for all types of machines under various loads.

In order to have something concrete to work upon the writer has taken up the heating and cooling characteristics of railway motors A brief analysis of the heating at the standard ratings is given. The fundamental equations defining the temperature rise of a motor on a continuous or short-time load are developed, and finally the applications of these equations are made in several specific examples.

CONTENTS

THE adoption of standard motor ratings for various types of service has greatly facilitated the correct application of the motors. However, the motor's performance can be relied upon only in those applications where the duty required of the motor is equivalent to that specified by the motor's rating. This introduces a factor of uncertainty in the application of the motor to such irregular and intermittent service as is required of crane, hoist, steel mill, and railway motors.

The selection of a proper motor for a particular railway service is without doubt one of the most difficult problems in motor application. For instance the street car motor is subject to daily rush hour loads; to possible heavy peak loads due to a steep track grade; and in addition to this it is called upon to deliver abnormal overloads resulting from conditions such as holiday crowds, trailer operation, snow or the necessity of pulling in a disabled car, and these conditions are apt to be accompanied by a low line voltage.

Railway motor failures may be classed as mechanical and electrical. A large part of the electrical failures is due either to poor commutation and flashing or to excessive temperatures. In the modern commutating-pole motor mechanical failures and those electrical ones which are caused by poor commutation have been greatly reduced; however, the possibility of breakdown due to high operating temperatures is still present. The modern high-speed, ventilated, commutating-pole motor will deliver a much greater output per pound of motor than the early types of railway

Presented at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

motors. This means of course that the motor's capacity for the storage of heat on short-time overloads has been reduced and has resulted in making the peak load temperatures the predominating factor in some railway motor applications.

The purpose of this paper is primarily to discuss the heating of railway motors on the standard test floor runs and to develop a general method by which the heating can be predetermined for any given service. However, the analysis of the heating problem as given is general, and is applicable to the temperature predetermination of any rotating electric machine.

Standard Motor Ratings

The adoption of a simple test or combination of tests which would be a criterion of a motor's performance in any railway service has been recognized as impractical. With such intermittent loads the best general method of rating should be based upon the motor's overload or thermal capacity and upon its continuous rating. Thus the Standards of the American Institute of Electrical Engineers say that the nominal rating of a railway motor is that output which the motor will develop for one hour with a temperature rise by thermometer at the end of the run of not over 90 deg. cent. on the commutator, and 75 deg. cent. at any other normally accessible part. With this short-time run a majority of the heat losses is stored up in the motor so that this rating is to a certain degree a measure of the thermal capacity of the machine as a unit.

The continuous rating is defined as the input in amperes at which it may be operated continuously at ½, ¾ and full voltage respectively without exceeding a temperature rise of 65 deg. cent. by thermometer (85 deg. cent. by resistance) for Class A[1] insulation and 80 deg. cent. by thermometer (105 deg. cent. by resistance) for Class B[2] insulation.

Thus the continuous rating is a measure of the motor's ability to dissipate heat.

Distribution and Disposal of Heat Losses

With regard to ventilation there are three general classes of railway motors, namely, totally enclosed, self-ventilated and separately ventilated motors. The Institute Standards define a "totally enclosed" motor as one so enclosed as to prevent circulation of air between the inside and the outside of the case, but not sufficiently to be termed "air-tight." A "self-ventilated" machine is one in which the ventilating air is circulated through the machine by a fan, blower or centrifugal device integral with the machine. A "separately ventilated" machine has its ventilating air supplied by an independent fan or blower external to the machine.

1. Class A insulation is composed of specially treated cotton, silk, paper or similar materials.

2. Class B insulation is composed of material capable of resisting high temperatures such as mica and asbestos.

Nominal One-Hour Rating

Table I gives the distribution of losses on four typical types of motors at the one-hour and the continuous rating. This nominal rating is purely an arbitrary one. As previously mentioned the rating

TABLE I.
DISTRIBUTION AND DISPOSAL OF LOSSES IN RAILWAY MOTORS

Type of Ventilation	Enclosed		Self Ventilated				Separate Vent*	
Rating—Time	1 hr.	Cont	1 hr.	Cont	1 hr.	Cont	1 hr.	Cont

Per cent dissipated from frame	10.8	100	4.6	62.0	12.5	45.0	4.9	14.3
Per cent carried away by the ventilation air through motor	7.8	0	13.5	38.0	30.0	55.0	26.1	85.7

*Separate ventilation on the continuous rating only.

is intended to be a standard of measurement of a motor's thermal capacity. The requirement for this is that no heat loss shall be dissipated from the motor, that is all of the losses must be stored in the motor masses. This condition is approximated in totally enclosed machines where the heat losses from the external frame by radiation and convection rarely exceed 10 per cent of the total loss.

In the early non-commutating-pole motors it was necessary to observe carefully commutation during this one-hour run and this necessitated the removal of the commutator cover. This practise is still used in the modern motors. In fact Rule No. 5202 of the Standards of the A. I. E. E. says that the covers should be arranged to secure maximum ventilation without external blower.

Some of the self-ventilated motors will circulate as much as 50 per cent more air with all covers off than with covers on as in service. This has resulted, as

shown later, in the nominal rating being dependent upon ventilation as well as the thermal capacity of the motor. The table shows that of the total losses, from 59.1 to 69.0 per cent is found in the armature. Since the armature weight is only about one-third of the total motor, its thermal capacity (ability to store heat) on short-time loads will be less than that of the motor as a unit. It results in an armature loss per pound of armature of 5.28 to 8.58 watts. The armature copper loss per pound of copper ranges from 14.7 to 36.4 watts. A loss of 4.5 watts per pound of armature will raise its temperature 75 deg. cent. in one hour if all the loss is stored in the iron and copper. Hence in the 25-h. p. high-speed motor at least (8.58 – 4.5)/8.58 or 48 per cent of the total armature loss must be transferred elsewhere; with the larger motors this percentage is considerably reduced. A loss of 3.75 watts per pound of copper if all stored in the metal will raise its temperature 75 deg. cent. in one hour. This means that toward the end of the one-hour run with this motor by far the greater part of the heat loss generated in the armature copper must be transferred to the iron or air and but little of that loss is stored.

On the one-hour run the motor losses are stored up in the iron and copper, carried away by the ventilating air through the motor and dissipated from the external frame by radiation and convection. Table I shows that of the total loss about 81 per cent is stored in the motor parts for the first two motors while for the last two more highly ventilated motors this percentage is 57.5 and 69. This shows that the one-hour rating is not a true indication of the motor's thermal capacity, since the percentage of the heat loss stored in the motor during this run is a function of the motor's ventilation.

Continuous Rating

On continuous duty all of the heat losses in the motor must be transferred to the surrounding air, that is, this rating is not affected by the heat storage capacity of the motor. In a totally enclosed motor the total losses are transferred to the frame and are then liberated by radiation and convection. The frame temperature rise is approximately proportional to the watts per square inch to be liberated. The heat dissipated from the frame is about 0.013 watt per square inch of surface per deg. cent. rise. This is an average value from many tests. The surface is taken as that of a solid cylinder whose over-all dimensions are equal to those of the motor. The actual effective surface is greater than this due to the roughness of the castings and the numerous irregular projections. This accounts for the high value of this constant since the heat loss from a smooth surface due to natural convection and radiation is only about one-half of the above value. With a car speed of 10 mi. per hr. the above constant is approximately doubled. The internal temperature drop from the armature to the frame is a function of the ventilating surface and the internal ventilation. It is evident that the external ventilation on the frame can not affect this internal drop. The external frame rise on continuous duty averages about 60 per cent of the internal temperature rise when measured on the test floor by thermometers. The rating on an enclosed motor is limited by this low heat flow from the frame and by the temperature gradient necessary to cause the armature loss to be transmitted to the internal air and then from this air to the inner frame surface. For continuous-rated enclosed motors the weight per h. p. increases with the motor size. This may be seen for example by the fact that by doubling the motor's dimensions the external ventilating surface is increased to four times its first value while the weight is increased to eight times the original weight.

Ventilated Motors

When air is circulated through a motor by either an internal or external fan the effect is two-fold. It reduces the internal air temperature and for a given loss it decreases the temperature gradient between the ventilating surface and the internal air. It is possible to reduce this temperature drop to a very small value with separate ventilation; however, the internal insulation drop is still present. This temperature difference between the copper and the ventilating surface is the limitation to the degree of ventilation economically possible. Thus Table I shows that the small 25-h. p. self-ventilated motor on the continuous run can dissipate 2.56 watts per pound of motor while the heavy locomotive motor (insulated for 1500 volts) with separate ventilation can get rid of only 1.71 watts on the basis of the same copper temperature rise. This is due to the large internal temperature drop in the windings and insulation of the larger motor which is independent of ventilation. The first two motors listed in the table give a comparison of continuous rating possible on a totally enclosed and a self-ventilated motor of the same weight. It shows that for the same internal temperature rise the enclosed motor can dissipate a loss of 2075 watts while the self-ventilated motor can dissipate 3150 watts. This difference will increase with the speed of the armature.

Application of Motor

The usual method of applying a railway motor to any given service is to estimate the average root-mean-square current from the conditions known. The motor must have a continuous rating at least equal to this r. m. s. current. With this rating known the average operating temperature rise can be estimated from the above current. Due to the irregularity of the load it is necessary to see if the motor has sufficient overload or thermal capacity to take the peak loads without excessive temperature rise. This predetermination of temperature rise on intermittent duty is a very difficult

problem, for which a rigid mathematical solution is practically impossible. However, a· comparatively simple approximate solution is possible.

SOLUTION OF PROBLEM[3]

The following solution of this problem has been made on the assumption that the heat losses and ventilation in the motor or any part thereof considered are uniform'y distributed. This s not strictly correct; practically however it is permiss:ble since the heat losses will to a certain degree distribute themse ves by conduction through the iron and copper.

(5) Total energy loss = stored energy + dissipated energy.

The solution of this equation is given in the appendix. The final equations are:

$$t = 2.3\, t_1 \log_{10} \frac{T_c - T_s}{T_c - T_t} \qquad (10)$$

or an equivalent form:

$$T_t = T_c - (T_c - T_s)\, e^{-t/t_1} \qquad (11)$$

where (e) is the Naperian base (2.718)

t = Time in hours the load is applied.

T_s = Temperature rise at start, deg. cent.

T_t = Temperature rise at end of time (t).

[4]T_c = Final temperature rise on continuous duty, and

$$T_c = \frac{W}{S_e\, r\, K_e + \dfrac{V\, S_i K_i}{V + 0.9\, S_i K_i}} \qquad (8)$$

W = Watts loss of motor or part considered.

S_e = External surface of motor frame in sq. in. This may be figured by considering the motor as a solid cylinder.

K_e = Heat dissipation from the external surface in watts/sq. in/deg. cent = 0.013 approximately when frame is stationary.

r = Ratio of external frame rise to the internal surface rise. This ratio is a function of the degree of ventilation of the motor. On enclosed motors it averages about 0.60; on self-ventilated motors 0.40; and with separately ventilated motors 0.20 to 0.30.

V = Volume of air passing through the motor in cu. ft./min.

S_i = Internal ventilating surfaces of the motor which come in contact with the ventilating air, sq. in.

K_i = Heat transfer from the ventilating surface to the air in watts/sq. in. of surface/deg. cent. difference between the surface and adjacent air. This is determined by the air velocity, direction of air flow with respect to the surface, and the nature of the surface. Fig. 1 shows the curve of an average value for this constant which was obtained from many tests made upon actual machines and experimental apparatus.

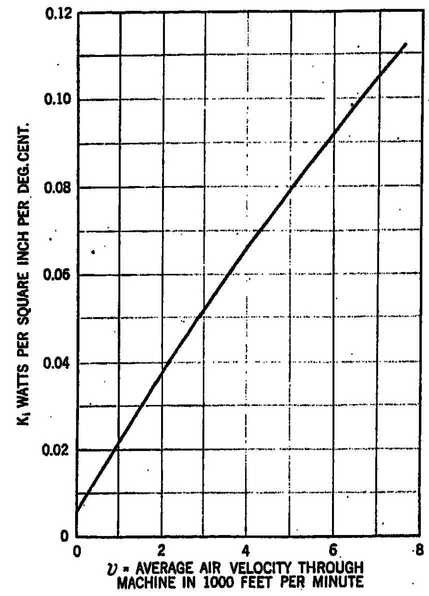

FIG. 1—SURFACE HEAT DISSIPATION

In watts per sq. in. of surface per deg. cent. difference between surface and air temperature.

It is incorrect to use the above equation (8) for self-ventilated motors where the air volumes V are relatively small. Under these conditions the heat transfer constant K_i is determined more by the peripheral speed of the armature than by the actual air velocity through the motor. Where separate ventilation is used the heat dissipation is practically independent of the armature speed; in this case the above equation is applicable.

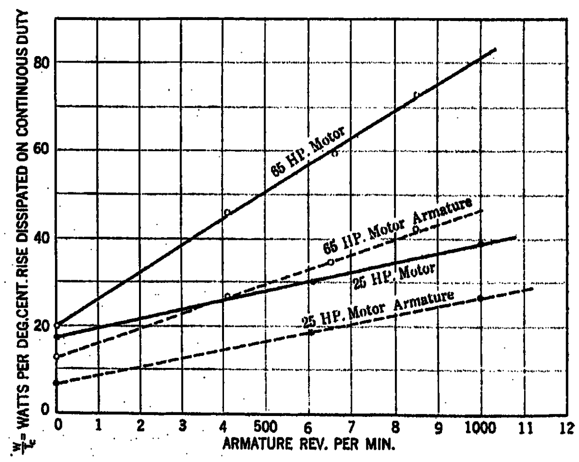

FIG. 2—HEAT LOSS

In watts per deg. cent. rise dissipated at various speeds at the continuous ratings for the motor and motor armature.

For self-ventilated motors the value of the continuous temperature rise T_c should be based upon test results.

3. The method of solving this problem was first suggested to the writer by Mr. C. E. Wilson.

4. These temperatures are the average surface temperatures as obtained on the iron core.

This value is usually known for two or more speeds, that is the rating at 300 and 450 volts. If the watts loss per degrees centigrade rise (W/T_c) is plotted against the armature rev. per min. the points fall approximately on a straight line as shown in Fig. 2. The value of this constant for zero speed is approximately equal to 0.006 times the external surface of the motor. When the armature only is considered the value of W/T_c becomes approximately equal to 0.003 times the external motor surface for standstill conditions. Hence with one other test point the line is determined.

In equation (9)

$$t_1 = 0.06 \frac{(P_a + r\,P_i)}{W}\, T_c$$

t_1 = The thermal time constant of the motor and is the time in hours necessary to raise the temperature of the motor T_c deg. cent. with the loss W and no ventilation, that is with all of the energy absorbed in the motor.

P_a = Weight in pounds of the motor parts which have losses generated in them.

P_i = Weight in pounds of the motor parts which have no losses generated in them, such as the frame and end housings.

This constant t_1 can also be determined from tests. It is necessary to have a continuous and a short-time temperature test. Substitution in equations (10) or (11) will give the value of t_1.

Part I of the Appendix is a general solution and can be applied to the motor as a unit or to any part thereof. It may be advisable in some cases to consider the armature alone and in other cases to consider the fields. The temperature rises referred to here are the surface temperatures as measured by thermometers.

Part II gives the method to be used in order to obtain the actual internal copper temperature of the fields or armature windings.

Method of Application

An example will probably clarify the above method for determining the temperature rise of a motor. For instance, calculate the heating curve of a particular 75 h. p. low-speed motor, separately ventilated with 800 cu. ft. of air per minute; the load to be 90 amperes at 600 volts. First find the final surface temperature rise T_c with the loss W, equation (8):

$$T_c = \frac{W}{S_e\, r\, K_e + \dfrac{V\, S_i\, K_i}{V + .9\, S_i\, K_i}}$$

Where:

W = 6610 watts (total motor loss)

S_e = 4740 sq. in. (external frame surface)

r = 0.30 (ratio of frame rise to the internal surface rise)

K_e = 0.013 heat dissipation from frame in watts/sq. in./ deg. cent.

V = 800 cu. ft./min. (air volume)

S_i = 5460 sq. in. (internal ventilating surface)

v = 2070 ft./min. (average air velocity through motor ducts)

K_i = 0.038 (heat dissipation constant, see Fig. 1).

Substituting these constants in the above equation the final rise T_c = 35.5 deg. cent.

The thermal time constant (see Equation 9) is

$$t_1 = \frac{0.06\,(P_a + r\,P_i)\,T_c}{W}$$

where the weight of active material (P_a) = 1780 lb. and the weight of inactive material (P_i) = 1850 lb. With r, T_c and W as given above t_1 = 0.774. Hence with the initial temperature rise (T_s) known the rise at the end of any time (t) can be found from equation (10), where

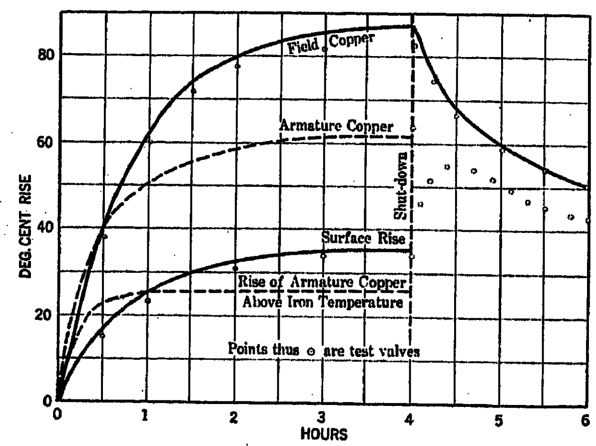

Fig. 3—Heating Curve of 75-H. P. 600-Volt D-C. Railway Motor

Forced ventilation.
Load, 90 amperes, 600 volts.
Curves as calculated.

$$t = 2.3\, t_1 \log_{10} \frac{T_c - T_s}{T_c - T_t}\,.$$

These values are plotted in Fig. 3. The results found in actual tests are also given.

The temperature rise of the armature and field copper can also be found by using the method as given in Part II. The final rise of the commutating-pole copper (see equation 12) is the surface rise, calculated above, plus the insulation drop. Thus

$$T_c = 35.5 + \frac{W\,h}{S_t\, K_t}$$

where the loss W = 1010 watts; insulation thickness (h) = 0.15 in.; the cross-section of the insulation for heat flow S_t = 1180 sq. in. and the thermal conductivity coefficient K_t = 0.0025. Hence the continuous field copper rise T_c = (35.5 + 51.5) = 87 deg. cent.

The surface temperature rise of the coil as given in Fig. 3 is seen to rise abruptly after shut-down when the ventilation is reduced. It is due to the decreased

heat flow from the surface which results in a decrease in the temperature difference between the copper and the surface, in other words, the surface temperature must rise. The maximum point reached after shut-down will be somewhere between the copper temperature and the running surface temperature. The exact value of this will depend upon the thickness of insulation, the relative thermal capacity of the copper and the insulation; and the ratio of the ventilation when running and at shut-down. It is thus seen that this temperature rise of the surface at shut-down is a transient phenomenon and the temperature found by thermometer bears no fixed relation to the actual copper temperature for all conditions.

The final rise of the armature copper T_c above the iron (see equation **12**)

$$= \frac{W\,h}{S_t\,K_t}$$

where the loss $W = 1500$ watts; the insulation thickness $h = 0.10$; surface $S_t = 2280$ sq. in. and the coefficient of thermal conductivity $K_t = 0.0025$. This gives the copper rise above the iron of 26.3 deg. cent or a final copper rise of (26.3 + 35.5) 61.8 deg. cent. The heating curve of the armature copper rise above the iron can be calculated from equation (**10**). Where (see equation **13**)

$$t_1 = \frac{0.05\,P\,T_c}{W}\,.$$

T_c and W are given above; the equivalent weight of copper $P = 264$ lb. So that $t_1 = 0.231$. The temperature rise of the armature copper above the iron is shown in Fig. 3 plotted in dotted lines. The addition of this to the average surface rise of the motor will give the heating curve of the armature copper.

The air rise

$$T_a = 1.8\,\frac{(W - S_e\,r\,K_e\,T_e)}{V}$$

W being the total motor loss; the factor $(S_e\,r\,K_e\,T_e)$ being the loss dissipated from the frame. Substitution of these constants in the equation gives an air rise of 13.4 deg. cent. Test value was 13 deg. cent.

The following example will show how the temperature rise of a self-ventilated street car motor is calculated for a given cycle run. Given a 25-h. p. 600-volt, 37-ampere, d-c. motor to operate on the following cycle:

(1) A r. m. s. current of 27 amperes for three hours, schedule speed of 10 mi. per hr. with 26-in. diameter wheels and a gear ratio of 13/74.

2) 32 amperes for one hour; schedule speed of 8 mi. per hr.

(3) 27 amperes for two hours, schedule speed of 10 mi. per hr.

(4) 50 amperes for 30 minutes with a schedule speed of 6 mi. per hr.

What will the operating temperatures of the armature iron and copper be under the above cycle?

In this case only the armature is considered. The loss is composed of the copper, iron and stray power, brush and one-half of the friction and windage loss. The following tabulation gives the value of the constants and final equation for obtaining the heating curves of the armature iron or core:

Portion of Cycle	1	2	3	4
Amperes	27	32	27	50
Rev. per min.	735	588	735	441
Total armature loss (W)	937	1056	937	2105
Watts/deg. cent. of iron (see Fig. 2) W/T_c	21.6	18.7	21.6	15.6
Continuous core rise (T_c)	43.3	56.5	43.3	135.4
Weight of armature (P)	200 lb.	..	..	..
Thermal time constant: $t_1 = 0.06\,P\,T_c/W$	0.556	0.642	0.556	0.770

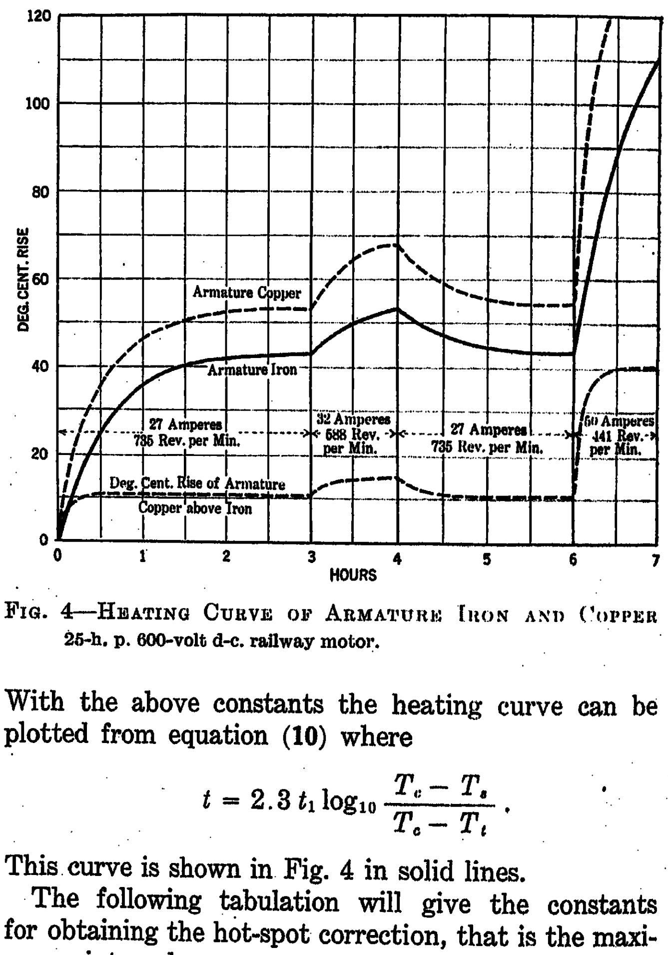

FIG. 4—HEATING CURVE OF ARMATURE IRON AND COPPER 25-h. p. 600-volt d-c. railway motor.

With the above constants the heating curve can be plotted from equation (**10**) where

$$t = 2.3\,t_1 \log_{10} \frac{T_c - T_s}{T_c - T_t}\,.$$

This curve is shown in Fig. 4 in solid lines.

The following tabulation will give the constants for obtaining the hot-spot correction, that is the maximum internal copper temperature rise above that measured by thermometers on the iron core.

Portion of cycle	1	2	3	4
Amperes	27	32	27	50
Imbedded cop. loss (W)	241	338	241	900

Constant copper rise above iron (see equation **12**):

$$T_c = \frac{W\,h}{S_t\,K_t} = 10.8\,\text{deg.cent.}\ 15.1\ \ 10.8\ \ 40.3$$

Equivalent copper weight (P) = 45 lb.

Thermal time constant:

$$t_1 = \frac{0.05\,P\,T_c}{W} \text{ (see equation 13)} = 0.101$$

With the above constants the heating curve giving the copper temperature rise above the iron can be found by using equation (**10**) where

$$t = 2.3\,t_1 \log_{10} \frac{T_c - T_s}{T_c - T_t}.$$

This curve is shown in dotted lines (Fig. 4). The addition of this curve to the heating curve obtained for the rise of the armature core will give the heating curve for the armature copper.

Both Figs. 3 and 4 illustrate the fact that the armature copper on the average ventilated motor has comparatively little thermal capacity. It is seen that on loads of thirty minutes or more practically all of

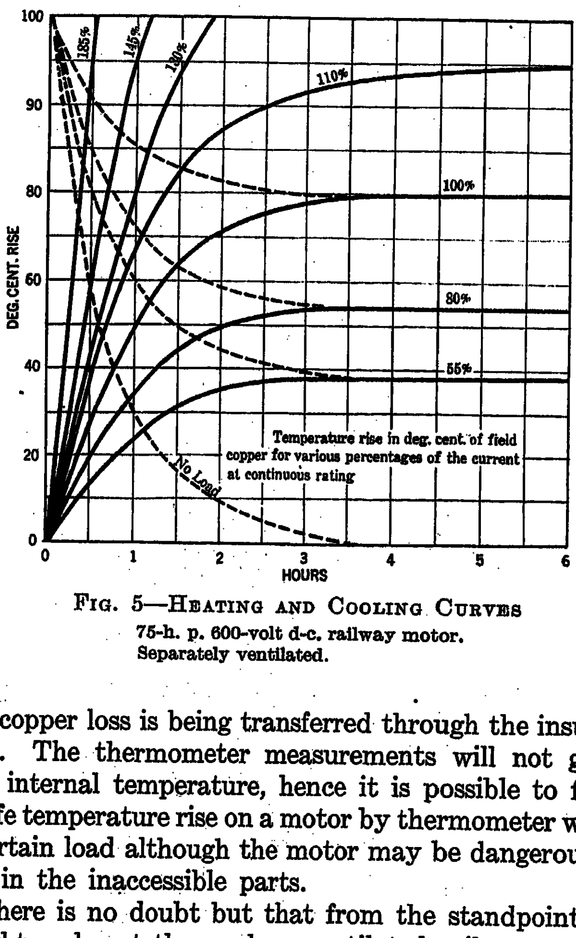

Fig. 5—Heating and Cooling Curves
75-h. p. 600-volt d-c. railway motor.
Separately ventilated.

the copper loss is being transferred through the insulation. The thermometer measurements will not give this internal temperature, hence it is possible to find a safe temperature rise on a motor by thermometer with a certain load although the motor may be dangerously hot in the inaccessible parts.

There is no doubt but that from the standpoint of weight and cost the modern ventilated railway motor has an inherent advantage over the totally enclosed motor. It has been shown that since the ventilated motor can get rid of more heat losses than the same motor enclosed it is possible to rate the motor higher. This increases the continuous rating without materially increasing the one-hour or overload rating. The effect of ventilation is to decrease the surface temperature and to increase the gradient between the copper and the surface temperature. When a ventilated motor is applied to an intermittent cycle such as found in railway service, full advantage of the continuous rating cannot be taken since a margin in temperature is necessary in order to carry the heavy peak loads.

With the heavy enclosed motors the ratio of the hour to the continuous rating is high so that the application of such a motor on the basis of the average r. m. s. current is generally safe. The inherent thermal capacity of the motor will usually take care of the peak loads.

On the other hand the tendency of increasing the ventilation is to bring the continuous and the hour rating together. Hence the economical application of the modern high-speed ventilated motors must be made with more care, and the motors' performance from a thermal standpoint on such applications should be known.

The method of predetermining the temperatures of such motors on intermittent service as previously outlined based on actual tests at the continuous rating will give results safer and more accurate than the approximate method given in the Standards of the A. I. E. E. under Rule No. 5502.

For standard motors, heating and cooling curves such as shown in Fig. 5 can be calculated which will facilitate the proper application of these motors. The solid lines are the heating curves at various loads, while the dash lines are the cooling curves either with no-load or with definite loads. The time origin can be shifted to suit the initial temperature conditions.

Conclusions

(1) The temperature limitation is the predominating factor in railway motor application. This limitation is found in the maximum "hot-spot" temperature at the peak loads.

(2) The armature copper has relatively little thermal capacity which may result in high internal temperature gradients on short-time loads.

(3) The ratio of the one-hour to the continuous rating approaches unity as the ventilation of the motor is increased.

(4) The application of the ventilated motor on the basis of the average r. m. s. current to an intermittent duty is incorrect if the maximum internal temperature at the peak load is ignored.

(5) It is the maximum internal temperature which first starts insulation failure. Hence motor ratings should be based upon this temperature and not upon the surface temperature as measured by thermometer.

(6) There is no fixed relation connecting the internal maximum and the surface temperature as found by thermometers. This relation is affected by insulation thickness, degree of ventilation, duration and magnitude of load, together with size and accessibility of the motor windings.

(7) Thermocouple measurements provide the best means for obtaining these maximum temperatures. These temperatures can be approximated from the

maximum hot resistance of the windings. However, the obtaining of these hot resistances requires very quick and accurate work. Either of the above methods requires special apparatus and the services of expert observers in service tests.

It is obvious that the temperatures of a motor in service as obtained by thermometers may be so far from the maximum internal temperatures as to give misleading results.

Thermal characteristics of the motor, such as relation of thermometer to the thermocouple temperatures, must be known for all degrees of load in order to estimate the internal temperatures from the thermometer readings.

(8) The nominal rating as defined by the Standards of the A. I. E. E. and as applied to self-ventilated railway motors is a fictitious rating since it specifies the run to be made under abnormal conditions of ventilation due to the removal of ventilating and commutator covers and due to the fact that the motor speed is usually higher than the average speed found in service. This has resulted in its being no longer a true measure of the motor's thermal capacity. It is merely a measure of the motor's overload capacity under the conditions given.

It would be more logical to make this test under conditions of ventilation as used in service.

The writer, however, believes that the original purpose of the one-hour run, that is a measurement of the motor's thermal capacity, is essential and should be approximated as closely as possible. This can be done either by reducing the time of the run or by reducing the effect of the ventilation.

Appendix

PART I

Temperature Rise of Electric Machines on Continuous and Short-Time Duty

Symbols.

Let W = Total watts loss in motor or part considered.

T_c = Final average surface rise deg. cent. on continuous duty.

T_t = Surface rise at end of time (t).

t = Time in hours the load is applied.

T_s = Average surface rise at start of cycle.

T_a = Temperature rise of ventilating air deg. cent.

V = Cubic feet of air per minute through the machine.

A = Cross-sectional area for air flow in sq. ft.

v = V/A = average air velocity through machine in ft./min.

S_e = External surface of machine in sq. in.

S_i = Internal ventilating surface of machine in sq. in.

K_i = Heat flow from internal ventilating surface in watts/sq. in./deg. cent. See Fig. 1.

K_e = Heat dissipated from external surface in watts/sq. in./deg. cent. Approximately 0.013 when stationary.

r = Approximate ratio of external frame rise to the internal surface rise.

P_a = Weight in pounds of active material.

P_i = Weight in pounds of inactive material.

With a given load applied having a loss of (W) watts for a time (t) the following statement is true:

Total Energy = stored energy + dissipated energy. (1)

But (a) Total energy = $W t$

(b) Stored energy = $0.06\,(P_a + r\,P_i)\,(T_t - T_s)$

Note: 0.06 is amount in watt-hours necessary to raise one pound of iron one deg. cent. based on a specific heat of 0.1135.

(c) Dissipated energy

$$= \int_0^t S_e K_e\, r\, T_t\, d\,t + \int_0^t S_i K_i\,(T_t - T_a/2)\, d\,t$$

(d) But $S_i K_i\,(T_t - T_a/2) = T_a V/1.8$
$= 0.555\, T_a V.$

Note: 0.555 is amount in watt-min. required to raise one cu. ft. of air one deg. cent.

(e) Hence $T_a = \dfrac{2\, S_i K_i T_t}{1.11\, V + S_i K_i}$

(f) Substitute (e) in (c) dissipated energy

$$= \int_0^t T_t \left(S_e\, r\, K_e + \frac{V\, S_i K_i}{V + 0.9\, S_i K_i}\right) d\,t$$

Substitute (a), (b), and (f) in (1)

$$W\,t = 0.06\,(P_a + r\,P_i)\,(T_t - T_s) + \int_0^t \left(S_e\, r\, K_e + \frac{V\, S_i K_i}{V + 0.9\, S_i K_i}\right) T_t\, d\,t \qquad (2)$$

Taking the derivative of (2) with respect to t;

$$W = 0.06\,(P_a + r\,P_i)\,\frac{d\,T_t}{d\,t} + \left(S_e\, r\, K_e + \frac{V\, S_i K_i}{V + 0.9\, S_i K_i}\right) T_t \qquad (3)$$

or

$$\frac{0.06\,(P_a + r\,P_i)\, d\,T_t}{W - T_t\left(S_e\, r\, K_e + \dfrac{V\, S_i K_i}{V + 0.9\, S_i K_i}\right)} = d\,t \qquad (4)$$

Let $D = S_e\, r\, K_e + \dfrac{V\, S_i K_i}{V + 0.9\, S_i K_i}$

Hence
$$\frac{0.06\,(P_a + r\,P_i)\, d\,T_t}{W - D\,T_t} = d\,t \qquad (5)$$

The integral of this equation is

$$\int_{T_s}^{T_t} \frac{0.06\,(P_a + r\,P_i)\, d\,T_t}{W - D\,T_t} = \int_0^t d\,t \qquad (6)$$

$$\text{or} \quad \frac{-0.06\,(P_a + r\,P_i)}{D} \log_e (W - D\,T_t) \Big]_{T_s}^{T_t} = t \Big]_0^t$$

$$\text{or} \quad \frac{0.06\,(P_a + r\,P_i)}{D} \log_e \frac{W - D\,T_s}{W - D\,T_t} = t \quad \textbf{(6a)}$$

$$\text{or} \quad \frac{W - D\,T_s}{W - D\,T_t} = e^{\frac{D\,t}{0.06(P_a + rP_i)}}$$

$$\text{or} \quad \frac{W - D\,T_t}{W - D\,T_s} = e^{-\frac{D\,t}{0.06(P_a + rP_i)}} \quad \textbf{(7)}$$

When t = infinity $T_t = T_c$
Hence $W - D\,T_c = 0$
or $T_c = W/D$

$$= \frac{W}{S_e\,r\,K_e + \dfrac{V\,S_i\,K_i}{V + 0.9\,S_i\,K_i}} \quad \textbf{(8)}$$

$$\text{Let } t_1 = \frac{0.06\,(P_a + r\,P_i)}{D} = \frac{0.06\,(P_a + r\,P_i)\,T_c}{W} \quad \textbf{(9)}$$

$$\text{Substitute (8) \& (9) in (6a) } t = t_1 \log_e \frac{(T_c - T_s)}{(T_c - T_t)} \quad \textbf{(10)}$$

$$\text{or} \quad t = 2.3\,t_1 \log_{10} \frac{T_c - T_s}{T_c - T_t}$$

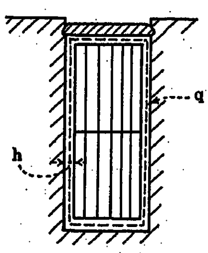
The above can also be expressed as

$$T_t = T_c - (T_c - T_s)\,e^{-t/t_1} \quad \textbf{(11)}$$

Where (e) is the Naperian base (2.718)

PART II

The above equations (**10** or **11**) will also apply to the heating of armature or field copper where the factors are defined as given below. A uniform copper temperature is assumed.



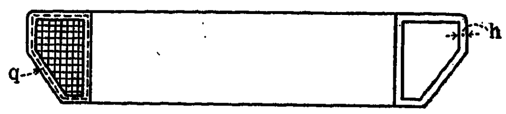
W = Total imbedded copper loss.
T_c = Final copper rise above iron.
T_t = Copper rise above iron at time (t).
t = Time in hours load is applied.
T_s = Copper rise above iron at start.

$$T_c = \frac{W\,h}{S_t\,K_t} \quad \textbf{(12)}$$

Where h = Insulation thickness inches.
S_t = Mean slot periphery (q) × No. of slots × core length.
K_t = Thermal conductivity of insulation in watts/sq. in./deg. cent.
Varies from 0.0025 to 0.0035.

$$t_1 = 0.05 \frac{P\,T_c}{W} \quad \textbf{(13)}$$

When P = Equivalent pounds of copper of winding considered.
= 0.32 (volume of copper + 1/4 volume of insulation[1] in cubic inches)



For field winding the same terms are used except as noted below:
W = Total field copper loss.
T_c = Final copper rise above outside surface.
T_t = Copper rise above outside surface at time (t).
T_s = Copper rise above outside surface at start.
S_t = Length of mean coil turn × periphery (q) × No. of coils.

1. The factor 1/4 is used since the insulation has approximately 1/2 the thermal capacity of copper for the same volume and the insulation rise above its outside surface is 1/2 that of the copper.

Discussion

M. R. Hanna: Mr. Luke has shown the difficulty of calculating accurately the temperature of the various parts of a motor when operating on an intermittent duty cycle. However I would like to point out that it is possible to obtain quite satisfactory results without any great difficulty by considering larger sections of the motor. In the case of inclosed or slightly ventilated motors we can consider the motor as a whole and in the case of well-ventilated motors we may consider the armature as a whole and each of the field windings as separate units.

After we have calculated the losses in the motor under the

various conditions of load, then if we know the watts that the motor or its various parts will dissipate at any given temperature rise and the watt-hours that it absorbs in attaining this temperature rise we can, by a simple calculation, obtain the temperature rise at the various points of the duty cycle. The ratio of these two quantities, the watts dissipated and the watt-hours absorbed is practically constant for any particular motor or part of motor under any given conditions of ventilation. This ratio definitely fixes the rate of heating or cooling. By rate I mean the time required to reach a given percentage of the ultimate temperature change. The relation is the simple logarithmic equation with which we are so familiar in its application to the rise of current in an inductive circuit. The first of these factors, the watts dissipated, can be determined from continuous heat runs such as would be made to determine the continuous rating. The second factor, the watt-hours absorbed for a given rise could be obtained by calculation from heat runs such as Mr. Luke suggests as a measure of the thermal capacity or may be calculated from the weight of material. If we are considering the motor as a whole it is surprising how good a value for the thermal capacity can be obtained simply from the weight of the bare motor. To illustrate this point I have taken values from Mr. Luke's table of distribution and disposal of losses in railway motors. In the columns for one-hour runs we find values for watts loss per pound of motor and also a value for the per cent absorbed. Now if we multiply these two values together we have, the watts absorbed per pound of motor during the one-hour run or the watt-hours absorbed per pound of motor for 75 deg. rise.

This multiplication gives the following results:

60 h. p. inclosed motor	1.96
65 h. p. self-ventilated motor	2.28
25 h. p. self-ventilated motor	1.85
200 h. p. separately ventilated motor	1.93

The average of these values is 2.01 watt-hours per pound. Note that the table covers a wide range of designs from 25 to 200 h. p. inclosed, self-ventilated and separately ventilated. The maximum variation from the average is only 13 per cent. This is fairly close for a quantity of this nature which is rather difficult to determine accurately and which is to be used, as Mr. Luke points out, in an equation based upon the assumption of a more uniform distribution of heat than actually exists. Incidentally this average value of watt-hours per pound of motor from Mr. Luke's table checks almost exactly with a value of two watt-hours that I have used for the past ten years in rough calculations of duty cycles in railway service.

In his conclusions Mr. Luke states that temperature limitation in railway service is found in the hot-spot temperature at peak loads. While this is a perfectly logical conclusion from the calculations presented, there are certain practical considerations that should not be overlooked. Time as well as temperature is an important factor in the deterioration of insulation. It is a matter of general knowledge that cotton when properly impregnated as required to meet the conditions of Class A material will stand temperature considerably in excess of that specified for Class A material for many days without serious deterioration. In an application where weight of equipment is of such great importance and where peak loads of such severity occur as in railway service it would not be economically correct to limit hot-spot temperatures at peak loads of short duration to the temperatures prescribed for continuous service. We must make some allowance for the element of time.

C. J. Fechheimer: I believe that one of the most interesting things in connection with various physical phenomena is that the equations which are derived for one kind of phenomenon apply to another; for instance, the equation for the magnetic field or for the electrostatic field are known to be very similar and practically identical. I refer to the flow lines and equal-potential lines. The gravitation field, the heat flow field, the hydrodynamic field pertaining to the flow of fluids, are mathematically at least, the same kinds of phenomena.

The particular case in point, in connection with Mr. Luke's paper, is his time-temperature curve equation, which is similar to that of the equation pertaining to the building up of current in an inductive circuit.

Mr. Luke's equation, (using his symbols) is, if the datum for reference be taken as T_s, (that is, T_s is taken as zero for reference): $T_t = T_c\,(1 - \epsilon^{-\frac{t}{t_1}})$
The time constant, $1/t_1$, is:

$$1/t_1 = \frac{S_e\, r\, K_e + \dfrac{S_i\, K_i}{1 + \dfrac{0.9\, S_i\, K_i}{V}}}{.06\,(P_a + r\, P_i)}$$

The first term in the numerator represents the watts dissipated from the external surface per degree. The second term will also be seen to increase with the watts loss.[1]

Therefore, the numerator is a factor which is nearly proportional to the watts liberated. The denominator is a constant—depending upon the specific heat times the weights. Therefore, the denominator represents the heat stored. In other words, the time constant, $1/t_1$, is equivalent to the ratio of the energy consumed to the energy stored.

The well-known equation for the growth of electric current in an inductive circuit is:

$$i = I_0\,(1 - \epsilon^{-\frac{r}{L}t})$$

This equation is in every way similar to Mr. Luke's equation as written above, provided the time constant R/L is similar to the time constant $1/t_1$. This will be seen to be the case, for R/L represents the ratio of the energy consumed indicated by R, to the energy stored in the magnetic field, indicated by L. Thus, i, the current at any instant, is comparable with T_t, the temperature at any instant; I_o and T_c are comparable, both being the values for the steady state.

I want to call attention to the fact, mentioned also by Mr. Luke, that equations of this character can be considered only as approximate. I want to emphasize that point, so that any one using such equations would not be likely to be misled. The conditions might be compared, perhaps, with those which would obtain in the building up of current in an inductive circuit, if the factor L were not a constant, but one which depended on the permeability of the iron. You could see at once how extremely difficult a solution of that problem would be in the electric circuit if the permeability were variable. Some of the uncertainties are that the temperatures are not uniform, and therefore the rates of dissipation of heat are not uniform. We get all values of temperature, for instance, from the outside surface of the motor. Non-uniform temperatures also mean that there are complex internal heat flows—flows from high to low temperatures—which complicate the problem tremendously. Such factors it is next to impossible to incorporate in any mathematical derivations.

The constants entering into the equations are quite uncertain; such as the rates of dissipation of heat from any one of the surfaces. That nominal constant is very much complicated by the effect of eddies in the air. If the air moves in perfectly straight lines, it does not pick up nearly so much heat for a given rise of temperature of the surface above the air as it does if the air is highly turbulent. When highly turbulent, each particle

1. If 1 be neglected, the second term becomes simply $V/0.9$, [a constant for a given machine.] If the other term be ignored, the second term becomes $S_i\, K_i$, = watts liberated om the internal ventilating surface.

of air comes into contact with the dissipating surface, and therefore each particle serves directly to pick up heat; otherwise, only those particles of air which come into contact with the particular surface are heated directly; with smooth flow, some particles are heated indirectly, that is, by conduction.

As time goes on, as the air-heats,—the mass of air must necessarily decrease, assuming that the volume of air is constant; and as the amount of heat which the air can take up is a function of the mass of air per minute which passes through the motor, the air becomes less effective for carrying away the heat.

Again, the ratio "r" which Mr. Luke has in his equations, is also subject to experimental determination, and a great many tests are required before it can be determined with sufficient accuracy.

However, I do not want, by any means to disparage the value of Mr. Luke's paper, as I think it is quite a valuable contribution. As a matter of fact, the duty cycle of the railway motor is very uncertain; much more so than the factors which come in in the determination of the time-temperature curves. We can approximate sufficiently close for ordinary use, by means of Mr. Luke's equations, the conditions which obtain in general service in railway motors.

I think that if a complete solution were obtained it would be advisable to estimate roughly the influence of longitudinal heat flow in the copper, as well as the transverse heat flow. I attempted to do this in a paper which I read a year ago before the Institute.[2] That solution covers the steady state only; if, in addition, time is considered as an independent variable, the equations become so complicated that a solution is well nigh impossible.

I want to mention two more points; first, the enormous influence of air pockets. This was spoken of in discussing Mr. Shanklin's paper. In the insulating wrappers on coils, whether paper, or cloth, or mica, or what not, there are certain values of thermal conductivities for the individual layers of insulation. If these layers of insulation are put one above the other, as in ordinary practise, it is impossible to avoid tiny air pockets between them. The effect of these air pockets, (or "contact resistance"), is to decrease the thermal conductivity to about half the value which would obtain for the individual layers. This means, of course, that it is far more difficult for the heat to escape as the result of these air pockets than would be the case if they were not present. Furthermore, this decrease in thermal conductivity, due to the voids, makes the determination of temperature more uncertain because the thermal conductivity has a more uncertain value in wrappers, than when the individual layers alone are dealt with.

The other point: We are accustomed to speak of heat dissipated from machinery, or from any other heated body, as radiation. We speak, for instance, of those devices which are the agents for heating our rooms as radiators. As a matter of fact, nearly all the heat is dissipated from them by free convection currents, and only a little by radiation, radiation pertaining to heat waves in the ether. The heat which escapes from the incandescent lamp filament is almost entirely by radiation, because the temperature of the filament is so very high compared with the surrounding bodies, but not so with the heat from an electrical machine. There it is almost entirely dissipated by convection currents. Why should we not speak of the surfaces from which heat is dissipated as "heat-dissipating surfaces" rather than as "heat-radiating surfaces?"

F. W. Peters: From experience I feel that the designing engineers have pretty well mastered the subject of railway motor heating, the topic under discussion in the paper. This is borne out from a practical standpoint by the fact that there are relatively few failures emanating from straight overheating where motors are operated within the service for which they are recommended. Design constants are well known and a reasonable factor of safety used in application to motors with the result that the pure heating situation seems to be quite well taken care of.

However, I wish to read a sentence in Mr. Luke's paper as follows: "Railway motor failures may be classed as mechanical and electrical. A large part of electrical failures is due to poor commutation and flashing or to excessive temperatures."

On the basis of experience with failures of railway motors from a manufacturer's standpoint, it appears that failures because of excessive temperatures are relatively very few in number. Often it is difficult to determine the cause of a failure, and many times erroneous conclusions may be arrived at, because evidence of the primary cause for the failure may be destroyed. A failure, apparently due to temperature, is very often the result of a contributing cause initiated by a mechanical failure. For example, if a coil becomes loosened in a slot and mechanical chafing of the insulation results in an electrical breakdown, it is possible to attribute the failure to excessive temperatures, whereas it is primarily a mechanical failure.

Railway motors are subjected to very severe service with respect to operating under conditions of moisture. We are all familiar with the fact that failures in winter are much greater than in summer. Put two similar motors in equivalent service with one operating under severe moisture and the other under dry condition, the former motor would be expected to fail in a shorter time than the latter because of water and the dirt carried with it which more rapidly harms the insulation. While the heating conditions for the two motors are identical we would expect shorter life on one than the other because of an outside contributing cause. When such a motor fails it may be attributed to excessive temperatures, whereas it may in reality be due to the severe mechanical conditions to which the insulation has been subjected.

Other failures that we have to contend with are those caused by flashing which may harm the insulation, and on the occasion of a burnout may make it appear that excessive temperature was the cause; whereas the failure was accelerated by an abuse of the insulation.

A. C. Lanier: Mr. Luke's paper has brought out in a very interesting fashion the possibility of approaching what is rather a complex problem in a rational way, and getting results which are simple and yet dependable within reasonable limits. When conditions affecting heat dissipation are known, such as the losses and their distribution, the weights of material which absorb the heat energy, the volume of cooling air available, and the extent and character of the surfaces with which that air comes in contact, probable temperature rises may be predicted under known sets of conditions.

The same method of approach would very naturally suggest itself for motors in ordinary industrial applications, but with the ordinary industrial motor, some difficulties enter which are absent or less pronounced in the case of the railway motor. Of course, there is relief, on the other hand, from a good many difficulties which the railway service imposes. If we consider, for example, the open motor with natural ventilation, we find considerable variation in the ventilating characteristics even of individual machines of the same general line. For example, there is a difference in the effectiveness of multiple turn coil and single turn coils; this difference seems chargeable both to unequal fanning action, and unequal amounts of coil end surface exposed to the convection currents of air. Frequently with different motors and different coils, the flow of air is not found with any great degree of definiteness, it is very variable,—you might find different parts of the motor resisting rather than contributing to a definite air flow.

When the question of degrees of enclosure is introduced, the problem of ventilation and temperature rise is further compli-

2. Longitudinal and Transverse Heat Flow in Slot-Wound Armature Coils, TRANS. 1921, A. I. E. E. p. 589.

cated and is rendered still less definite. With total enclosure, the total external radiating surface of the motor sets a fairly definite limit to the losses which may be dissipated. With partial enclosure there is not only a reduction in the amount of cooling air carried into the motor, as compared with the open type, but its direction of flow may also be considerably modified.

I should think, however, that though a larger number of constants might be necessary in applying these general relationships, which Mr. Luke has given to the ordinary industrial motor with natural ventilation, still with sufficient experimental data, his method might work out very well. I should like to know whether Mr. Luke has extended his investigations into the field of motors in industrial applications.

G. E. Luke: Mr. M. R. Hanna has shown that the watt-hours absorbed by the motor at the one-hour rating are approximately equal to two watt-hours per pound of motor and is practically independent of the type or degree of ventilation. Mr. Hanna mentioned the fact that insulation life is affected by not only high temperatures, but also by the time these temperatures existed. This point is well taken, since tests have been made under load conditions which caused the insulation to "smoke," involving temperatures ranging from 175 to 200 deg. cent for a few minutes duration. Examination of the insulation (Class A) showed it to be still in good condition. However, there is no doubt but that continued application of these high temperatures would soon cause failure. For example, tests on Class A insulation at 150 deg. cent. for three months rendered it lifeless as far as mechanical strength is concerned.

The poor thermal conductivity of insulating materials due to air pockets in the built up material was mentioned by Mr. C. J. Fechheimer. Proper impregnation of the insulation will reduce these high resistance paths to the flow of heat. Dipping and baking of the armature and fields is also beneficial in making the insulation more compact and homogeneous.

As stated by Mr. Fechheimer, radiation plays a minor part in the cooling of electric motors. For example the factor of 0.013 has been previously given as the watts *dissipated* from the external surface of a railway motor frame in watts per square inch per deg. cent. rise. This is the resultant of radiation, natural convection and a very small factor due to conduction through the motor supports. Of this constant (0.013) 20 to 30 per cent is due to radiation, and the remainder is mostly the resultant of natural convection.

Mr. F. W. Peters brought out the fact that a relatively small percentage of failures is caused by roasting or excessive heating of the insulation. Fortunately this fact is true especially when the motors are not loaded beyond the limits recommended by the manufacturer, and when weather conditions are not abnormal.

However many cases develop where a motor must be overloaded in order to maintain the schedules in an emergency. It should be clearly understood that on such abnormal overloads if failure occurs it is apt to be due to overheating since the factor of safety used from a mechanical standpoint is much greater than that feasible from the heating standpoint.

The purpose of this paper was to bring out the temperature limitations of the motor under different load conditions so that the lightest motor economically possible, consistent with satisfactory operation, could be used.

Prof. Lanier asked whether the method of calculation of temperature could be applied to industrial motors. The method as mentioned in the paper is more applicable to separately ventilated motors, where the air conditions are more definite, since the air is restrained to move in more or less definite paths. In the case of industrial motors where the machine is cooled by natural convection currents or the fanning action of the armature ducts and end windings, the conditions of ventilation are not definite enough to calculate with any degree of accuracy, from the fundamental physical conditions. However, if one continuous rating is known, other ratings on the same machine may be calculated at different loads and speeds as explained in the paper for self-ventilated motors.

The "Indumor"

A Kinematic Device which Indicates the Performance of a Polyphase Induction Machine*

By VLADIMIR KARAPETOFF
Fellow, A. I. E. E.
Professor of Electrical Engineering, Cornell University

Subject of the Paper.—*A kinematic device is described and illustrated which represents the vector diagram of a polyphase induction machine. The parts are made to assume at will different positions corresponding to different loads of an induction motor or generator. The primary and the secondary constants, the magnetizing current, and the core loss, are also adjustable at will. The device permits the visualization of the performance of an induction machine and can be used for a study of a given machine or for a selection of the constants to give the desired performance characteristics of a new machine. The input, output, torque, speed, power factor, etc., can be read off on the device as in an actual brake test.*

The kinematic connections consist mainly of generalized proportional dividers and of parallel tongs, so combined as to satisfy a system of simultaneous vectorial equations which represent the properties of the machine. Further applications of the device to polyphase commutator motors are suggested.

CONTENTS

INTRODUCTION

The Meaning of the Word "Indumor." An abbreviation of the words "induction motor."

What the Indumor is. A combination of movable and adjustable bars (Fig. 1) which can be set to repre-

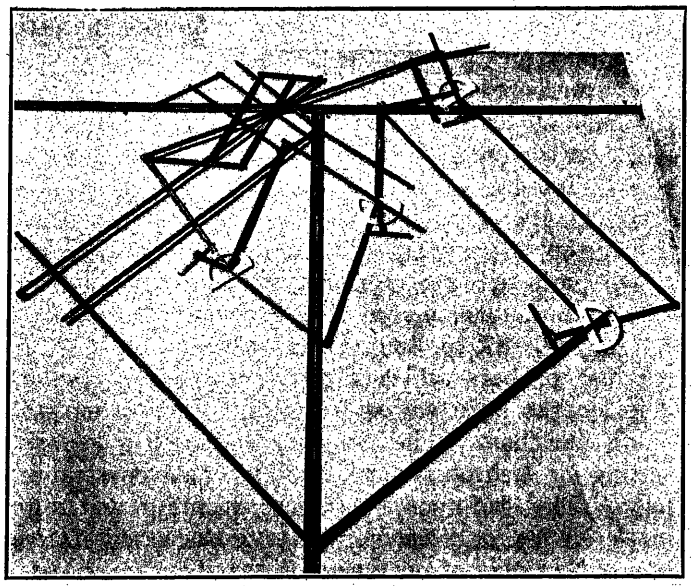

FIG. 1—THE INDUMOR

sent to a certain scale a vector diagram of voltages, currents, m. m. fs. and fluxes in a polyphase induction motor or generator of any desired constants. The parts of the device are kinematically so constrained that the diagram set correctly for one load remains correct at any other load.

The Purposes of the Device. (1) To enable a designer to select the best electrical constants and to "test" an induction motor or generator before it has been actually built. (2) For some applications to take the place of an involved analytical theory; it is often difficult to see the effect of separate factors upon the performance characteristics, and it takes considerable mathematical skill to deduce the equations of the various loci. (3) For some purposes to take the place of the circle diagram which becomes quite complicated when the primary resistance is taken correctly into consideration. (4) To add the judgment of the eye and the skill of the hands to the purely mental ability in selecting the constants of a machine for a desired performance, or in judging the characteristics for assumed constants. (5) To enable an investigator or a student to familiarize himself with the machine as if he had one available for tests. This is of particular importance with large machines for which no facilities may be available for testing.

The Performance Curves that the Indumor Enables One to Draw. Current, torque, speed, slip, input, output, efficiency, power factor, and magnetizing current. These may be obtained just as easily at a constant applied voltage as at a voltage which varies in any desired manner.

The Factors Which May be Taken into Account and varied separately at will in the Indumor. Per cent magnetizing current; per cent primary and sec-

Presented at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

*The investigation upon which this paper is based was supported by a grant from the Heckscher Foundation for the Advancement of Research, established by August Heckscher at Cornell University.

ondary resistance; per cent primary and secondary reactance; core loss; friction.

Limits of Rating and Output. Like any other graphical device, the Indumor requires certain scales to be chosen for each particular problem. A convenient scale has to be selected for amperes, and another for volts. The device can represent the performance of a fractional horse-power motor as well as of one whose output runs into thousands of kilowatts; of a 110-volt machine as well as of one wound for 11,000 volts. As in any graphical device, there are limitations due to a finite length of the links. With a certain setting the device may give an accurate performance say between no-load and 1.5 times the rated current. If a heavier overload is desired a smaller scale may have to be chosen for amperes.

B. General Description of the Indumor

The first complete Indumor was built in the shops of Cornell University during the summer of 1921 and is shown in Fig. 1. The same device is shown as a single-line diagram in Fig. 8. It is made of flat steel bars, not over one cm. wide and a few millimeters thick. The lengths of the principal members, between centers, in centimeters, are shown in Fig. 8. Some bars are of constant length, others are of adjustable useful length, holes being drilled every few millimeters. Most bars are connected to each other by means of pivot joints; others are set at a constant angle to each other by means of the protractors clearly seen in Fig. 1.

The device is assembled on a table provided with two grooves, at right angles to each other. The ends of some bars are constrained to move in these grooves. Different bars have to be placed in different horizontal planes to enable them to cross each other without interference. In Fig. 8 the bars nearest to the table are marked 1, those immediately above them are marked 2, etc. The particular sequence selected is not essential since the device is intended to represent a vector diagram in a plane.

A detailed description of the functions of different parts is given below in connection with the theory of the Indumor. It suffices to state here that the device is set for chosen design constants at a certain load. The setting is done by selecting suitable scales for volts and amperes and adjusting the lengths of a few bars and the angles accordingly. The Indumor then represents a set of four simultaneous vectorial equations which together characterize the machine, viz.:

(a) The primary electric circuit;

(b) The secondary electric circuit;

(c) The main magnetic circuit;

(d) The relationship between the induced e. m. f. the flux.

After having been properly set, the kinematic combination becomes a *system with one degree of freedom*, that is, if any point of it is moved, all other points move in a perfectly definite manner. It is well known that an induction motor at a constant applied v[illegible] a system. As the load varies, all the elec[illegible] teristics and the speed vary in only one [illegible] It differs in this respect from a shunt-w[illegible] current motor in which the field current [illegible] independent variable, or a second degre[illegible]

Having set the device, the lower knob [illegible] and down in the groove. This causes all o[illegible] to assume new positions. For any posi[illegible] knob readings can be taken of the current, [illegible] torque, slip, output, etc., as in any brake te[illegible] are measured with an ordinary meter scal[illegible] displacements may be either measured [illegible] the sighting goniometer shown in Fig. 9, [illegible] from the measured projections of vectors, a[illegible] below.

The Principle of the Indumor. The de[illegible] on the principle of ordinary dividers. [illegible] legs on a pair of dividers be denoted A [illegible] with the pivot at B. The length to be [illegible] AC, and AC can be varied at will by openi[illegible] the dividers, even though the length of [illegible] legs is constant.

Similarly in the Indumor the variabl[illegible] not represented by the bars themselves, [illegible] distances between the ends of two bars. [illegible] vector directly represented by a bar is that [illegible] voltage because it remains constant. [illegible] the Indumor shown in Fig. 1 gives a comp[illegible] diagram of an induction motor, the vectors [illegible] are represented only by imaginary lines [illegible] the ends of various bars. By drawing su[illegible] usual vector diagram is obtained, such as [illegible] Figs. 3 and 4.

At the 1918 Midwinter Convention of th[illegible] the author demonstrated another kinem[illegible] which imitated the performance of th[illegible] series commutator motor (The Secomor, Tra[illegible] E. E., Vol. 37, p. 329). That device was [illegible] the use of bars which directly represent[illegible] The lengths were varied by means of slid[illegible] along the bars. The Secomor required a [illegible] setting for each point since it did not have [illegible] links. The Indumor is a more accurate [illegible] matic device; once set correctly for one point [illegible] the whole range of operation of the machine [illegible] of properly designed constraining motions.

The Performance Diagram of a [illegible] Induction Motor

It is well known that for certain purp[illegible] phase induction motor may be replaced by [illegible] lent combination of resistances and reacta[illegible] shown in Fig. 2 (see for example the author'[illegible] Circuit", Chap. XII). In this diagram [illegible] only is represented; r_1, x_1, r_2, and x_2, are the [illegible] and the secondary resistances and reactan[illegible] secondary quantities being reduced to the [illegible] circuit, (see for example the author's [illegible]

Circuit", p. 133). The susceptance b_0 is of such a magnitude that the current I_m passing through it is equal to the actual magnetizing current of the motor. The conductance g_0 causes a joulean loss numerically equal to the primary core loss of the actual machine.

The mechanical load of the actual machine is replaced by an adjustable resistance R; the $I_2^2 R$ loss in this resistance can be made equal to a desired motor load. Strictly speaking, this load, in addition to the useful output, includes the friction, windage, and the secondary core loss. In approximate computations the friction and windage losses are sometimes taken into account in the conductance g_0, but it is better to subtract the mechanical losses from the total output. A still better approximation to the actual conditions could probably be obtained by using three shunted constant conductances, one across the line terminals A B, one across M N, and one between C and D.

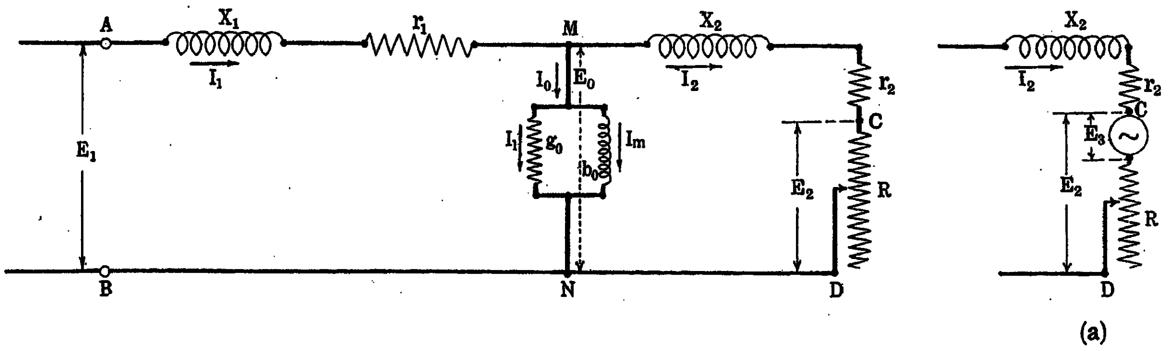

FIG. 2

A combination of resistances and reactances shown in Fig. 2 gives nearly the same performance curves as the actual motor. Let a certain brake load be applied to the actual motor and let the resistance R of the equivalent combination be so adjusted that the primary current is the same as in the actual motor. Then it will be found that the primary input and the power factor are also the same and that the brake load is equal to $I_2^2 R$ watts, less the friction and windage.

The slip, being equal to the percentage of secondary loss, can be computed as the ratio of r_2 to $(R + r_2)$, and checks very closely with the actually measured slip. The torque, in synchronous watts, is equal to the input into the secondary circuit and therefore is equal to $I_2^2 (R + r_2)$. The voltage E_0 between M and N is a measure for the air-gap flux. Thus, all the important characteristics of the motor can be obtained from the equivalent diagram, either by test or by computation.

For the operation as an induction generator, above synchronism, the resistance R should be assumed negative. At synchronism this resistance is infinitely great, and in the transition from motor to generator it jumps from $+ \sim$ to $- \sim$. Then it remains negative, decreasing in its absolute value. Another way of representing the generator range is to replace the resistance R by a counter-e. m. f. E_2. At synchronism E_2 must be equal and opposite to the voltage E_0 between M and N in order to reduce the secondary current to zero. As the generator load increases, E_2 must be made greater than E_0, always keeping E_2 in phase with the scondary current, I_2, which is now reversed.

The Vector Diagram. The relationships shown in Fig. 2 are represented vectorially in Fig. 3, which is the familiar transformer diagram at non-inductive load. Beginning with the vector of the air-gap flux, the magnetizing current, I_m, is drawn in phase with it and the core loss component, I_l, in quadrature with it. This gives the total exciting current, I_0, through

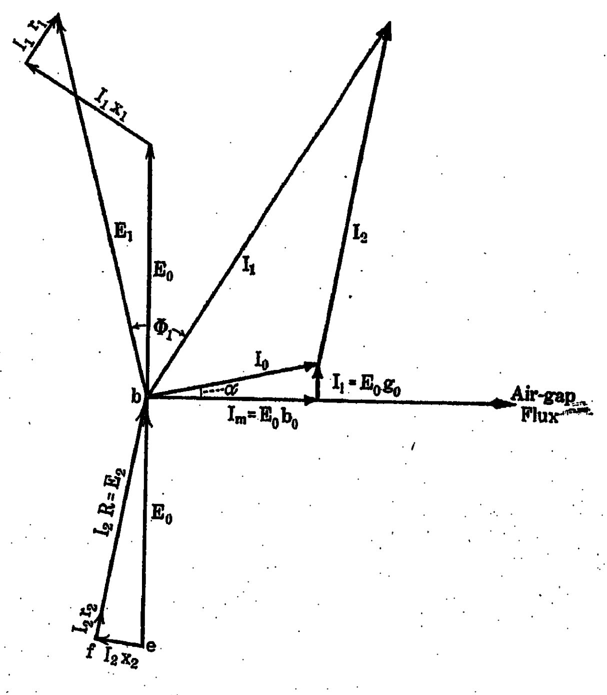

FIG. 3

the shunted admittance between M and N in Fig. 2. This current leads the flux by an angle α.

The voltage E_0 balances the e. m. f. induced by the air-gap flux, and is therefore drawn in leading quadrature with it. The applied voltage consists of E_0 and of the parts $I_1 r_1$ and $I_1 x_1$ lost in the primary impedance. The voltage E_0 is used up in the secondary circuit, partly in the impedance of the winding, partly

in the resistance R. The primary current, I_1, is equal to the secondary current, I_2, plus the exciting current I_0.

We thus have the following four fundamental vectorial relationships which must be simultaneously fulfilled in the Indumor:

(a) The geometric sum of E_0, $I_1 r_1$, and $I_1 x_1$, must be equal to the applied voltage E_1.

(b) After subtracting the vector $I_2 x_2$ from E_0, the remainder, $f b$, must be in phase with I_2.

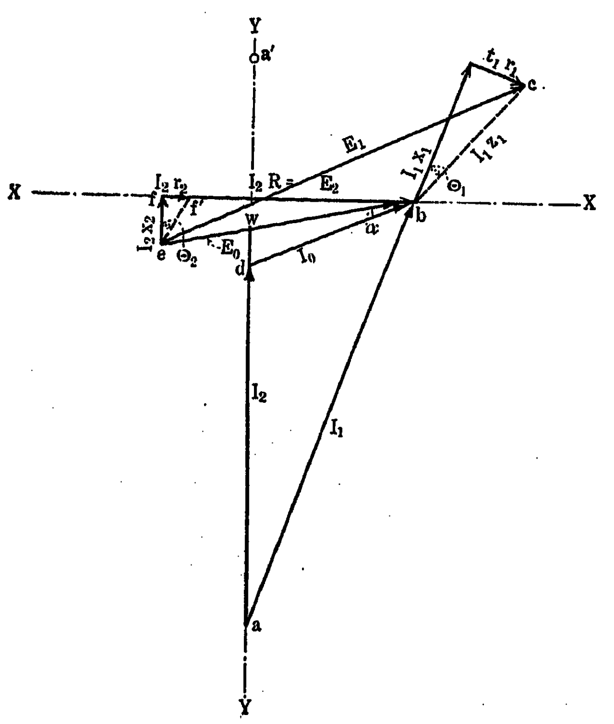

FIG. 4

(c) The geometric sum of I_0 and I_2 must be equal to I_1.

(d) I_0 must be proportional to E_0 and the angle between the two must be constant.

The diagram in Fig. 4 is identical with that shown in Fig. 3, except that some vectors are rearranged in order to simplify the construction of the Indumor. The direction of the secondary current, I_2, is taken as the $Y\,Y$ axis, and the triangle $I_2\, I_0\, I_1$ is drawn accordingly. The triangle $b\,f\,e$ is turned back by ninety degrees, so that E_0 forms the angle α with I_0, instead of $(90° - \alpha)$. Similarly, the quadrilateral built on the primary voltage E_1 is turned back by ninety degrees, and is so placed that E_0 is its common side with the triangle of secondary voltages. The vector $I_2 R = E_2$, which in Fig. 3 is parallel to I_2, is now perpendicular to I_2, and chosen as the direction of the $X\,X$ axis.

In Fig. 4, as well as in the Indumor, all the voltage vectors are turned back by 90 deg. with respect to their true positions in Fig. 3. Or else, the voltages in the Indumor may be said to be in their correct position, but the currents advanced in phase by 90 deg. This must be borne in mind when measuring the phase angle between the primary current and voltage. The operation of the device is not otherwise affected since the currents and the voltages form separate closed figures.

The reason for turning the voltages, or the currents, in the Indumor is that it is mechanically much simpler to make two lengths vary in a constant ratio when they are nearly in line with each other than when they are perpendicular to each other. Neglecting the core loss, the magnetizing current, I_0, in Fig. 3 is at right angles and proportional to E_0. In Fig. 4 I_0 is nearly in phase with E_0, and proportional dividers have been developed which can keep the two vectors in a constant ratio and at a constant angle, when both vectors vary with the load.

Figs. 4 and 8 can be directly compared, the corresponding quantities being denoted by the same letters. Thus, $a\,d$ is the secondary current, $a\,b$ is the primary current and $d\,b$ is the exciting current. The primary impedance drop is $b\,c$, the secondary reactive drop is

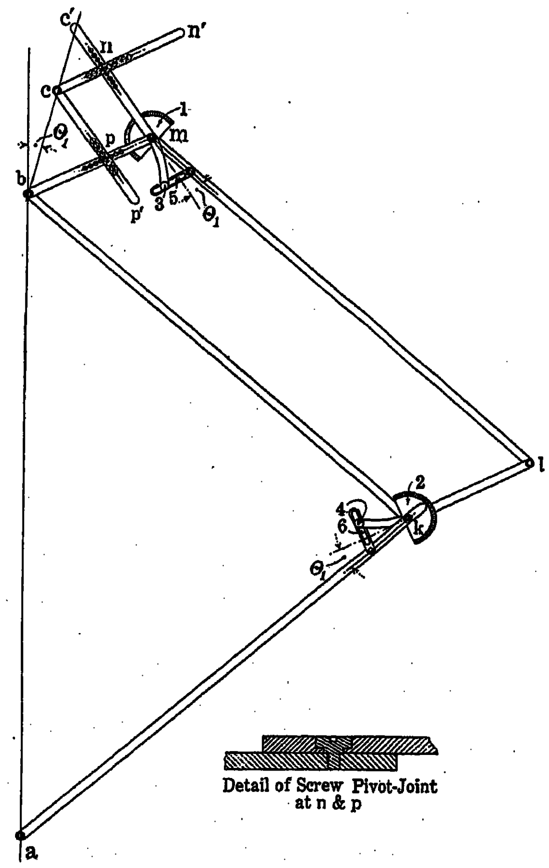

FIG. 5—PROPORTIONAL DIVIDERS

$e\,f$, the applied voltage is $e\,c$, etc. Since the Indumor is based on the principle of dividers, all the variable vectors are measured between the pivot points of different bars and not along one and the same bar.

THE KINEMATIC DETAILS OF THE INDUMOR

Having established the relationship between the vector diagram in Fig. 4 and the linkages in Fig. 8, it

remains to show how the various points are constrained to move along certain paths in order that the four above-mentioned conditions remain fulfilled with any setting of the device.

I. Proportional Dividers for the Primary Impedance Drop

In Fig. 4 the primary current, $I_1 = a\,b$, and the primary impedance drop, $I_1 z_1 = b\,c$, are proportional to each other and their vectors are inclined to each other at a constant angle θ_1, where $\tan\,\theta_1 = z_1/x_1$. Proportional dividers which permit this relationship to be realized are shown in Fig. 5, the corresponding points being also marked a, b, c. The three bars, $a\,k$, $b\,k$, and $l\,m$, are of the same length between the centers. The shorter bars, $k\,l$, $b\,m$, and $c'\,m$, are also of equal length. By means of protractors 1 and 2, the bars $c'\,m$ and $k\,l$ are set at the desired angle, θ_1, to the longer bars, and are fastened in that position by means of slotted bars 5 and 6 and head screws 3 and 4. This makes the triangles $b\,m\,c'$ and $a\,k\,b$ similar to each other, with their corresponding sides inclined at the angle θ_1 to each other. By opening or closing the dividers, the distance $a\,b$ may now be varied at will, and the distance $b\,c'$ will always remain proportional to it and inclined at the angle θ_1.

The desired length $b\,c$ is different from $b\,c'$, and point c is located by means of the bars $c\,n'$ and $c\,p'$, by making $b\,p = p\,c$ and $c\,n = c'\,n$. The holes in the upper bars are drilled and counter-sunk; those in the lower bars are drilled and tapped, as shown in the detail sketch. Machine screws are used at points p and n for fastening the bars together. These screws do not prevent a free rotation of the bars relatively to each other. The triangle $b\,p\,c$ is similar to $b\,m\,c'$, so that $b\,c$ also remains proportional to $a\,b$.

The bars $a\,k$ and $k\,b$ must be long enough to allow the dividers to be opened for the greatest length $a\,b$ of the vector of primary current for which the Indumor is designed. The shorter bars must allow a setting for the highest percentage of primary impedance drop that will ever be used with the apparatus. To illustrate, let the total length of the bar $e\,c$ (Fig. 8), which represents the primary applied voltage, be 150 cm., and let the highest primary impedance drop, that may ever be encountered under the extreme practical conditions, be say 10 per cent of the applied voltage. Then the length $b\,c'$, with the dividers fully opened, should be not less than 15 cm. Should a special motor have the primary impedance drop of over 10 per cent, it is only necessary to use a shorter length for the primary terminal voltage. For example, with the vector of primary voltage 75 cm. long, an opening $b\,c' = 15$ cm. corresponds to a primary impedance drop of 20 per cent. Any smaller value of primary impedance drop down to zero, can be obtained by properly setting the point c.

When adjusting the dividers it must be remembered that the reactive drop is set in phase with the current, and the ohmic drop in quadrature with it, because in the Indumor the currents are turned by 90 deg. with respect to their true position in Fig. 3. The dividers just described are denoted in Fig. 8 by the same letters.

II. Proportional Dividers for the Secondary Reactive Drop

In the Indumor the secondary reactive drop is taken into account separately from the secondary resistance drop, because the latter is used in measuring the slip and must therefore be represented by a separate length. In the primary circuit the resistance drop and the reactance drop are combined into one vector which is represented by the above described proportional dividers.

The proportional dividers for the secondary circuit are simpler than those for the primary circuit, since their only purpose is to give a length $I_2\,x_2$ proportional to I_2 and in line with it. It will be remembered that in the Indumor the voltages are turned by 90 deg. with respect to their true position in Fig. 3, so that the reactive drop is in phase and not in quadrature with the current.

When the two protractors in Fig. 5 are set on zero, the segments $a\,b$ and bc lie on the same straight line, and such a device can be used for the secondary current and reactance drop. The protractors, the slotted bars, and the head screws, can be omitted altogether and the members $a\,k$ and $k\,l$ made of one piece of steel. Similarly, $c'\,m$ and $m\,l$ can be made of one piece. If now the larger opening, ab, of such simplified proportional dividers be applied between points a and d (Fig. 4), the smaller opening, bc, when properly set, will give the length $d\,w$, equal to the secondary reactive drop. This length is transferred into the position $e\,f$ by means of the parallel double-tongs described under III below.

The secondary proportional dividers are shown in Fig. 8 in their actual position. The secondary current is $a\,d$ and the corresponding reactive drop is $d\,w$. The three long bars are $a\,r$, $r\,w$, and $q\,d$. The shorter bar is $d\,u$. Holes are drilled and tapped in some of these bars (Fig. 1) so that $d\,w$ can be made of any desired length. The dividers simply consist of two similar triangles, $a\,r\,w$ and $d\,u\,w$, held together by the bar $q\,d$ so as always to keep the sides $d\,u$ and $a\,r$ of the triangles parallel to each other.

III. Parallel Double-Tongs

The secondary reactive drop $d\,w$ (Fig. 4) obtained by means of the proportional dividers, has to be transferred to the position $e\,f$ at the end of the vector E_1. As the load varies, the distance between d and e also varies, both in magnitude and in direction, so that it is necessary to connect the points d, w, and e, by means of an adjustable translating device, whose fourth point would give the correct position of point f.

Such a device, which might be called "parallel double-

tongs," is shown in Fig. 6 in two positions. The four end-points are lettered d, w, e, and f, to correspond to Fig. 4. The construction of the device is such that $f\,e$ is always equal and parallel to $w\,d$. If $f\,e$ be kept constant and stationary, the tongs will allow only such displacements of the points w and d at which the distance $w\,d$ remains equal and parallel to itself,

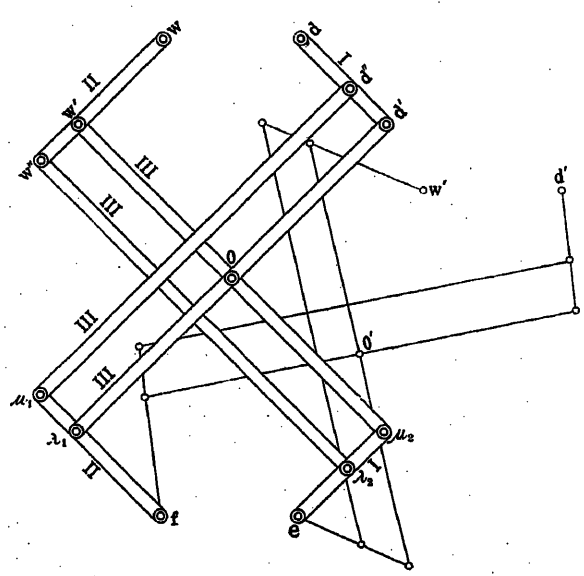

Fig. 6

as shown by the dotted lines. If $f\,e$ be varied in direction and in magnitude, $w\,d$ will vary accordingly.

The device consists of eight pivoted members. There are two short bars of equal length, marked *I*, two equal bars, *II*, of intermediate length, and four long bars, *III*, of equal length. The length $w\,w'$ between the centers must be equal to $d\,d'$, and $w'\,w''$ must be equal to $d'\,d''$. The pivot joint o must be at the center of both long bars which it connects. In other respects the dimensions of the device are arbitrary and depend upon the range of the distances which it is designed to cover. A given distance may also be connected between f and w, instead of between f and e, and an equal and parallel distance is then maintained between e and d.

The parallel double-tongs are shown in Fig. 8 between the points d, w, e, and f, and are marked with the same letters as in Fig. 6; they may also be seen in Fig. 1. In the actual use of the Indumor it has been found convenient to have two pairs of tongs, one for larger distances, when a long bar is used for the applied voltage, and one for shorter distances, for use on overloads and near the starting point of the motor, at a reduced terminal voltage. When the limit of one pair of tongs has been reached they are removed and the other pair is slipped in its place.

The proof of the parallel double-tongs is as follows: Let point o be kept stationary, and let point f occupy any desired position. The vectors $o\,f$ and $o\,d$ are equal and opposite because of the chosen lengths of the links. Similarly the vectors $o\,e$ and $o\,w$ are always equal and opposite; they are also independent of the other half of the device. Thus, the triangles $o\,f\,e$ and $o\,w\,d$ are equal and turned by 180 deg. with respect to each other. Hence, the vectors $f\,e$ and $w\,d$ are equal and parallel.

IV. Proportional Dividers for the Magnetizing Current

In Fig. 4 the magnetizing current, I_0, is drawn at a constant angle α to the voltage E_0. As the load varies, both E_0 and I_0 vary, but their ratio remains constant (neglecting magnetic saturation). As shown in Figs. 2 and 3, the value of the angle α is determined by the relationship

$$\tan \alpha = g_0/b_0 \tag{1}$$

Generalized proportional dividers which permit I_0 and E_0 to vary while satisfying these conditions, are shown in Fig. 7. The lines $b\,d$ and $b\,e$ have the same meaning as in Fig. 4. By turning Fig. 7 by 90 deg so that point b is on top, it will readily be seen that these proportional dividers are practically identical with those shown in Fig. 5, except for somewhat different proportions. Therefore no new proof is needed for the fact that the triangle $e\,b\,d$ remains similar to itself as the dividers are opened or closed. These dividers are shown in the assembly (Fig. 8) marked with the same letters as in Fig. 7.

The angle which corresponds to θ_1 in Fig. 5 is denoted by β in Fig. 7, and the protractors are set for this angle. It will be seen that angle β is different from the required angle α at b. Since the device is intended to represent angle α, it is necessary to know the

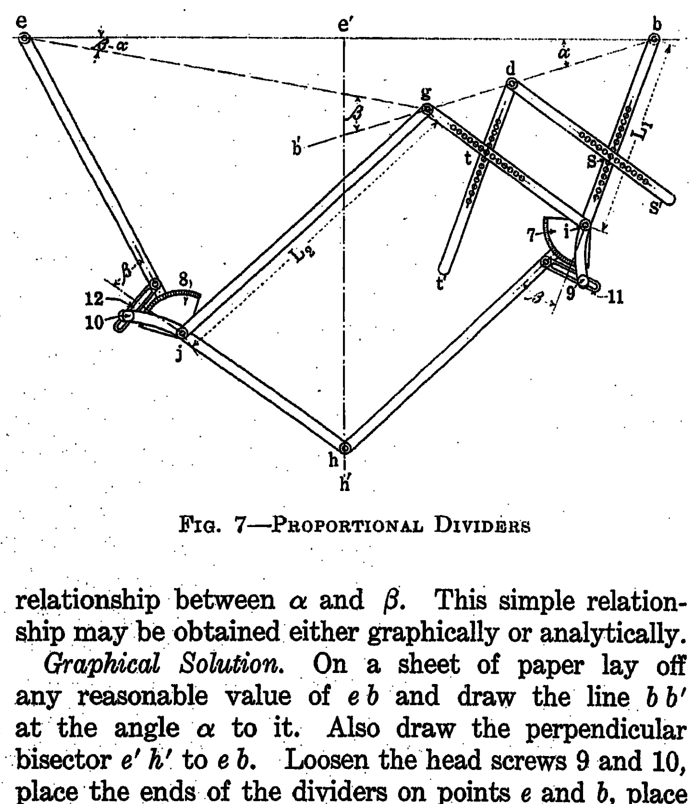

Fig. 7—Proportional Dividers

relationship between α and β. This simple relationship may be obtained either graphically or analytically.

Graphical Solution. On a sheet of paper lay off any reasonable value of $e\,b$ and draw the line $b\,b'$ at the angle α to it. Also draw the perpendicular bisector $e'\,h'$ to $e\,b$. Loosen the head screws 9 and 10, place the ends of the dividers on points e and b, place point h on $e'\,h'$ and point g on $b\,b'$. The readings on

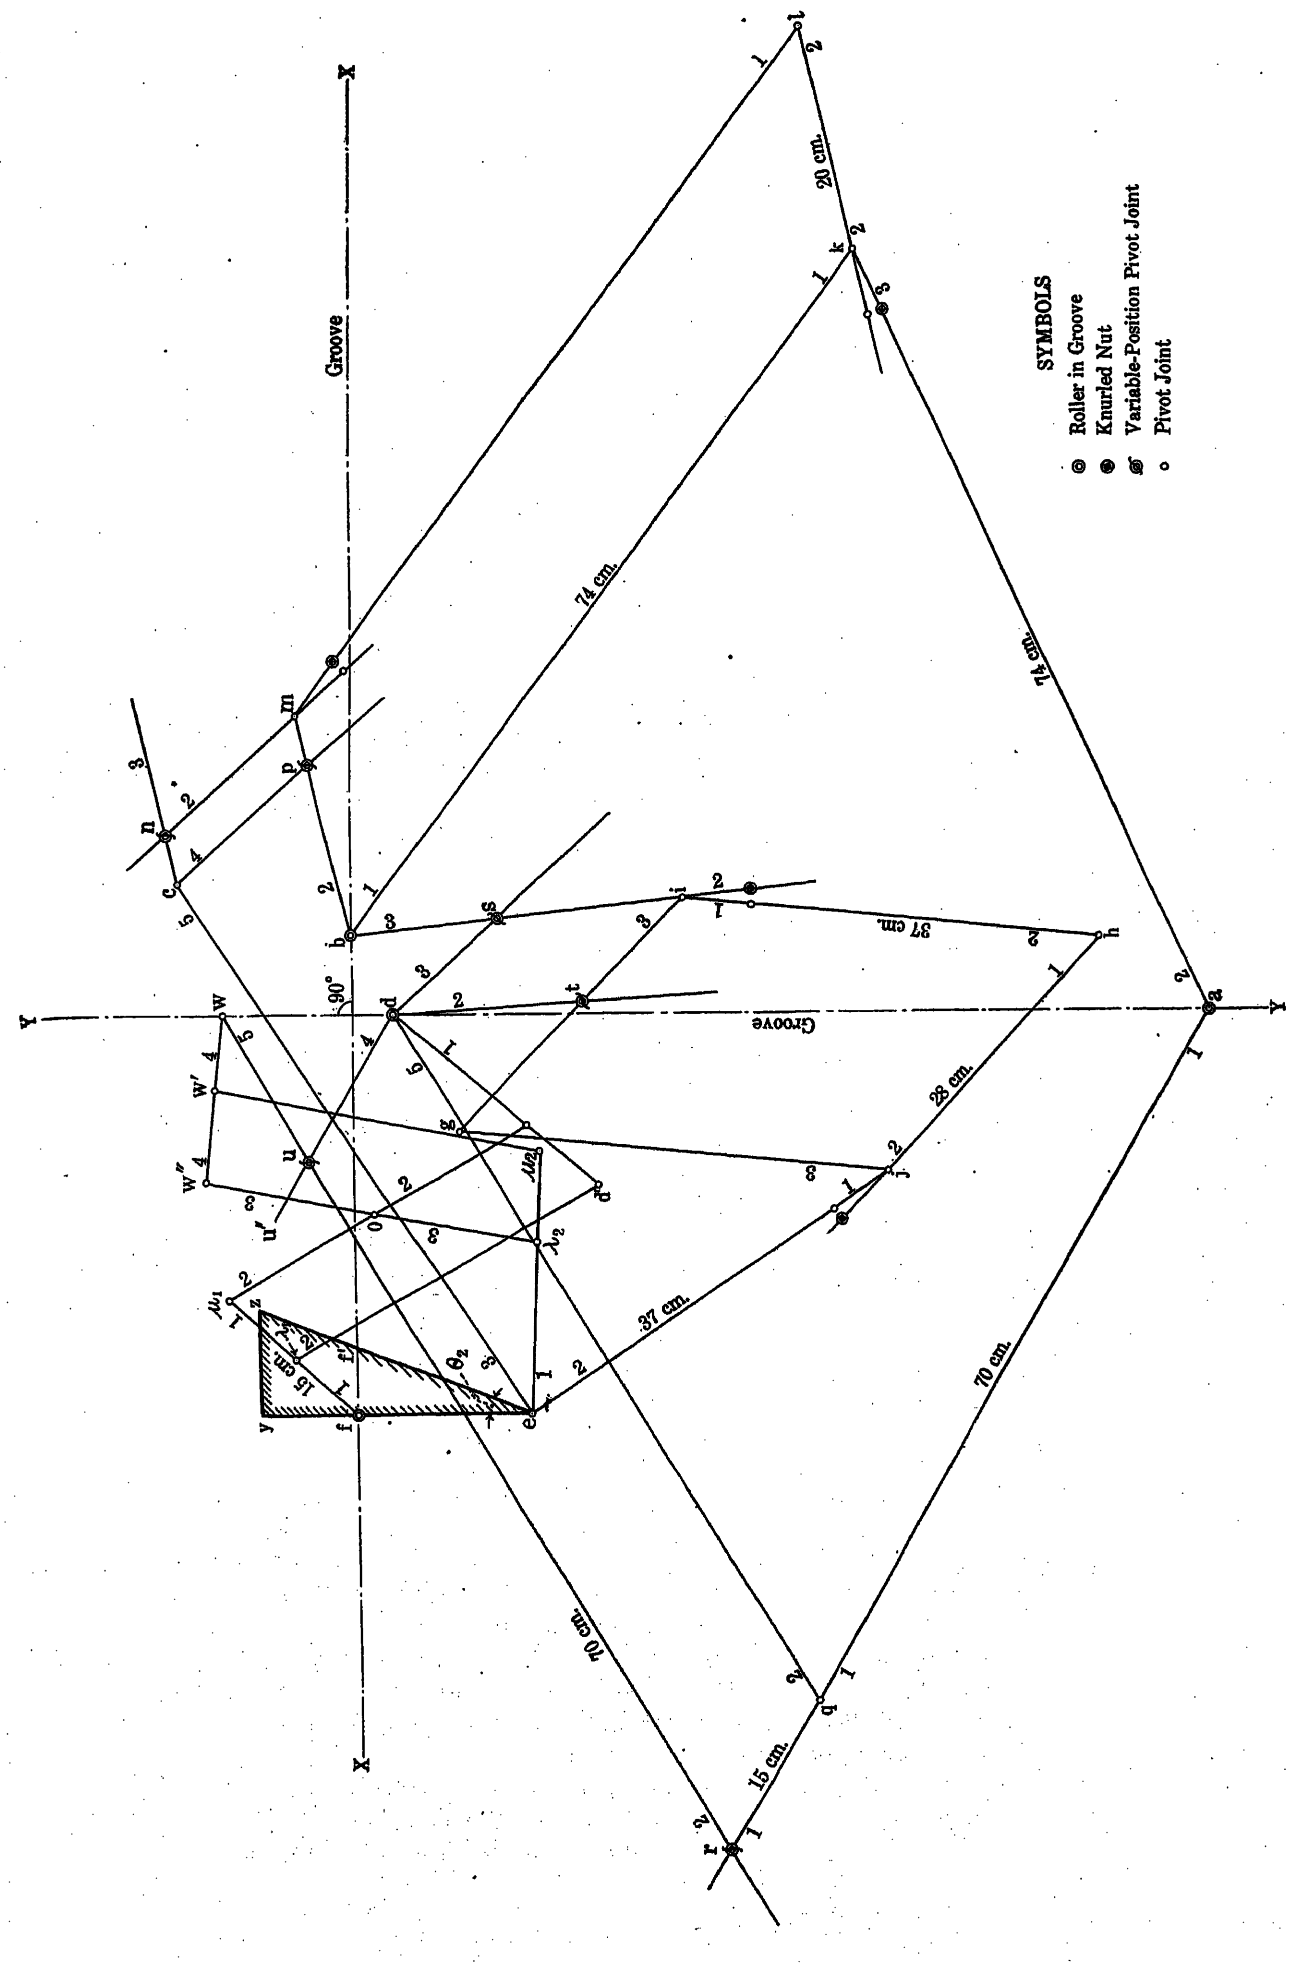

FIG. 8—SINGLE-LINE DIAGRAM OF THE INDUMOR

the two protractors should then be equal and the headscrews should be fastened in this position. As a check, the angle $e\,g\,b'$ should be also equal to β.

Analytical Solution. From the triangle $e\,b\,g$ we have:

$$g\,b/e\,g = \sin(\beta - \alpha)/\sin\alpha \qquad (2)$$

From the similar triangles $e\,g\,j$ and $g\,b\,i$ we have:

$$g\,b/e\,g = L_1/L_2 \qquad (3)$$

Equating the right-hand sides of eqs. (2) and (3), and solving for $\sin(\beta - \alpha)$, we get

$$\sin(\beta - \alpha) = (L_1/L_2)/\sin\alpha \qquad (4)$$

The right-hand side of this equation contains known quantities only, hence the angle $(\beta - \alpha)$ can be found from trigonometric tables and thus β determined. For given dividers, with constant lengths L_1 and L_2, it is convenient to plot once for all a curve of values of β against values of $\tan\alpha$ as abscissas, the values of $\tan\alpha$ being given by eq. (1). It is also possible to mark directly on the protractors values of α opposite the corresponding values of β; then no computations whatever are necessary.

The dimensions of the dividers shown in Fig. 7 are determined by the desired maximum length of the bar $e\,c$ (Fig. 8) which represents the applied voltage E_1. For example, if $e\,c$ is never greater than 120 cm. then the dividers must have a maximum opening between b and e of about the same length, because at no load the voltages E_0 and E_1 are practically equal. The maximum opening $b\,g$ depends upon the largest desired value of magnetizing current. If the maximum length of the vector of primary current at the rated load is to be, say 100 cm., and if the magnetizing current in an extreme case amounts to 40 per cent of that, then the maximum opening $b\,g$ should be about 40 cm. Should the magnetizing current in an unforeseen case amount to over 50 per cent of the full-load current, the scale of primary current for that particular machine may be so chosen that the rated current be equal to say 70 cm. Then a vector of magnetizing current 40 cm. long can be obtained on the dividers, and is over 50 per cent of the rated primary current.

V. Grooves for Keeping the Secondary Current and Secondary Voltage at Right Angles to Each Other

It will be seen in Fig. 4 that the vector of secondary current, I_2, is always perpendicular to the external voltage drop, $I_2\,R$, and to the drop $I_2\,r_2$ in the rotor itself. As the load varies, the magnitudes and the relative positions of the vectors $a\,d$ and $f\,b$ vary, but the vectors remain normal to each other. The author has not succeeded in devising any simple kinematic linkage that would keep two variable vectors at right angles to each other while leaving them otherwise independent of each other. He therefore uses two perpendicular grooves cut in the table or drafting board on which the Indumor is placed. These grooves are marked $X\,X$ and $Y\,Y$ in Fig. 8 and are plainly visible in Fig. 1; their center lines also serve as axes of coordinates.

The points b and f (Figs. 4 and 8) are made to move in the groove $X\;X$, and the points a and d in the groove $Y\,Y$. Each point is guided in the groove by a horizontal roller. The required condition of perpendicularity of the two vectors is thus fulfilled without interfering in any other way with the free motion of the four points.

The advantage of the grooves over a linkage is that they are below the surface of the table, and do not add to already numerous bars which must be spaced in different horizontal planes. The disadvantages of the grooves are (a) the device requires a special table and (b) the rollers sometimes bind in the grooves and the bars have to be moved slowly.

VI. The Slip Triangle

In Figs. 4 and 8 the length $f\,b$ is equal to the sum of $I_2\,r_2$ and $I_2\,R$. In order to compute the slip and the output of the motor, it is necessary to measure separately the length $f\,f' = I_2\,r_2$, because the slip

$$s = f\,f'/f\,b = r_2/(R + r_2) \qquad (5)$$

and the output is

$$P_2 = I_2\,E_2 = a\,d\,.\,f'\,b \qquad (6)$$

A separate triangle, *eyz* (Fig. 8), is cut out of ordinary cross-section paper and is used to measure the length $f\,f'$. The angle θ_2 is such that

$$\tan\theta_2 = r_2/x_2 \qquad (7)$$

This triangle is placed with one of its sides in the direction $e\,f$, as shown in Fig. 8, and the length $f\,f'$ is read off directly.

The length $f\,b$ is measured with a meter scale, and the torque, in synchronous watts, is computed from the equation.

$$T = I_2\,(E_2 + I_2\,r_2) = a\,d\,.\,f\,b \qquad (8)$$

THE USE OF THE INDUMOR

The separate parts of the Indumor are assembled as shown in Figs. 1 and 8; the bar $e\,c$, which represents the constant applied voltage, serves as the closing link. This bar is provided with several holes, so that a voltage scale can be selected which best suits the constants of the motor and the desired region of operation. Actual experience seems to indicate that a long bar $e\,c$ gives better results on light loads and up to the rated current, while shorter lengths are more suitable for representing overload conditions. A selection of the length $e\,c$ determines the voltage scale.

For a three-phase motor, the star or Y voltages and currents can be used, and the results for the input, output and torque later multiplied by three. The line voltage and delta currents can also be used if desired, or the line voltage and the total equivalent single-phase current. In this respect the Indumor can be treated like any vector diagram of a balanced polyphase circuit.

For a motor of given voltage and rating, the limits of primary current between no-load and a reasonable overload can be readily estimated, and a current scale

can be selected that will permit a free motion of the links within the range of the device.

Knowing the primary resistance and reactance of the machine, the primary proportional dividers (Fig. 5) are set by adjusting the two protractors and the links $c\,n'$ and $c\,p'$, as explained above. Knowing the rotor reactance, the secondary proportional dividers are set accordingly. The slip triangle $e\,y\,z$ is cut out to correspond to the given or assumed rotor resistance.

If the total leakage reactance has been computed from a short-circuit test, the parts to be assigned to x_1 and to x_2 cannot be ascertained, and in ordinary cases the total reactance is divided about equally between the primary and the secondary circuit. To the writer's best knowledge, there is no way of separating the two reactances from the no-load and short-circuit tests alone. The separation can be done if in addition a set of readings is given at some load, preferably at a considerable slip. For a motor which is being newly laid out, the two reactances can be separately estimated by the designer.

From the no-load readings of the machine the proportional dividers shown in Fig. 7 can be set for the proper angle α, as is explained above. It is more nearly correct to allow in the angle α only for the primary core loss, and to subtract the friction and windage losses from the total output computed from eq. (6). The magnetizing current at no-load is known, and E_0 is practically equal to E_1. Therefore, by opening the dividers (Fig. 7) to the length of the applied voltage, the position of point d can be ascertained.

The device has now been completely adjusted for a motor of given constants, and can be set for any desired current or slip by moving the knob, a in the slot $Y\,Y$. At any position of the knob, all or some of the following readings can be taken, depending upon the purpose in view:

*Primary current, $a\,b$.

Primary impedance drop, $b\,c$.

Voltage E_0 corresponding to the air-gap flux, $e\,b$.

*Secondary current, $a\,d$.

Secondary reactive drop, $e\,f$.

*Secondary ohmic drop, $f\,f'$.

Secondary impedance drop, $e\,f'$.

Exciting current, $d\,b$.

Magnetizing component of the exciting current, projection of $d\,b$ on $e\,b$.

Core loss component of the exciting current, distance of d from $e\,b$.

*The energy component of the secondary voltage, $f\,b$.

*Angle between I_1 and E_1.

Projections of E_1 on $X\,X$ and $Y\,Y$.

Projections of I_1 on $X\,X$ and $Y\,Y$.

Any other angles between vectors that may be of interest.

For obtaining the usual performance characteristics of the machine, only the quantities marked with an * need be measured. From these quantities the following results can be computed:

Volt-ampere input
Power input
Primary power factor
Slip, eq. (5)
Secondary output, eq. (6)
Torque, eq. (8)
Separate losses
Efficiency.

If the angle α (Fig. 7) has been set to account only for the core loss, then the expressions for the output and the torque include the friction and windage which must be subtracted if net values aredesired.

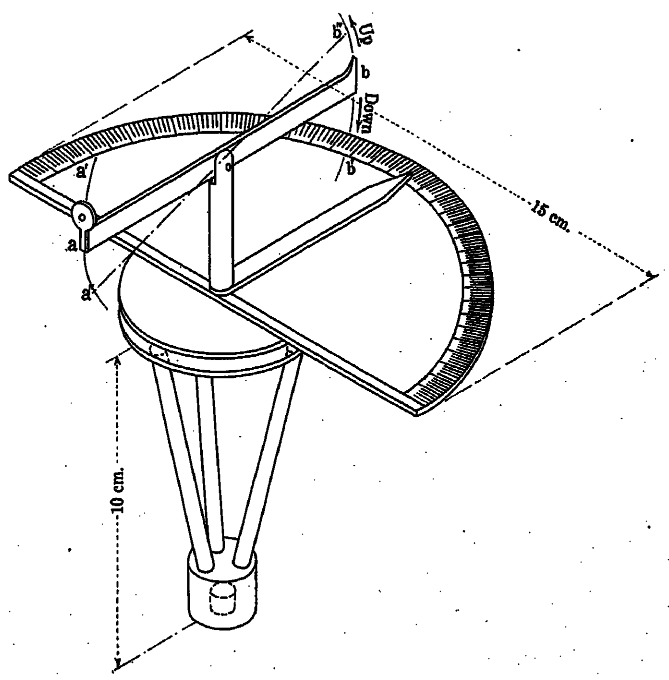

Fig. 9—Sighting Goniometer

The phase angle between E_1 and I_1 may be measured directly with the sighting goniometer shown in Fig. 9; or else a protractor may be used for determining the angles which each of these vectors forms with one of the axes of coordinates. The phase angle may also be computed from the measured projections of I_1 and E_1 upon the axes $X\,X$ and $Y\,Y$. In any case it must be borne in mind that in the Indumor the angle between these two vectors is complementary to the actual phase angle (compare Figs. 3 and 4).

In order to compute the phase angle from the projections of the vectors it is necessary to assume some positive directions of the axes. Let, for example, in Figs. 4 and 8 the X-direction be positive to the reader's right and the Y-direction be positive upward. Let the projections of the current vector, I_1, on these two axes be i and i' respectively, and those of E_1, *in its true position* (Fig. 3), be e and e'. Let the *actually measured projections* of the E_1 bar in the Indumor be

E_x and E_y. We then have, by advancing E_1 by 90 degrees,

$$\left.\begin{aligned} e &= -E_y \\ e' &= E_x \end{aligned}\right\} \tag{9}$$

The phase angle ϕ_1 is computed from the familiar formula

$$\tan \phi_1 = \frac{(e'/e) - (i'/i)}{1 + (e'/e)\,(i'/i)} \tag{10}$$

See for example the author's "Electric Circuit," p. 91, eq. (144). The positive and negative signs of the projections must be carefully observed.

The power input can be computed either from the expression $E_1 I_1 \cos \phi_1$, or from the same projections of the vectors, using the formula

$$P_1 = e\,i + e'\,i' \tag{11}$$

(*ibid.*, eq. 143).

Indumor in the Generator Range

The operation of an induction motor as a generator may be characterized in the equivalent diagram (Fig. 2) by the phase reversal of the secondary current I_2. Therefore, a continuous transition from motor to generator would be possible in the Indumor if the knob a (Fig. 8) could be pushed upward beyond the groove $X\,X$. The proportional dividers would not allow such a motion, and therefore the generator range has to be obtained with a below the $X\,X$ line. This is done by simply considering the actual Indumor as an image of a fictitious one, $X\,X$ being the reflection line taken as a plane mirror.

Let, in Fig. 4, a point, say a', be selected on the $Y\,Y$ axis above the $X\,X$ axis, and let a complete vector diagram of currents and voltages be drawn, following exactly the method used for the point a below the $X\,X$ axis. The new diagram will give an operating condition of the machine working as a generator. Let now an image of the new diagram be drawn below the $X\,X$ axis, as if this axis were a plane mirror. Comparing this image diagram with one actually shown in Fig. 4 for the motor range, it will be found that the two differ from each other only in the direction of the vectors of primary and secondary ohmic drop, $I_1 r_1$ and $I_2 r_2$. *The vectors of ohmic drop in the generator "image" diagram are drawn in the opposite directions from those in the motor diagram.*

This relationship gives a simple method of using the Indumor for the generator range. It is only necessary to set the two protractors in Fig. 5 for a negative angle θ_1, and to turn the triangle $e\,y\,z$ (Fig. 8) about $e\,y$ so as to get a point f' to the left of f; this will give a negative slip.

A watch placed horizontally in front of a vertical mirror seems to run counter-clockwise when observed in the mirror. Similarly, a counter-clockwise vector diagram of the generator, when reversed into its image, becomes a clockwise diagram. This fact must be kept in mind in the interpretation of the results when operating the Indumor as an image of the real diagram.

Improvement of Power Factor and Speed Control

In Fig. 2, to the right, a separate sketch (a) shows the equivalent secondary circuit of an induction motor to which an external alternating e. m. f., E_3, has been added. It is well known that the magnitude and the phase angle of this external e. m. f. may be so chosen as either to change the speed of the motor or to improve its power factor, or both. This usually requires either an additional commutator machine or a conversion of the induction motor itself into a polyphase commutator motor.

Fig. 10 shows a corresponding adaptation of the Indumor to a polyphase machine in which an external e. m. f., E_3, has been added to the secondary circuit. The lettering is the same as on the left-hand side of Fig. 8.

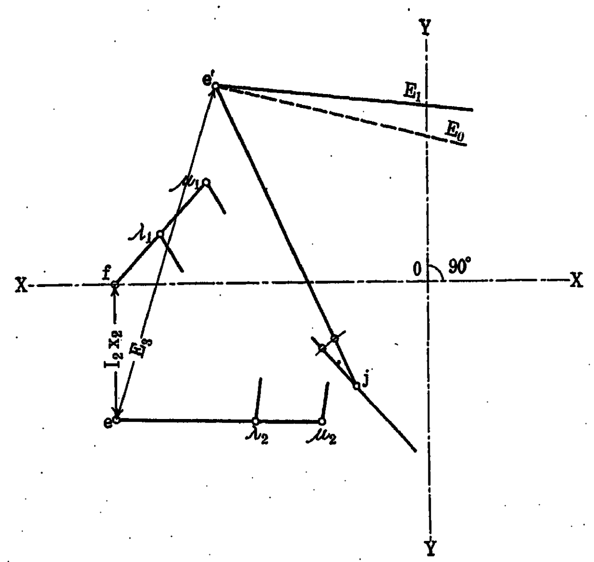

Fig. 10

The added e. m. f., E_3, is represented by the vector ee'. The extremity of the vector E_1 and of the proportional dividers for E_0 are transferred from e to e'. Otherwise the device remains the same. Electrically this means that the voltage E_0 is now balanced by the geometric sum of $I_2\,(R + r_2)$, $I_2\,x_2$, and E_3.

In Fig. 8 the primary current, I_1, lags by a considerable angle behind E_1, when the latter is turned by 90 deg. forward into its real position. In Fig. 10 the bar E_1 has been turned back sufficiently to bring the true vector E_1 almost into phase coincidence with I_1, thus raising the power factor of the machine almost to unity. By taking E_3 in the direction of the $X\,X$ axis the speed of the induction machine may be varied economically within wide limits.

The additional linkage $e\,e'$ has to be connected to the rest of the device in accordance with the nature of the external e. m. f. E_3. For example, if this e. m. f. is constant in magnitude and forms a constant phase angle with E_1, then $e\,e'$ is simply another bar rigidly connected at a certain angle to the bar E_1. This is the case in a shunt-excited polyphase commutator

motor, E_1 being the voltage applied to the stator and E_3 that applied to the armature brushes. We thus obtain a new kinematic device which may be called the *Shucomor* (an abbreviation of the words "shunt commutator motor").

When a series-wound polyphase commutator motor is connected in series with the rotor windings of an induction motor, as is sometimes the case, the e. m. f., E_3, of this motor is proportional to the secondary current I_2 and the phase angle between the vectors E_3 and I_2 is constant. In this case E_3 can be represented on the Indumor in the same manner as $I_2 x_2$ or $I_1 z_1$. The secondary proportional dividers must be provided with two protractors, like the primary dividers, and $I_2 x_2$ and E_3 combined into one vector whose length is determined by the opening of the dividers which give I_2.

The author hopes to report later more in detail upon these additional possibilities of the Indumor in the study of polyphase commutator motors. As a matter of fact, he started to develop a "Shucomor," and the Indumor came out as a first attempt in this direction.

An interesting computing device has been described by Prof. R. G. Warner in an article entitled "Induction Motor Nomogram," in the A. I. E. E. JOURNAL for October 1921 (Vol. 40, p. 808). The device is based on the simple circle diagram and gives directly the numerical data for performance characteristics of three-phase 60-cycle induction motors. It is hoped that engineers interested in induction motor characteristics will investigate the relative advantages and disadvantages of the Nomogram and the Indumor, and will find out by actual experience the particular field of usefulness of each.

The development of the Indumor has been made possible through the generosity of Mr. August Heckscher of New York City, who gave to Cornell University a special fund the income from which is used for the promotion of research. To him the author's sincere gratitude is due. The device has been in a preliminary stage of development for some years previous to the grants from the Heckscher Foundation, and several of the author's students as well as the mechanicians of the College of Engineering have contributed generously of their ideas. The author wishes to express his appreciation to them all.

Discussion

Lawrence E. Widmark: We have lately been presented with two mechanical devices to replace the Behrend-Heyland Circle Diagram, one from Cornell University and the other one from Yale, and I would like to say a few words in defence of the old diagram.

We all know that the chief trouble with this diagram has been that where high precision is most desired the lowest one is obtained, depending on "that little lower left hand corner," you know, where the characteristics of the ordinary running conditions are to be found. Now, seeing the Yale device this thought suggested itself: "Have we to go to all that trouble to overcome these difficulties?" Well, at the Star Electric Motor Co. we have had in successful operation an arrangement of the diagram which I think meets requirements.

As a matter of fact, the Behrend-Heyland diagram employs a circle of *varying size* for every separate case which circle is fitted into a *fixed* coordinate system. We have reversed this procedure and are using a *fixed circle* and a *variable coordinate system*, varying with the impedance. This arrangement makes possible the "standardized diagram sheet" which I am showing here. The purpose of the larger circle is to give an enlarged view of the ordinary load conditions and the smaller one to get the maximum load and torque values in a scale just sufficient to give the desired information.

As an extra advantage of this diagram I have found interesting possibilities in respect to motor design in general which I think measure up to those promised by Prof. Karapetoff's machine. Besides this, the new diagram facilitates corrections for primary drop and saturation.

Prof. Karapetoff in his device also is able to take care of the primary drop. Neglecting saturation is, however, more questionable as I think that most of us motor designers would in a short time be out of business if we did not pay due respect to this condition.

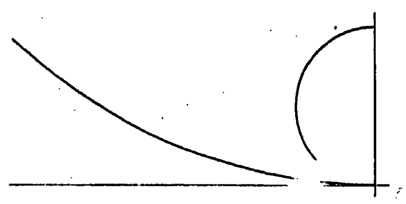

FIG. 1

H. M. Hobart: I do not think that the time-saving element in Prof. Karapetoff's device is its principal advantage. I believe that its use should lead to obtaining better designs. Many years ago designers felt that they had reached the ultimate best design, or had come pretty near to it. But succeeding years have always brought forth cheaper or better designs; usually designs which were *both* cheaper and better. This process continues, and the limit does not appear to be in sight. I believe that the progress toward the limit is slow largely because of the labor of preparing and comparing enough alternative designs to clear our minds on the subject. One who is designing an induction motor, for a certain rating works through half a dozen designs for comparison. By that time he has expended so much time and labor that he is tempted to conclude that the best design he has been enabled to arrive at by that amount of calculating must be about the right one to build. But by these new methods of Prof. Karapetoff, you can go far more extensively into the subject. You can study a much greater range of combinations and you can introduce a great many modifications and much more clearly guide your mind than when you are all tired out through laborious step by step calculations. You can much more intelligently take into account the relative influences of the many variables and limitations that are involved.

It is for these reasons that I have not the least doubt that with the introduction of these mechanical methods, the chief advantage will not be the saving in labor, but the more rapid evolution toward both cheaper and better designs. I see in the room an engineer who some six or more years ago showed me some mechanical machinery he was getting up for designing transformers, and I, at that time, was exceedingly enthusiastic for this very same reason, namely, not so much that it would save a great deal of time in calculations, but that it would lead more quickly to better and cheaper designs for a given rating. That engineer found that he did not have time enough to give to this,

as it was a sort of side interest with him, but he had already at that time carried his machine to an encouraging stage of completion. I see another engineer here who, together with his colleagues has done a great amount of such work, in connection with electro-mechanical methods of calculating transmission lines.

I mention this as suggesting, perhaps, that we are at the beginning of an era of solving many complicated problems by mechanical methods, and I want again to emphasize that the most important object in these methods, in my opinion,—although it is important to save time,—is the obtaining of much better results, better economics and better characteristics of the machines.

P. Trombetta: I recognize with great respect Professor Karapetoff's very ingenious device. Unfortunately, however, it is not as easy as it might seem to change one constant of a motor without changing all the rest and this is due to the fact that the distribution of magnetism can not be restricted to any given circuit in a similar way that we can restrict the flow of electricity, and to the additional fact that the permeability of iron is not constant. Therefore, when Prof. Karapetoff states that if he wishes to change the characteristics of a motor, all that is necessary is to change the length of the particular lever which represents that particular constant which we wish to alter, he forgets the fact that by varying that constant all the rest of the constants are automatically changed. For instance, suppose it is desired to change the internal resistance of a motor, it is found that both the dimensions and configuration of the tooth and slot are altered with the resistance, which alterations give rise to changes in leakage reactance, magnetizing current, power factor, heating and so on, which may in turn make it necessary to vary the pole pitch, the diameter, the axial length of the cores and the new characteristics obtained by the indumor would therefore be meaningless.

On the other hand, in case of the calculations of line constants, in which the magnetism around the line conductor flows only through air, the permeability of which is constant, this apparatus may prove to be of great value.

V. Karapetoff: Mr. Widmark has apparently developed an improvement in the circle diagram, and I am the first one to welcome it, because I fully appreciate the wonderful usefulness of the circle diagram. I am offering a new computing device, not to supplant anything that exists, but merely something that might in some cases be also useful.

In connection with the circle diagram, I want to say that recently we have done at Cornell University something that may also add a new lease of life to this useful method, the circle diagram; namely, we have found an easy method of determining additional points on the circle diagram. In a large motor, the center of the circle lies at the same height above the axis of abscissas as the no-load loss line, but in the case of a machine with an excessive primary loss, the center of the circle lies in a different position. For such machines it is desirable to determine experimentally a third point on the circle, in addition to the no-load and the short-circuit points. We have found that it is very easy to determine the point of maximum power factor. We connect a power-factor meter in the motor circuit, and let the motor run up to speed at no-load, or else we load it until it stops. An observer follows the pointer of the power-factor meter, with a pencil, and when the pointer commences to go in the opposite direction, he leaves the pencil at that point. This gives him the maximum power factor, and a tangent to the circle. Therefore the circle can be drawn much more definitely.

I am glad that Mr. Widmark brought up the question of saturation. We have been lately working on a similar device (named the Blondelion) to imitate the performance of the synchronous machine, both the generator and the motor. In a synchronous machine it is, of course, necessary to have the saturation in the magnetic circuit properly taken into account. I am happy to say that we have solved this problem, completely so that almost any saturation curve can be imitated with that device. For highly saturated induction machines this additional linkage may be incorporated in the Indumor.

Now as to whether or not transmission lines could be treated in the same way: We have a device practically completed which imitates perfectly the performance of a long transmission line with distributed constants. We have named this device the Heavisider, after our honorary member, Oliver Heaviside. The problem is not as difficult as it may seem, and it is possible to represent kinematically the regular performance of a long transmission line without complex quantities or hyperbolic functions. The problem that interests me now is to develop a device which would represent transient phenomena on a transmission line, and not established conditions.

In conclusion I wish to point out the existence of certain useful analogies in different branches of natural science, analogies which help in the solution of certain problems. For example, take a direct-current network with known resistances and voltages, and with unknown currents. To determine the unknown currents, we have to write down and to solve a system of linear algebraic equations. Now reverse the problem,—let in a problem (which may not be an engineering problem at all, agriculture, finance, or what not) a system of simultaneous equations be given. You can connect an electrical network in which the constants of the problem will be represented by given resistances and e. m. fs., then you can insert an ammeter in each branch and read the currents. You have thus solved electrically a problem which has nothing to do with electricity.

The other day a client wanted me to solve for him a problem in mechanical oscillations. I looked at the differential equations and I saw at once that an electrical system could be built which would be expressed by similar equations. I told him that we could build for him an electric system, insert a galvanometer, follow the oscillations of the galvanometer needle, and that such a device would give him the desired information about the mode of oscillation of his entirely different mechanical system.

Skin Effect and Proximity Effect in Tubular Conductors

BY HERBERT BRISTOL DWIGHT
Member, A. I. E. E.
Canadian Westinghouse Company, Ltd., Hamilton, Ont.

The effective a-c. resistance of tubular conductors is required to be predetermined by designers, for radio installations, for large underground cables with non-magnetic cores, and for electric furnace circuits. (See Examples I to IV).

For the above purpose, sets of curves are given in this paper. The skin effect ratio for isolated tubes is shown in Fig. 1. For stranded conductors, the resistance must be multiplied also by a ratio for the spirality effect, as is approximately indicated in Fig. 2. When the return conductor is near, a ratio for the proximity effect, as indicated in Fig. 3, is also to be used. A calculation for the proximity effect ratio for thin tubes is made, and the results are compared with tests in Fig. 3.

Some of the requirements for future research work on skin effect are discussed.

The conclusion is expressed that it seems scarcely worth while providing a non-magnetic core with a 2,000,000 cir. mil, 25-cycle cable in order to reduce the skin effect, but with the other cases considered, the tubular form seems very advantageous.

THE effective resistance of tubular conductors to alternating current is desirable to know in at least three classes of work in electrical engineering: Namely in radio work, where small currents are to be carried at high frequencies; in the design of large 60-cycle single-conductor underground cables with non-magnetic cores; and in the design of electric furnace circuits where currents of the order of 30,000 or 50,000 amperes at 25 and 60 cycles are to be carried. In all of these cases, tubular conductors of convenient shape may be designed, whose effective a-c. resistance will be not much greater than their d-c. resistance, while, if the tubular form were not adopted, the a-c. resistance would be from 30 to 200 per cent, or more, greater than the d-c. resistance. The large saving of copper by this device is obvious. However, the saving does not seem worth while for 2,000,000-cir. mil, 25-cycle cables.

In this paper, curves are given by which one can estimate the a-c. resistance of tubular conductors of various kinds. The skin effect ratio for isolated tubes is shown in Fig. 1. For stranded conductors, the resistance must be multiplied by an additional ratio for the spirality effect, as is approximately indicated in Fig. 2. When the return conductor is near, a ratio for the proximity effect as indicated in Fig. 3, is also to be used. A calculation for the proximity effect in thin tubes is given, and the results are compared with tests.

It is noteworthy that the curves and formulas given in this paper are not based directly on the frequency, size of conductor or specific resistance, but only on the ratio of f to R_{dc} where f is the frequency and R_{dc} is the d-c. resistance in ohms per 1000 feet of the complete conductor. Thus, skin effect ratios measured at 100,000 cycles are applicable to large 60-cycle conductors when their proportionate shape is the same, and the proportionate shape and position of the return conductors are the same. This principle was stated by the writer in a previous A. I. E. E. paper,[1] and a mathematical proof of it was given by J. Slepian in a discussion of the same paper[1] on page 1401.

The principle may be stated as follows: A conductor, or a combination of conductors, of a certain proportionate shape and a certain value of $\frac{f}{R_{dc}}$ will have a definite value of $\frac{R_{ac}}{R_{dc}}$. This is true of isolated conductors and single-phase and polyphase circuits.

If this principle of similitude is adopted by those making skin effect tests, they will plot their test results on a base of $\frac{f}{R_{dc}}$ or $\sqrt{\frac{f}{R_{dc}}}$ instead of on a base of f as has been usually done. If the principle is adopted by designers who require to know skin effect values, they will make use of tests made on any size of conductors and at any frequency, and will correct them mathematically according to the principle of similitude, having confidence that the results so obtained will apply to their particular case.

For the particular case of proximity effect in two tubular conductors forming a return circuit (See Fig. 3) the resistance ratio depends on the ratios $\frac{f}{R_{dc}}$, $\frac{t}{d}$ and $\frac{s}{d}$. When these ratios have been determined, the proximity effect ratio is fixed.

The principle is in agreement with the various calculated formulas for skin effect and proximity effect whether for wires, tubes or straps and whether isolated or in close proximity. In fact, the principle seems almost obvious to one calculating a skin effect formula, for the first step is often to calculate the voltage drop due to resistance and reactance at any point of the cross-section of the conductor. On equating

Presented at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

1 "Skin Effect in Tubular and Flat Conductors," by H. B. Dwight, TRANS. A. I. E. E., 1918, page 1398.

this to a constant, one finds that the distribution of current over the cross-section of the conductor depends on the ratio f/R_{dc}. This is the basis of Mr. Slepian's general mathematical proof referred to above.

The writer has not seen any reliable test results of skin effect which tend to throw doubt on the above principle. In all tests published, the skin effect of

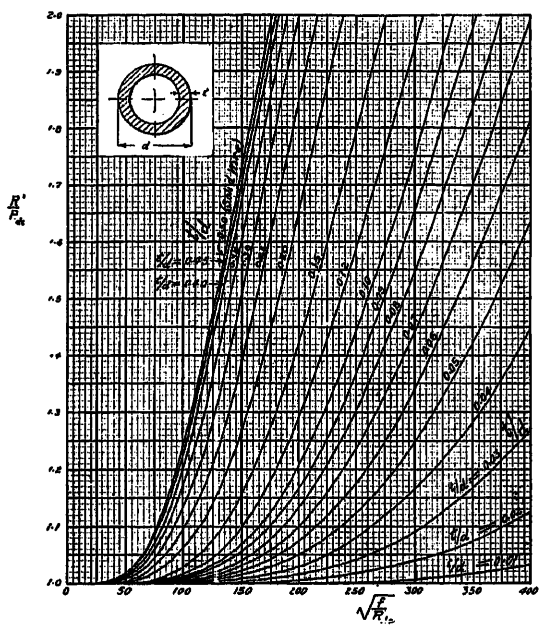

FIG. 1—SKIN EFFECT IN ISOLATED TUBES AND WIRES
R_{dc} in ohms per 1000 feet.

round, non-magnetic isolated wires has been found to agree with the standard Bessel function formula within the limits of the errors of observation. Most experimenters have first checked up the accuracy of their measuring apparatus by making this standard test, and this seems a logical and even necessary thing to do, for skin effect ratios are admittedly difficult to measure precisely. The measurements which, judged by this standard test, appear to be made the most accurately, show the closest agreement with the principle stated above. This applies also to the effect of the spirality of stranded conductors, which is, of course, only one feature of the shape of the conductors. It may be stated that the published tests made at 60 cycles do not show the same evidence of good accuracy as tests made at higher frequencies.

The curves of Fig. 1 show the skin effect in isolated tubes and wires. The skin effect in wires is well-known and a very complete and accurate table has been published by the Bureau of Standards.[2] The curves for skin effect in tubes are based on those published by the writer (see Dwight, loc. cit., Fig. 3). The curves for wires and tubes given in the present paper are plotted on $\sqrt{f/R_{dc}}$ which makes them much more useful for practical purposes. This method of plotting makes the curves independent of specific conductivity and temperature. The specific conductivity is difficult to measure precisely, as it depends on the small dimensions of the cross-section. On the other hand, the value of R_{dc}, the d-c. resistance per 1000 feet, is easy to measure precisely. The d-c. resistance of the conductor must be measured in every case in order to measure the ratio R'/R. The length of conductor whose resistance is taken is easily measured as it is several meters. This length and the d-c. resistance should always be stated when publishing skin effect tests. Thus, by plotting the curves on $\sqrt{f/R_{dc}}$, they are made of almost universal application, being applicable to copper or aluminum, high or low conductivity, high or low temperature, high or low frequency, large or small conductors and, except for spirality effect, solid or stranded conductors.

The curves are plotted on $\sqrt{f/R_{dc}}$ instead of f/R_{dc} because this makes the curves of Fig. 1 approach straight lines as asymptotes. This is indicated by the following formula, which is based on that derived by the writer, loc. cit., page 1403.

$$R'/R = \sqrt{f/R_{abs}}\sqrt{\frac{\pi\, t\,(q+r)}{r^2}}\left[1 + \frac{1}{m\, r\sqrt{2}} + \frac{3}{8\, m^2 r^2} + \frac{0}{m^3 r^3} + \ldots\right] \qquad (1)$$

where
$$m\, r = \sqrt{f/R_{abs}}\sqrt{\frac{8\,\pi\, r^2}{t\,(q+r)}} \qquad (2)$$

where q is the inside radius of the tube, r is the outside radius and t is the thickness (See Dwight, loc. cit., page 1403) and where R_{abs} is the d-c. resistance of one cm.

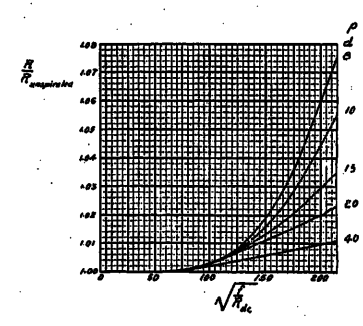

FIG. 2—SPIRALITY EFFECT RATIO IN SEVEN-WIRE CABLES
p = pitch of spirals.
d = diameter of cable.
R_{dc} in ohms per 1000 feet.

of the conductor in absohms. Note that $R_{abs} = 32{,}800 \times R_{dc}$ in ohms per 1000 feet. Equation (1) is applicable for large values of $\sqrt{f/R_{dc}}$ and it may be used to give approximate values of R'/R for parts of the curves beyond the range of Fig. 1. While Fig. 1 has been drawn up to cover as broad a range as possible, yet there are cases in which the value of t/d is extremely small, where it may be more convenient to use the curves of the writer's previous paper, loc. cit., Fig. 3.

2. Scientific Paper No. 169 of the Bureau of Standards, by E. B. Rosa and F. W. Grover, page 226.

Spirality Effect

As previously mentioned, the stranding of a conductor and the spiraling of the strands are features of the shape of the conductors. Therefore, a curve plotted on $\sqrt{f/R_{dc}}$ will show the effect of stranding and spiraling for a certain proportionate shape. Accurate tests have been published for seven-wire cables with both long and short pitch of spiraling[3] and the results are shown in Fig. 2. A test on a larger seven-wire cable made up to 5000 cycles[4] shows similar results. It is seen that even when the spiraling has a very short proportionate pitch, as in the case of the curve $p/d = 8$, only a small per cent is added to the a-c. resistance of an unspiraled or solid conductor of the same cross-section, for the range covered by the tests.

It has been shown by very accurate measurements (Kennelly and Affel, loc. cit., Fig. 10 and page 536) that the mere fact of dividing a conductor into parallel unspiraled strands touching one another does not increase the a-c. resistance appreciably. The increases shown in Fig. 2 are evidently due to the angle of spiraling and are

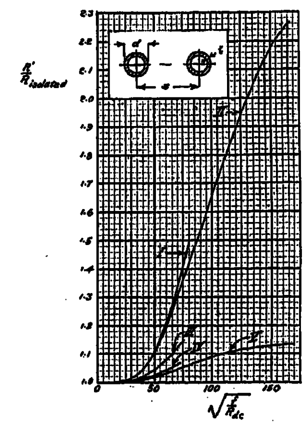

Fig. 3—Proximity Effect Ratio in Tubes
R_{dc} in ohms per 1000 feet.
I. $s/d = 1.0$, $t/d = 0$ (calculation).
II. $s/d = 1.008$, $t/d = 0.125$ (test).
III. $s/d = 1.5$, $t/d = 0$ (calculation).
IV. $s/d = 2.0$, $t/d = 0$ (calculation).
V. $s/d = 2.03$, $t/d = 0.125$ (test).

approximately inversely proportional to the pitch of the spiral. From the above it appears that Fig. 2 can be used to some extent at least for approximate results with cables of more than seven wires, and with stranded conductors with non-magnetic cores, that is, with stranded, tubular conductors.

The increase due to spirality is only a small fraction of the usual increase due to skin effect in a solid conductor, and it is, therefore, even more difficult to measure with precision. When tests at 500 cycles show a ratio due to skin effect plus spirality effect of 1.07 to 1.1 for a seven-wire cable of 0.0457 ohm per 1000 ft.,[5] and when it is known that this cable, if unspiraled, would have a calculated skin effect ratio of 1.284, the low test value can be ascribed only to an

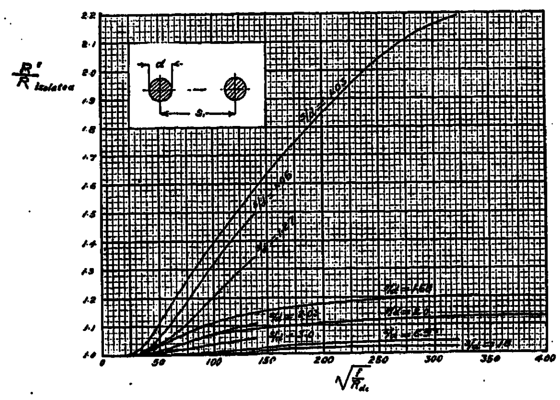

Fig. 4—Proximity Effect Ratio in Wires
R_{dc} in ohms per 1000 feet.

error in measurement. The possibility that there are errors in measurement in the low-frequency tests referred to is also indicated by the fact that measurements of the same a-c. resistance sometimes differ by as much as 8 per cent (See Table IX, Middleton and Davis, loc. cit., The conclusion stated by the authors that a seven-wire cable has much less skin effect than a cable of the same size in circular mils but with a larger number of smaller wires, and, in general, that copper cables with coarse strands have less skin effect than cables with fine strands, is quite untrustworthy. It is a generalization from a single test, and that test result is in direct contradiction to the proved accurate results of references 3 and 4.

Proximity Effect

When conductors are comparatively close together, there is an increase in their a-c. resistance caused by

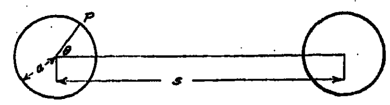

Fig. 5—Cross-Section of Return Circuit of Thin Tubes

the distortion of current due to their proximity. The proximity effect ratio may be defined as the ratio of the a-c. resistance when the conductors are near each other, to their a-c. resistance when they are isolated. So far as the writer is aware, only two or three tests have been published which show the proximity effect in tubular conductors. In the following paragraphs, mathematical formulas are developed for the proximity effect ratio of two extremely thin tubes forming a return circuit. The calculated results are plotted in Fig. 3, together with test results. The curves in Fig. 4, which are somewhat similar, show the proximity effect ratio in wires. From the above data, an approxi-

3. A. E. Kennelly and H. A. Affel, *Proceedings* of the Institute of Radio Engineers, May, 1916. Fig. 17.

4. A. E. Kennelly, F. A. Laws and P. H. Pierce, Transactions A. I. E. E., 1915, page 1970, Table VI.

5. W. I. Middleton and E. W. Davis, Journal of the A. I. E. E., Sept., 1921, page 760, Table VII.

mate estimate can be made of the proximity effect ratio in tubular conductors in a given case.

As in the calculation of the formulas developed by the writer for skin effect in tubes and thin straps (Dwight, loc. cit., pages 1380 and 1392), a uniform current density over the section will first be assumed, and then successive increments of voltage drop and current will be calculated to agree with the actual condition that the voltage drop is uniform over the section.

The calculation applies to the case in which the ratio of the thickness of the tube to its diameter is very small. In such a case, the change in current density from the inner surface to the outer surface is inappreciable compared with the changes in current density in different parts of the tube, due to the proximity of the return conductor.

The reactive drop at the point P, Fig. 5, due to a uniform current density b_0 absamperes per sq. cm. in both tubes, is equal to

$$\omega\, 4\,\pi\, b_0\, a t \left[\text{logh}\ \frac{s}{a} - \left\{ \frac{a}{s}\cos\theta + \frac{a^2}{2\,s^2}\cos 2\,\theta + \frac{a^3}{3\,s^3}\cos 3\,\theta + \ldots \right\} \right]$$

abvolts per cm. (3)

where $\omega = 2\,\pi\, f$ (4)

f = frequency in cycles per second (5)

and t = thickness of the tube. (6)

The reactive drop at P due to a current density $c_n \cos n\,\theta$ absamperes per sq. cm. in both tubes is

$$j\, l^2\, c_n\, \rho \left[\frac{\cos n\,\theta}{n} - \frac{a^n}{n\, s^n} \left\{ 1 + \frac{n}{\underline{/1}}\, \frac{a}{s}\cos\theta + \frac{n\,(n+1)}{\underline{/2}}\, \frac{a^2}{s^2}\cos 2\,\theta + \frac{n\,(n+1)\,(n+2)}{\underline{/3}}\, \frac{a^3}{s^3}\cos 3\,\theta + \ldots \right\} \right]$$

abvolts per cm. (7)

where n is not equal to zero, ρ is the specific resistivity of the conductor material in absohms per cm.³, (8)

and
$$l^2 = \frac{\omega\, 2\,\pi\, a\, t}{\rho} = \frac{2\,\pi\, f}{R} \qquad (9)$$

R being in absohms per cm. The angle θ is measured from the line joining the centers of the tubes.

Expressions (3) and (7) are derived in a manner similar to that used by H. L. Curtis[6] in calculating the proximity effect between wires for values of $\sqrt{f/R_{dc}}$ up to 140 (R_{dc} in ohms per 1000 ft.)

Assume that a current of uniform density, b_0 absamperes per sq. cm., flows in the tubes. The reactive drop at any angle θ is given by (3), and the total current is $2\,\pi\, a\, t\, b_0$ absamperes. Now assume a current of density b_1 whose resistance drop is equal and opposite to the terms in θ of (3). The reactive drop at any angle θ due to b_1 is obtained by applying equation (7) to the various terms in the expression for b_1. Numerical values of the coefficients for the Fourier series in $\cos\theta$, $\cos 2\,\theta$ etc., may be written down for a given value of s/a. Thus, when $s/d = 2$ ($d = 2\,a$), the reactive drop at angle θ due to b_1 is

$$(j\, l^2)^2\, 2\, b_0\, \rho \left[-\,0.06350 + 0.23387\cos\theta + 0.01152\cos 2\,\theta + 0.00069\cos 3\,\theta - 0.00002\cos 4\,\theta - \ldots \right]$$

abvolts per cm. (10)

The term independent of θ in formula (10) is $(j\, l^2)^2\, 2\, b_0\, \rho\, (-\,0.06350)$ which is obtained from the series

$$(j\, l^2)^2\, 2\, b_0\, \rho \left[-\frac{a^2}{s^2} - \frac{a^4}{2^2\, s^4} - \frac{a^6}{3^2\, s^6} - \frac{a^8}{4^2\, s^8} - \ldots \right] \qquad (10a)$$

This series is applicable for any value of s/a, and when $s/a = 4$ ($s/d = 2$) it gives

$$+\, l^4\, 2\, b_0\, \rho \times 0.063504$$
$$= b_0\, \rho\, l^4 \times 0.12701$$

as in the second term of equation (13).

Since b_1 contains only terms in $\cos\theta$, $\cos 2\,\theta$, etc., the total current due to b_1 is zero, as is shown by the integral

$$\int_0^{2\pi} \cos n\,\theta\, d\,\theta = 0 \qquad (11)$$

The process is continued by calculating the currents b_2, b_3 etc. The series for $I\,Z'$ will be composed of the terms independent of θ in the various expressions similar to (10).

Now
$$I\,R = 2\,\pi\, a\, t\, b_0\, \frac{\rho}{2\,\pi\, a\, t} = b_0\, \rho \qquad (12)$$

By dividing this into the series for $I\,Z'$, we obtain the series for

$$\frac{R' + j\,X'}{R}.$$

The real terms give a series for R'/R.

Thus, when $s/d = 2$,

$$R'/R = 1 + 0.12701\, l^4 - 0.10965\, l^8 + 0.09599\, l^{12} - 0.08435\, l^{16} + 0.0742\, l^{20} - 0.0653\, l^{24} + \ldots \qquad (13)$$

When $s/d = 1.5$

$$R'/R = 1 + 0.22872\, l^4 - 0.17337\, l^8 + 0.13619\, l^{12} - 0.10804\, l^{16} + 0.0860\, l^{20} - 0.0684\, l^{24} + \ldots \qquad (14)$$

When $s/d = 1$

$$R'/R = 1 + 0.53530\, l^4 - 0.25686\, l^8 + 0.15408\, l^{12} - 0.0961\, l^{16} + 0.0604\, l^{20} - 0.0381\, l^{24} + \ldots \qquad (15)$$

6. Scientific Paper No. 374 of the Bureau of Standards, Washington, D. C., 1920, by H. L. Curtis.

Now, from equation (9),

$$l = \sqrt{f/R}\,\sqrt{2}\,\pi \tag{16}$$

when R is measured in absolute units. The principle that the value of skin effect depends on the value of f/R is self-evident for this type of circuit.

Equations (13) to (15) can be evaluated for values of l less than 1, that is, for values of $\sqrt{f/R_{dc}}$ less than about 72 (R_{dc} in ohms per 1000 ft.). Note that in this calculation the a-c. resistance when the tubes are isolated is the same as the d-c. resistance, since the tubes are assumed to be very thin.

Curves I, III and IV calculated as above for $s/d = 1, 1.5$ and 2 are plotted in Fig. 3 and are shown in comparison with test curves II and V, the data for which are given in Table VIII, of the paper by Kennelly, Laws and Pierce, loc. cit.

The curves for the proximity effect of wires (defined as R'/R_{isolated}) are not very different from those for tubes, when they are plotted on $\sqrt{f/R_{dc}}$. In Fig. 4 are plotted test curves described in Table V, Kennelly, Laws and Pierce, loc. cit., ($s/d = 1.03, 1.68, 6.5$ and 18), Table VI, Curtis, loc. cit., ($s/d = 1.06, 1.27, 2.03$ and 3.0) and a calculated curve for $s/d = 2.0$ published by J. R. Carson.[7]

These curves should be of some use in estimating the proximity effect in tubes, especially when the tubes are thick.

From the above it appears that there is opportunity for very useful measurements to be made of skin effect, spirality effect and proximity effect of tubular conductors as well as other types of conductors. The electrical engineering profession is much indebted to those who have made the tests so far published. These investigators have for the most part done their work so accurately that future tests, in order to add to our knowledge of the subject, must be made with very great precision and accuracy. Test results should not be presented as isolated results for certain sizes of conductor only, but they should be presented as general curves, applicable to all frequencies and all sizes of conductors or circuits of the specified shape. If there is any doubt in the minds of the investigators as to the propriety of doing this, they should remove such doubt by making a series of tests to check up the matter.

In this connection, it is necessary to point out that the "penetration formula" advocated by Middleton and Davis, loc. cit., is a formula which had been originally calculated and intended for very high frequencies, and it is inaccurate and liable to give rise to misleading results if used for large conductors at 60 cycles. This can be shown by plotting the results of the penetration formula alongside of the curve for solid wire in Fig. 1.

In deriving the penetration formula for solid wire, one starts with the high-frequency, asymptotic formula (1) of this paper, first making it applicable to solid wires by putting $t = r$ and $q = 0$. Next, discard all the terms of the series in the bracket except the first two, thus obtaining the equation of the straight line which is the asymptote to the curve of R'/R. This involves considerable error at low frequencies, where the curve of R'/R departs from a straight line, as is seen in Fig. 1. But there is another error, or approximation, still in the penetration formula. If R' is equal to the d-c. resistance of a tube of outer radius r and thickness t,

$$R/R' = \frac{2\,t}{r} - \frac{t^2}{r^2} \tag{15}$$

In order to compare this with (1), the reciprocal of (1) is expanded by the binomial theorem, assuming that $m\,r$ is large, and the series is written

$$1 - \frac{1}{m\,r\,\sqrt{2}}\,.$$

The combined effect of the two approximations is found by plotting the results on Fig. 1. Besides giving actual errors for solid wires, the penetration formula as used by Middleton and Davis, loc. cit., (formula B), has the following disadvantages:

In using the constant 0.00384 for cables, it is assumed that the specific resistance of a mixture of copper and air such as the cable, is the same as the specific resistance of solid copper, but this is not the case. (This assumption is made also in Table II, Middleton and Davis, loc. cit.) By specifying the single constant 0.00384 for copper, no allowance is made for copper of low conductivity, or for changes in temperature, and these items are of considerable importance. By taking the penetration from the center line of the outside wires, an arbitrary assumption is made in order to make a few readings more consistent. The impression is given that the penetration formula can be used to determine the skin effect ratio of tubes, which is not at all correct.

The curves of Fig. 1 overcome the above disadvantages of the high-frequency penetration formula.

A 2,000,000-cir. mil cable, whose increase in resistance due to skin effect is of the order of 30 per cent at 60 cycles, is evidently worth while redesigning in order to reduce the skin effect. The increase in cost of manufacture and installation of the lead-covered cable due to the larger outside diameter when designed as a tube must be balanced against the decrease in cost due to less copper being required for the same a-c. resistance. In order to make such a comparison it is necessary to have a method of determining the skin effect in various designs of tubular conductors, and curves such as those of Fig. 1, together with curves to give a correction for spirality effect provide such a method. (See Example III.)

Care should be taken not to allow a cable carrying a heavy current to approach any magnetic material when precise measurements of the resistance loss are

7. "Wave Propagation over Parallel Wires: The Proximity Effect," by J. R. Carson, *Philosophical Magazine*, April, 1921, page 632.

being taken. If the cable is near a steel beam, or possbily even a number of nails in a wooden floor on which the cable might be lying, an appreciable increase in the effective resistance could be caused.

It is to be hoped that further precise tests of skin effect will be made, so that the curves required in designing can be made more accurate and more complete.

Example I

Find the a-c. resistance at 60 cycles of a non-flexible lead for a 15,000-ampere resistance furnace. With certain types of furnace which have a long, narrow shape, it is necessary to construct such a lead 40 or 50 feet long parallel to the furnace and about 6 feet away from it. The furnace is itself the return conductor, so that interlacing is impossible.

First assume a round, solid conductor with average current density 1000 amperes per sq. in., that is, with 15 sq. in. cross-section.

$R_{dc} = 0.00072$ ohm per 1000 feet at 100 deg. cent.

$\sqrt{f/R_{dc}} = 288$ and $\sqrt{f/R_{abs}} = 1.59$

$R'/R = 1.59\sqrt{\pi} + 0.25 = 3.07$ by formula (1).

The proximity effect ratio is 1.03, since $s/d = 16$ (See Fig. 4).

Therefore, the a-c. resistance of the solid, round conductor is 0.0023 ohm per 1000 feet. The a-c. resistance of a bundle of cables is practically the same as that of the solid conductor. The a-c. resistance of any non-tubular form of conductor, such as a group of ventilated straps, is very much greater than the d-c. resistance and so it is worth while considering a tubular conductor, as in the following paragraph.

Assume that the conductor is a tube of 12 inches diameter, made of copper sheet 0.35 inch thick.

Section = 12.8 sq. in.

$R_{dc} = 0.00084$ ohm per 1000 feet at 100 deg. cent.

$t/d = 0.029$

$\sqrt{f/R_{dc}} = 267$

Therefore, $R'/R = 1.05$ from Fig. 1.

Since $s/d = 6$, the proximity effect ratio will be of the order of 1.1. (See Fig. 3).

The a-c. resistance of the tube at 60 cycles is thus about 0.0010 ohm per 1000 feet. The tubular conductor is seen to have double the a-c. conductivity of the non-tubular form, although the weight is 15 per cent less. The weight could evidently be reduced still further.

The large diameter of the tubular lead reduces the reactance and raises the power factor of the 60-cycle furnace load, which is sometimes desirable. If the heated air and the radiation from the furnace cause the lead to run too hot, the tubular shape is advantageous in that cool air from outdoors can be blown through it by a ventilating fan.

Example II

To estimate the a-c. resistance of a flexible electric furnace lead for 30,000 amperes.

First, if the lead is composed of a bundle of bare cables tied closely together, with the average current density in the copper equal to 1000 amperes per sq. in., the value of R_{dc} for the lead will be 0.00036 ohm per 1000 feet at 100 deg. cent. This depends directly on the fact that the cross-section of the copper is 30 sq. in. At 60 cycles

$\sqrt{f/R_{dc}} = 408$ and $\sqrt{f/R_{abs}} = 2.25$

$R'/R = 2.25\sqrt{\pi} + 0.25 = 4.25$ from formula (1).

The spirality effect ratio will be comparatively small, being of the order of 1.2. The proximity effect ratio for a three-phase circuit will not be greatly different from that for a return circuit indicated in Fig. 4. This ratio will also be small, being of the order of 1.03 if the leads are 6 feet apart, s/d being about 10.

The a-c. resistance of the lead is therefore approximately 0.0019 ohm per 1000 feet.

Second, if the lead is designed as a hollow, flexible cylinder composed of 70 cables of 400,000 cir. mils each, held apart by 20-inch circular spacers, the total section of copper is 22 sq. in. Therefore, $R_{dc} = 0.00050$ and $\sqrt{f/R_{dc}} = 346$ at 60 cycles and 100 deg. cent.

The cylinder made up of a single layer of cables is quite similar to a tube of thickness 0.72 inch or less so that $t/d = 0.034$. Therefore, from Fig. 1, $R'/R = 1.20$. The proximity effect ratio is about 1.2, as may be seen from Fig. 3, taking $s/d = 3.4$ The spirality effect ratio is of the order of 1.2 as for the more compact bundle of cables previously considered.

The a-c. resistance of the flexible tubular lead is, therefore, approximately 0.00086 ohm per 1000 feet.

It is seen therefore that the tubular lead, which has 25 per cent less weight than the non-tubular form, has over twice as much a-c. conductivity. Since the tubular lead is very well ventilated, its weight could doubtless be cut down considerably. The exact dimensions used above are for an example only to show the method of estimating the a-c. resistance.

The writer understands that this tubular form of flexible lead has been constructed and successfully used with electric furnaces and that it is sufficiently flexible for the purpose. A little calculation will show that its reactance is enough less to increase the power factor of the furnace load appreciably. An easy method such as the one here given of estimating the greatly increased conductivity of tubular leads compared with more usual designs should help make them be applied more frequently.

Example III

To find the a-c. resistance at 60 cycles of a 2,000,000 cir. mil cable both without and with a non-conducting core.

$R_{dc} = 0.0054$ ohm per 1000 feet.

$\sqrt{f/R_{dc}} = 106$

$R'/R = 1.29$ for the coreless cable, from Fig. 1.

Therefore the a-c. resistance is 0.0069 ohm per 1000 feet, neglecting spirality effect.

If a 2,000,000-cir. mil tubular cable be wound on a non-conducting core 1.125 inches in diameter, the outside diameter, d, of the copper will be approximately 1.96 inches.

Therefore, $t = 0.417$ inch and $t/d = 0.213$

As above, $\sqrt{f/R_{dc}} = 106$

and therefore, from Fig. 1, $R'/R = 1.08$. Thus the a-c. resistance is 0.0058 ohm per 1000 feet, neglecting spirality effect.

The spirality effect ratio would be small for both the above cases since $\sqrt{f/R_{dc}} = 106$ (See Fig. 2).

Example IV

To find the a-c. resistance at 25 cycles of a 2,000,000-cir. mil cable both without and with a non-conducting core.

$R_{dc} = 0.0054$ ohm per 1000 feet.

$\sqrt{f/R_{dc}} = 68$

$R'/R = 1.063$ for the coreless cable, from Fig. 1.

Diameter of copper = 1.67 inches. Assume that a return conductor is at a distance of 8 inches, center to center. Then $s/d = 4.8$ and the proximity effect ratio is about 1.010 (See Fig. 4). The spirality effect at 25 cycles is practically negligible (See Fig. 2).

Second, assume that a non-magnetic core of 0.625 inch diameter be provided, as recommended in Table XV, Middleton and Davis, loc. cit., for a 2,000,000-cir. mil cable at 25 cycles. The diameter of the copper is increased to 1.78 inches and from this

$t/d = 0.324$

Now $\sqrt{f/R_{dc}} = 68$ and therefore,

$R'/R = 1.035$ from Fig. 1.

As before, the spirality effect is practically negligible. The proximity effect ratio, as given by Fig. 3, is about 1.015. The slight increase in proximity effect is due to two reasons. First, the value of s/d has been decreased to 4.5 and, second, a comparison of Figs. 3 and 4 shows that the curves for tubes are slightly higher than those for wire, as would be expected from the nature of the problem.

Providing a non-magnetic core as above has therefore decreased the a-c. resistance 2.8 per cent as regards Fig. 1, increased the a-c. resistance 0.5 per cent as regards Figs. 3 and 4, and increased the diameter of the copper 6.6 per cent, thus increasing the surface for heat radiation slightly.

From these results, it does not seem to be worth while to put a non-magnetic core in a 2,000,000-cir. mil, 25-cycle cable in order to reduce the skin effect, and still less worth while in a 1,500,000-cir. mil, 25-cycle cable as recommended in Table XV, Middleton and Davis, loc. cit. The skin effect ratio of the latter cable, without a core is 1.03.

Discussion

E. W. Davis: Many learned and excellent papers have been presented before this society and other physical or technical societies, on the subject of skin effect in conductors carrying alternating currents. These papers have not, however, been interpreted for the average engineer to understand.

For radio frequencies and small sized conductors, theoretical formulas have been checked and it has been assumed that these formulas would apply to larger conductors at the lower power frequencies.

Except in the paper of Mr. W. I. Middleton's and the speaker's the data of tests conducted on actual commercial power cables at the low frequencies of 25 and 60 cycles have not been published as far as the speaker has been able to determine.

Tables furnished by manufacturers or put out by engineers of purchasing companies calling for rope cores in power cables show a remarkably wide variation in the size of cores for the same working conditions. Each table is based on some theoretical mathematical formula that is probably quite as correct as the one worked out by Mr. Dwight.

One of the simplest conceptions of skin effect and one that is quite universally used in elementary text books on electricity, is that of the depth of penetration of alternating current from the surface of a conductor. Most of us remember our high school or college instructors saying that an alternating current travels on the outside of a conductor. Alexander Gray in "Absolute Measurements in Electricity and Magnetism" gives a very interesting discussion of this conception of skin effect.

The experimental work of Mr. Middleton and the speaker in 1921 was done on commercial power cables at commercial frequencies, for the purpose of furnishing engineers with specific experimental information on the subject of skin effect in power cables. The work was done for a specific purpose, and that purpose was accomplished. The results published are quite trustworthy for the range of sizes tested and at some later date we hope to continue our tests on even larger sizes of conductors.

The constant 0.00384 used, and to which Mr. Dwight takes exception, was checked for the copper used in the actual construction of the cables.

We do not necessarily recommend the rope cores given for the smaller sizes of conductors at 25 cycles, but include them in our paper merely as an example of what these cores should be, if used.

A. S. Dana: I wish to call attention to some measurements which were made at the Massachusetts Institute of Technology in the year 1915, and which were determined to a considerable degree of accuracy under the guidance of Dr. A. E. Kennelly. The results on a 7-strand, 19- and a 37-strand are very different from those found by Middleton & Davis. The 7-strand cable, as I understand it, in the Middleton & Davis[1] paper has a much smaller skin effect than a solid conductor cable of the same cross section. The mean value measured by Davis 1.089 at 500 cycles, but that of a solid wire of approximately the same copper cross section is 1.293, or the skin effect Mr. Davis found on a 7-strand cable was about 20 per cent less than that of the equivalent solid wire. Mr. Dwight ascribed this large difference to an error in Mr. Davis' measurements. At frequencies above 1250 cycles and 60-cm. spacing of the return conductor Mr. P. H. Pierce found the skin effect of 7-strand cable was greater than the solid. I think Mr. Pierce in a publication[2] previous to 1915 was the first to note and publish this effect. Dr. Kennelly desired me to check these measurements on 7-strand, and solid wire in 1915. I found that the skin effect of a 7-strand conductor is greater than that of the solid conductor above a certain frequency depending on the spacing of the return conductor, and the paper by Kennelly & Affel[3] at radio frequencies proved the same conclusion, and the cause was ascribed to the spirality effect. The spirality effect was later taken up in more detail and Mr. Dwight has gone still further.

I think it is generally considered that by stranding a conductor the skin effect is reduced as the number of strands is increased (providing the number of strands is greater than 7). On the 19-strand and 37-strand cables we found this to be the case: the skin effect was less than in a solid conductor of the

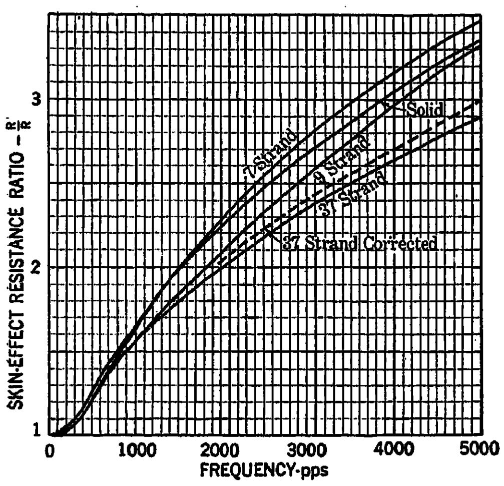

FIG. 1—EFFECT OF STRANDING ON SKIN-EFFECT

Separation approximately 60 cm., No. 0000 B & S Copper Cable. The 37-strand cable has smaller cross section than the others. Curve "37 Strand Corrected" takes this into account.

same cross section, and also the skin effect of the 37-strand was less than the 19-strand. I have obtained permission from the Institute to publish these results from 60 to 5000 cycles since I think that they may be of value to other people interested in this problem. They appear in Figs. 1, 2, 3, 4, 5, 6. Each cable was measured in the form of a rectangle with three different spacings of the long sides. The effect of the return conductor was negligible at 60-cm. spacing.

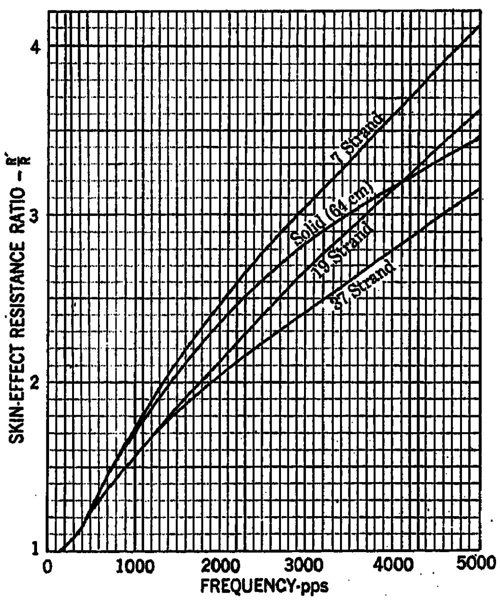

FIG. 2—EFFECT OF STRANDING ON SKIN-EFFECT

Separation approximately 2.4 cm. No. 0000 B & S Copper Cable. Temperature of Cable—Solid, 20.3 deg. cent.; 7-Strand, 15.6 deg. cent.; 19-Strand 27 deg. cent.; 37-Strand, 29 deg. cent.

Middleton & Davis, however, found just the opposite to be the case; *i. e.*, the greater the number of strands at 500 cycles the greater the skin effect. It is not safe to draw general conclusions from these measurements since at higher frequencies where more accurate results may be obtained, it is clear from the accompanying curves in Fig. 1 that the skin effect grows less as the number of strands is increased (above 7). Mr. Dwight[4] cast

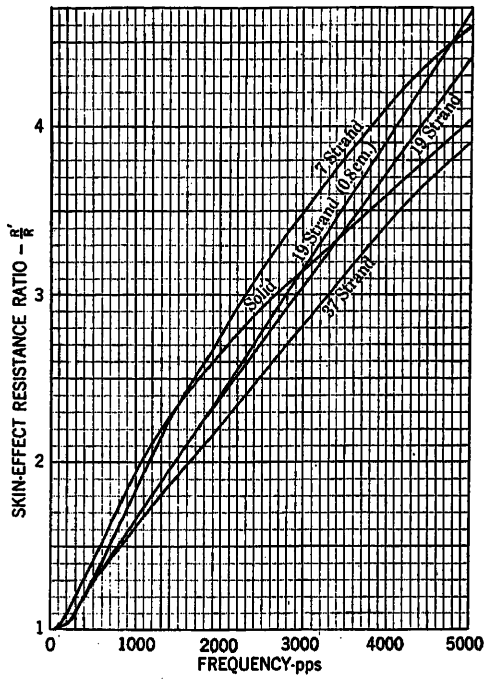

FIG. 3—EFFECT OF STRANDING ON SKIN-EFFECT

Separation approximately 0.9 cm., No. 0000 B & S Copper Cable

doubt on all the Middleton-Davis measurements and their conclusions, for the measurements of the same skin effect varied by 8 per cent. Those made by Pierce and myself were reproducible to better than 1 per cent and usually better than ½ per cent.

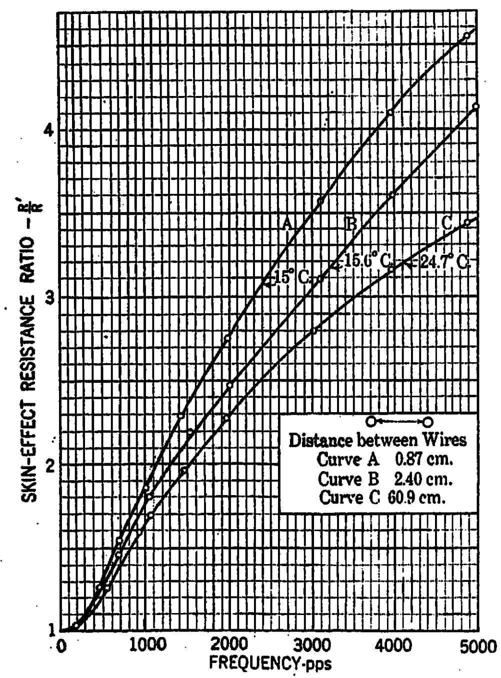

FIG. 4—SKIN EFFECT OF 7-STRAND COPPER CABLE, 211,700 CIR. MILS

Distance between wires—Curve *A*, 0.87 cm.; Curve *B*, 2.4 cm.; Curve *C*, 60.9 cm.

There is one thing more I would like to say—it may be an unfortunate choice of words, but Mr. Davis speaks of the pene-

tration of the current as being only to a certain distance from the exterior of the conductor. This is not true, for the current goes to the center. However, it decreases at a great rate, starting from the circumference, and what is usually meant is

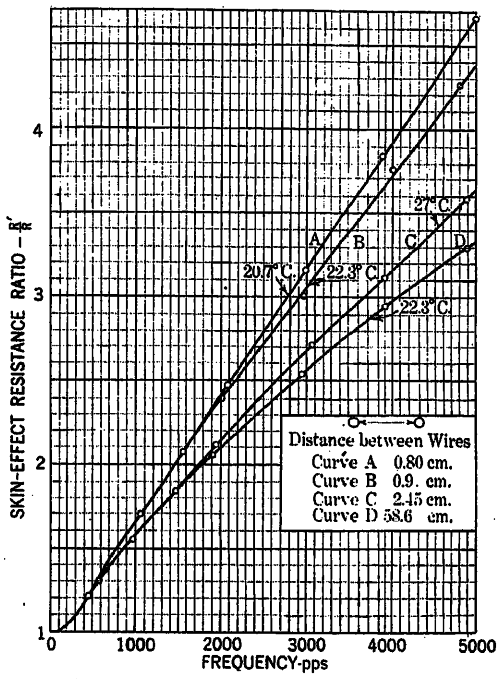

FIG. 5—SKIN EFFECT OF 19-STRAND COPPER CABLE, 210,700 CIR. MILS.

Distance between wires—Curve A, 0.80 cm.; Curve B, 0.9 cm.; Curve C, 2.45 cm.; Curve D, 58.6 cm.

that a tube having a thickness equal to this "penetration" of which they speak, will offer the same resistance to direct current, that the complete solid conductor offers to alternating current. Furthermore, I believe in the Middleton-Davis tests

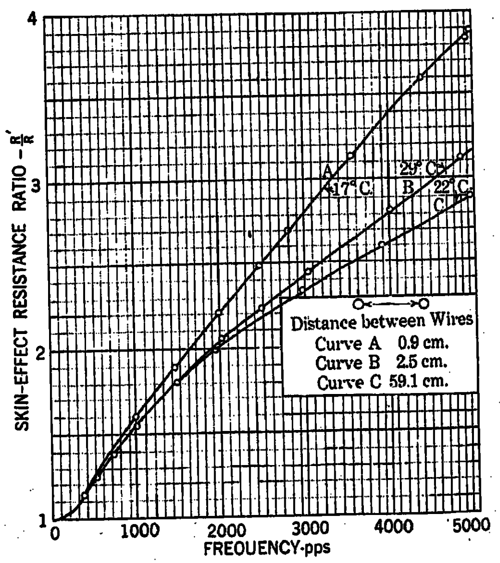

FIG. 6—SKIN EFFECT OF 37-STRAND COPPER CABLE, 198,200 CIR. MILS.

Distance between wires—Curve A, 0.9 cm.; Curve B, 2.5 cm.; Curve C, 59.1 cm.

they took solid conductors, computing this depth of penetration, or the equivalent conducting layer, and decided that the material inside this ring could be thrown away and rope substituted, giving approximately the same a-c. resistance.

You will find that this may be practically true in some cases where the diameter of the conductor and the frequency are high, but at the lower frequencies, the conductor with the center removed would have a greater resistance than the completed conductor.

For the benefit of those who care to use Gray's formula which was employed by Middleton & Davis, I think it should be pointed out that this formula is an approximation and only for use when the diameter of the conductor is so large or the frequency so high that the wire can be considered a strip of infinite width, or a tube of very small thickness. This formula does not contain any symbol for the radius of the wire, and would lead one to think that the depth of the equivalent conducting layer is independent of the radius of the wire, and varies only with the frequency and the conductivity. Using the notation which Dr. Kennelly has used in the three papers[2,3,5], I wish to call attention to the fact that the product of αX must be 6 or greater to use this formula with approximate accuracy. With the 2,000,000-cir. mil cable with an outside diameter of 1.625 in. in the Middleton & Davis paper at 60 cycles this product of αX is only about 3.42 instead of being greater than 6, hence that formula should not be used unless these conditions are understood, and only a rough result is desired. A formula for the equivalent skin thickness of any wire is given by Dr. Kennelly[2], page 790. In this the radius of the wire has an important part.

H. B. Dwight: In dealing with the problem of the skin effect in a conductor of a given form of cross-section, it is necessary to try to make all the measurements which have been made with that form of section, consistent with each other. There is no doubt that they ought to be consistent, for the phenomenon of skin effect in a non-magnetic conductor at high frequency is caused by a magnetic field of the same shape as that surrounding a similar conductor in a low-frequency test.

The way in which high-frequency tests can be compared with low-frequency tests to see if they are consistent is to correct them for frequency according to the "principle of similitude," described in the third and following paragraphs of my paper.

Mr. E. W. Davis, in the second paragraph of his discussion, states that it has been "assumed" that the same laws apply to high-frequency and low-frequency tests. The principle of similitude is not an assumption. The writer gave definite reasons for it in his A. I. E. E. paper in 1918 and Mr. J. Slepian published at the same time a conclusive mathematical proof of it. (Reference 1.) If, therefore, any one should wish to cast doubt on this principle, the burden of proof is on them, and they should show evidence, either mathematical or experimental, that the principle of similitude is not true.

The question of whether the penetration formula should be used in connection with large conductors at commercial frequencies is best considered by using a direct comparison between the results of this approximate formula and the correct results, as shown in the Fig. 7. The range required for large

60-cycle cables is up to 30 per cent increase of resistance. In this range it can be seen that the penetration formula gives 37 per cent increase of resistance where it should give 30 per cent. It gives 26 per cent where it should give 20 per cent, and it gives zero per cent where it should give 3 per cent.

Such large discrepancies show that the penetration formula

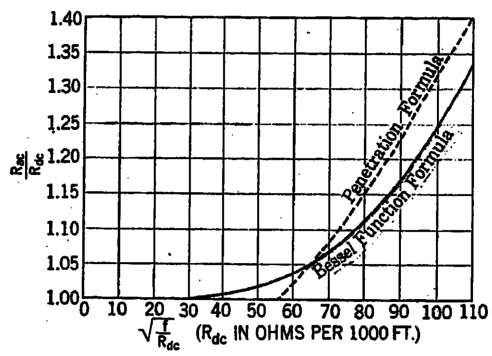

FIG. 7—SKIN EFFECT IN SOLID ROUND WIRE

does not give a close approximation for the range considered. If a calculation is to be of use in deciding questions of design of large cables, it should not give errors as large as 7 per cent in a quantity which amounts to not more than 30 per cent. The same statement applies to test results having discrepancies between duplicate readings amounting to several per cent.

The penetration formula was originally published by physicists who were discussing skin effect at high frequencies with increases in resistance of several hundred per cent. Under such conditions, the error due to the penetration formula is quite small.

If a series of rope core sizes is to be chosen for 25-cycle and 60-cycle cables, which shall be consistent with each other, the sizes of rope cores should have a definite relation to the improvement in skin effect obtained by using rope cores. The sizes of cores should therefore have a definite relation to the difference between the skin effect in the coreless cables, as given by the Bessel function formula, and the skin effect in the tubular conductors formed by the cables with cores, as given by Fig. 1 of my paper.

The sizes of cores will be very inconsistent if they are chosen as was done in the paper by Middleton and Davis, in accordance with skin effect values in coreless cables given by the penetration formula, and the incorrect assumption that the skin effect increase in resistance in the tubular conductors formed by the cables with cores, is zero per cent.

It is rather surprising that Middleton and Davis made no measurements of the skin effect in cables with rope cores, for that is the type of conductor whose design they were investigating.

In making future skin effect tests, I would suggest, since accurate tests results are so hard to obtain, that the instruments be first checked by measuring the skin effect in solid round rods. This has been calculated, and the calculations checked closely by measurements all the way from 60 cycles to 100,000 cycles. After it has been shown in this way that the instruments give correct and precise results, they can be used to measure the skin effect in more complicated conductors, and the results would be considered trustworthy if the conditions of testing the solid rods and the other conductors were substantially the same.

Heat Losses in Stranded Armature Conductors

BY WALDO V. LYON

Associate, A. I. E. E.

Assistant Professor of Electrical Engineering, Massachusetts Institute of Technology.

In the present paper, which is a continuation of one presented at the last annual convention, the author extends the method of complex hyperbolic functions to the solution of the problem of heat losses in stranded conductors embedded in rectangular slots. In the preceding paper the discussion was confined to solid conductors and to those having an infinite number of strands. In the latter case, the insulation between the strands was assumed to have no appreciable thickness. In the present paper, conductors are considered which have a finite number of strands separated by insulation of appreciable thickness. In the mathematical development which is to follow, free use is made of the results obtained in the first paper.

THE first step in the solution of the problem of heat losses in stranded armature conductors is to obtain an expression showing the relation between the currents in adjacent strands. If two strands are adjacent at any point, they are adjacent throughout their length. If the conductor is turned over in the end connection, the strand b, which is above a in one coil side, is below a in the next coil side, Fig. 1. The difference in pressure per half turn between these two strands is that between the lowest element of b and the highest element of a. If the conductor is turned over in the end connection, in the next half turn, this difference is between the lowest element of a and the highest element of b. The difference in pressure in each of these is cases given in equations (**6d**) and (**6r**). By the proper substitution, these equations can be written in terms of the currents in the adjacent strands and the current in the slot below them. See equations (**7a**) and (**7b**). These two equations are similar in form. Between the points at which the strands are joined together, the sum of all of these half-turn differences in pressure must be zero. This equation, (**8**), may be written in following form:

$$(I_{q(p+1)} - I_{q_p}) - \frac{\left(\alpha a + 2\tanh\frac{\alpha d}{2m}\right)\frac{\alpha d}{m}}{\dfrac{\frac{\alpha d}{m}}{\sinh\frac{\alpha d}{m}} + \dfrac{l_2}{l_1}}\left(I_0 + \sum_1^p I_{q_p}\right) = 0;$$

where α is calculated for the embedded portion of the winding. Compare this with the fundamental equation (**1**) in the preceding paper which for the case of infinitesimal strands may be written in the following form:

$$w\,dx\,d\text{ç} - \frac{\alpha^2 (dx)^2}{1 + \frac{l_2}{l_1}}\left(I_0 + \int_0^x w\,\text{ç}\,dx\right) = 0;$$

where α is also calculated for the embedded portion of the winding only, and l_1 and l_2 are respectively the length of the armature core and the length of an end turn. Notice that these equations are similar. The first term in each is the vector difference between the currents in adjacent strands. The coefficients of the second terms are the same when the number of strands, m, increases without limit and there is no insulating space, a, between them. It is further shown that the vector constants, I_0, are identical in the two equations. This similarity suggests that the

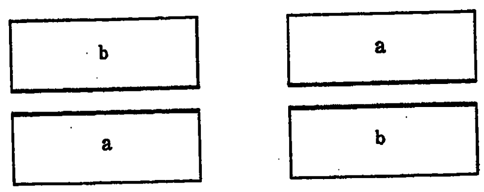

FIG. 1

currents in the strands of the stranded conductor may be equal to those in corresponding divisions of a solid conductor of the same depth. In the latter case, the imaginary strands would of course not be separated. (Fig. 2.)

Such proves to be the case provided the hyperbolic angular depth, βd, of the solid conductor has a certain value. This value is determined by the relation (Equation **10a**):

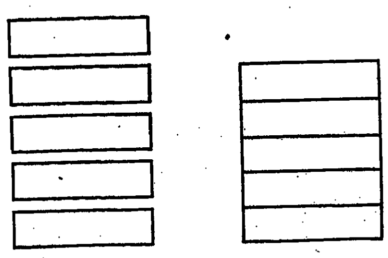

FIG. 2

$$\sinh^2\frac{\beta d}{2m} = \frac{\frac{\alpha d}{2m}\left(\frac{\alpha a}{2} + \tanh\frac{\alpha d}{2m}\right)}{\dfrac{\frac{\alpha d}{m}}{\sinh\frac{\alpha d}{m}} + \dfrac{l_2}{l_1}}$$

Were it not for this relation between the currents in the two cases the completion of the solution would be much more difficult. The reason is that the current

Presented by title only at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

up to any strand in the stranded conductor must be determined by a summation of vector quantities whereas in a solid conductor the current up to any point may be obtained by integration, a much simpler process. The current in any strand may also be obtained by integration between the proper limits.

This equality of the currents in a stranded conductor and a solid one recalls the equality of currents and of voltages that exists in an artificial transmission line and a smooth line when there is a certain relation between their constants.

We are now in a position to determine the expressions for the resistance drop in either the top or bottom strand of a conductor. It is only in the case of strands of infinitesimal thickness that the expressions are the same. Compare equations (**13b**) and (**14b**) with equation (**7**) in the preceding paper. They are identical except that M and N in the preceding paper are replaced by similar functions, M' and N' and that there are terms involving T' and S' which would disappear if the number of strands, m, were infinite and there were no insulating space, a, between them. We must also derive expressions for the pressure acting in conductors below a given one due to flux within the latter. These expressions are given in equations (**15b**) and (**16b**). These expressions are identical with the corresponding ones for solid or finely laminated conductors except that N' replaces N, that T' replaces $\alpha^2 d^2$ to which it reduces if there are an infinite number of laminations with no space between them, and that there is an added term involving S', a pure imaginary, which depends upon the insulating space between the laminations.

Having determined these four pressure equations, the determination of the heating loss or of the leakage impedance follows precisely the same procedure that was used in the preceding paper.

The author wishes to point out again a fact which he believes is not generally appreciated. A finely stranded conductor with the strands continuous throughout the whole coil will have a resistance ratio equal to that of a single finely stranded half turn of one half its depth, provided the coil has an even number of turns and the end connections are turned over on *one side only*. For conductors up to about one inch in depth, the alternating-current resistance is then but 1 or 2 per cent greater than the direct-current resistance.

Mathematical Analysis

The description of windings considered follows. The embedded portions of the winding are in open reactangular slots; there are two coil sides per slot; the pitch is either full or fractional; each coil side has n layers or conductors, and each layer has m laminations or strands; the strands occupy the same relative positions throughout the embedded portion of any half turn; the strands are arranged one above the other and have equal rectangular cross-sections; the strands are separated by insulation of uniform thickness; when the conductors are turned over or twisted in the end connections it is done in such a manner that any strand occupies the same relative position with respect to the bottom of the conductor of which it is a part that it does with respect to the top of the successive half turn; the coil as a whole is not turned over in the end connection; strands of any conductor may be joined at the beginning and end of a half turn, a full turn, or of a complete coil; the end connections may be turned over on neither side, on one side, or on both sides.

The strands are designated by the subscripts $q\,p$. The $q\,p$ strand is the p strand of the q conductor. The number of the strand may be counted from the bottom of the conductor of which it is a part, in which case the order of the strands is said to be direct, or from the top of the conductor of which it is a part, in which case the order of the strands is said to be reverse. Thus in a winding whose strands are continuous throughout a whole coil and whose end connections are turned over on both sides the strands are in the direct order in one coil side and in the reverse order in the other coil side of the same coil. The number of the conductor is always counted from the bottom of the coil side of which it is a part.

The armature currents are assumed to be balanced. In the end connections the r. m. s. current density throughout any strand is assumed to be constant. In the embedded portion of the coil the r. m. s. current density in any strand is variable. This vector r. m. s. current density in the embedded portion of the $q\,p$ strand is:

$$\dot{c}_{q_p} = \frac{m}{w\,d}\left(I_{q_p} \frac{\alpha\,d}{m} \frac{\cosh \alpha\,x}{\sinh \dfrac{\alpha\,d}{m}} - I_{b\,q_p} \frac{\alpha\,d}{m} \tanh \frac{\alpha\,d}{2m} \cosh \alpha\,x + I_{b\,q_p} \frac{\alpha\,d}{m} \sinh \alpha\,x \right)^{1} \quad (1)$$

$\dot{c}$ is the vector r. m. s. current density at points x centimeters from the bottom of the $p\,q$ strand; d is the net depth[2] of the conductor; d/m is the depth of one strand; w is the width of the conductor or strand; I_{q_p} is the current in the $q\,p$ strand; $I_{b\,q_p}$ is *all* of the current in the slot *below* the $q\,p$ strand;

$$\alpha^2 = j\,\frac{8\,\pi^2\,w\,f}{\rho\,s};$$

---

1. See: Heat Losses in the Conductors of Alternating-Current Machines presented at Annual Convention A. I. E. E., June 1921. (Equation (4). For solid conductors like the $q\,p$ strand I_o is all of the current in the slot below the conductor considered.)

2. The net depth of the conductor is the depth it would have if the insulation between the strands were of zero thickness.

where f is the frequency, w, the width of the conductor, and s, that of the slot, and ρ is the resistivity of the material of the conductor at the working temperature. ρ is assumed the same for every strand.

The current densities at the bottom, center and top of the $q\,p$ strand are respectively $c_{q_p b}$, $c_{q_p c}$ and $c_{q_p t}$. Substitution in equation (1) shows that

Since $x = O$,

$$c_{q_p b} = \frac{m}{w\,d}\left(I_{q_p} \frac{\frac{\alpha\,d}{m}}{\sinh \frac{\alpha\,d}{m}} - I_{b q_p} \frac{\alpha\,d}{m} \tanh \frac{\alpha\,d}{2\,m} \right) \quad (2)$$

Since $x = \dfrac{d}{2\,m}$, $$c_{q_p c} = \frac{m}{w\,d} I_{q_p} \frac{\frac{\alpha\,d}{2\,m}}{\sinh \frac{\alpha\,d}{2\,m}} \quad (3)$$

Since $x = \dfrac{d}{m}$, $$c_{q_p t} = \frac{m}{w\,d}\left(I_{q_p} \frac{\alpha\,d}{m} \coth \frac{\alpha\,d}{m} + I_{b q_p} \frac{\alpha\,d}{m} \tanh \frac{\alpha\,d}{2\,m} \right) \quad (4)$$

or

$$c_{q_p t} = \frac{m}{w\,d}\left\{ I_{q_p} \frac{\frac{\alpha\,d}{m}}{\sinh \frac{\alpha\,d}{m}} + I_{b q (p+1)} \frac{\alpha\,d}{m} \tanh \frac{\alpha\,d}{2\,m} \right\} \quad (4a)$$

It is shown in the paper already referred to that the flux, ϕ_{q_p}, within the embedded portion of any solid conductor, the q_p strand for example, due to current within the conductor, I_{q_p} or example, and to all of the current in the slot below it, which in this case is $I_{b q_p}$, is

$$\phi_{q_p} = \frac{1}{j\,\omega} \frac{l_1\,\rho\,m}{w\,d}\left(I_{q_p} + 2 I_{b q_p} \right) \frac{\alpha\,d}{m} \tanh \frac{\alpha\,d}{2\,m} \quad (5)$$

where l_1 is the length of the armature core. The flux, ϕ_a, between the $q\,(p+1)$ and the $q\,p$ strands is

$$\frac{4\,\pi\,l_1\,a}{s} I_{b q (p+1)},$$

which may be written in a form similar to equation (5). a is the thickness of the insulation between the strands

$$\phi_a = \frac{1}{j\,\omega} \frac{l_1\,\rho\,m}{w\,d}\left(I_{q_p} + I_{b q_p} \right) \frac{\alpha\,d}{m} \,.\, \alpha\,a \quad (5a)$$

The proper combination of these five equations, *viz.*, (2), (3), (4), (5) and (5a) will give the heat loss in any of the types of stranded conductors we are considering. The leakage reactance due to flux within the embedded portion of the conductor may also be found.

Relation between the Currents in Adjacent Strands of the Same Conductor

For strands numbered in the direct order, the difference in pressure between adjacent elements of adjacent strands is the difference in pressure between that in the topmost element of the p strand and the bottom element of the $(p+1)$ strand of the same conductor. For strands numbered in the reverse order this same difference is that between the pressures in the lowest element of the p strand and in the topmost element of the $(p+1)$ strand. The total difference in pressure between these adjacent elements must be zero between the points at which the strands are joined.

For strands numbered in the direct order this difference in pressure, D_d, for a half turn is

$$D_d = \left(l_1\,\rho\,c_{q(p+1)b} + l_2 \frac{\rho\,m}{w\,d} I_{q(p+1)} \right) - \left(l_1\,\rho\,c_{q_p t} + l_2\,\rho \frac{m}{w\,d} I_{q_p} + l_1 \frac{\rho\,m}{w\,d} I_{b q (p+1)} \frac{\alpha\,d}{m} \,.\, \alpha\,a \right) \quad (6d)$$

l_1 and l_2 are respectively the lengths of the armature core and of the end connections for a half turn. The second term in each parenthesis is the resistance drop in the end connections. The third term in the second parenthesis is the drop in pressure in the $q\,p$ strand due to the flux ϕ_a. The reactance drop in the end connections due to internal leakage flux is neglected, *i. e.*, the current density is assumed to be uniform in each strand of the end connections.

Substitute equations (2) and (4) in equation (6d)

$$D_d = \frac{m}{w\,d}\,\rho \left\{ \left[l_1 I_{q(p+1)} \frac{\frac{\alpha\,d}{m}}{\sinh \frac{\alpha\,d}{m}} - l_1 I_{b q (p+1)} \frac{\alpha\,d}{m}\left(\alpha\,a + \tanh \frac{\alpha\,d}{2\,m} \right) + l_2 I_{q(p+1)} \right] - \left[l_1 I_{q_p} \frac{\alpha\,d}{m} \coth \frac{\alpha\,d}{m} + l_1 I_{b q_p} \frac{\alpha\,d}{m} \tanh \frac{\alpha\,d}{2\,m} + l_2 I_{q_p} \right] \right\}$$

but $$I_{b q_p} = I_{b q (p+1)} - I_{q_p}$$

Thus:

$$D_d = \frac{m}{w\,d}\,\rho \left\{ \left(l_1 \frac{\frac{\alpha\,d}{m}}{\sinh \frac{\alpha\,d}{m}} + l_2 \right) \left(I_{q(p+1)} - I_{q_p} \right) - l_1 I_{b q (p+1)} \frac{\alpha\,d}{m}\left(\alpha\,a + 2 \tanh \frac{\alpha\,d}{2\,m} \right) \right\} \quad (6a)$$

For strands numbered in the reverse order the pressure difference, D_r, for a half turn is:

$$D_r = \left(l_1\,\rho\,c_{q(p+1)t} + l_2\,\rho \frac{m}{w\,d} I_{q(p+1)} \right.$$

$$+ l_1 \rho \frac{m}{w d} I_{b q_p} \frac{\alpha d}{m} \cdot \alpha a \Big)$$

$$- \left(l_1 \rho c_{q_p b} + l_2 \rho \frac{m}{w d} I_{q_p} \right) \qquad \text{(6r)}$$

Substitute as before

$$D_r = \frac{m}{w d} \rho \left\{ \left[l_1 I_{q(p+1)} \frac{\alpha d}{m} \coth \frac{\alpha d}{m} + l_1 I_{b q (p+1)} \frac{\alpha d}{m} \tanh \frac{\alpha d}{2 m} + l_2 I_{q(p+1)} \right] - \left[l_1 I_{q_p} \frac{\frac{\alpha d}{m}}{\sinh \frac{\alpha d}{m}} - l_1 I_{b q_p} \frac{\alpha d}{m} \left(\alpha a + \tanh \frac{\alpha d}{2 m} \right) + l_2 I_{q_p} \right] \right\}$$

Now $\quad I_{b q_p} = I_{b q (p+1)} + I_{q (p+1)}$

Thus:

$$D_r = \frac{m}{w d} \rho \left\{ \left(l_1 \frac{\frac{\alpha d}{m}}{\sinh \frac{\alpha d}{m}} + l_2 \right) \left(I_{q(p+1)} - I_{q_p} \right) + l_1 I_{b q_p} \frac{\alpha d}{m} \left(\alpha a + 2 \tanh \frac{\alpha d}{2 m} \right) \right\} \qquad \text{(6b)}$$

In equation (**6a**) $\quad I_{b q (p+1)} = I_{b q_1} + \sum_1^p I_{q_p}$;

where the first part is the current in the slot below the q conductor and the second part is the current in the q conductor below its $(p + 1)$ strand. In equation (**6b**) $I_{b q_p} = I_{b q_m} + I_q - \sum_1^p I_{q_p}$ where the first part is the current in the slot below the q conductor, the second part is the current in the q conductor and the third part, as before, is the current in the q conductor from the first strand to the p strand inclusive.

With these substitutions, equations (**6a**) and (**6b**) become

$$D_d = \frac{m \rho}{w d} \left\{ \left(l_1 \frac{\frac{\alpha d}{m}}{\sinh \frac{\alpha d}{m}} + l_2 \right) (I_{q(p+1)} - I_{q_p}) - l_1 \frac{\alpha d}{2 m} \left(\alpha a + 2 \tanh \frac{\alpha d}{2 m} \right) I_{b q_1} - l_1 \frac{\alpha d}{m} \left(\alpha a + 2 \tanh \frac{\alpha d}{2 m} \right) \sum_1^p I_{q_p} \right. \qquad \text{(7a)}$$

$$D_r = \frac{m \rho}{w d} \left\{ \left(l_1 \frac{\frac{\alpha d}{m}}{\sinh \frac{\alpha d}{m}} + l_2 \right) (I_{q(p+1)} - I_{q_p}) + l_1 \frac{\alpha d}{m} \left(\alpha a + 2 \tanh \frac{\alpha d}{2 m} \right) (I_{b q_m} + I_q) - l_1 \frac{\alpha d}{m} \left(\alpha a + 2 \tanh \frac{\alpha d}{2 m} \right) \sum_1^p I_{q_p} \right\} \qquad \text{(7b)}$$

Between the points at which the strands are joined together the sum of all of these differences in pressure in adjacent half-turn elements, *viz.*, $\Sigma (D_d + D_r)$, must be zero. In general this sum may be written in the form

$$\left(\frac{\frac{\alpha d}{m}}{\sinh \frac{\alpha d}{m}} + \frac{l_2}{l_1} \right) (I_{q(p+1)} - I_{q_p}) - \frac{\alpha d}{m} \left(\alpha a + 2 \tanh \frac{\alpha d}{2 m} \right) I_0 - \frac{\alpha d}{m} \left(\alpha a + 2 \tanh \frac{\alpha d}{2 m} \right) \sum_1^p I_{q_p} = 0 \qquad \text{(8)}$$

where I_0 is the sum of the $I_{b q_1}$'s and the $(- I_{b q_m} - I_q)$'s divided by $2 n$, that is in general

$$I_0 = \frac{1}{2 n} (I_{b q_1} - I_{b q_m} - I_q)$$

We will now calculate the values of I_0 for the cases that we wish to consider.

Case 1. *Strands joined at the beginning and end of each half turn.* For the q conductor of the upper coil side

$$I_0 = (q - 1) I + n I \angle \theta$$

The first part of I_0 is the current in the upper coil side below the q conductor and the second part is the current in the lower coil side which in general differs in phase by an angle θ. There are n conductors in each coil side. The current in each conductor is I amperes $(I_q = I)$.

Case 2. *Strands joined at the beginning and end of a whole turn but not turned over in the end connection.* For the q conductor of the coil:

$$I_0 = 1/2 \{ (q - 1) I + n I \angle \theta + (q - 1) I \}$$
$$= (q - 1) I + n/2 I \angle \theta$$

Case 3. *Strands joined at the beginning and end of a whole turn and turned over in the end connection.* For the q conductor:

$$I_0 = 1/2 \{ (q - 1) I + n I \angle \theta - (q - 1) I - I \}$$

$$I_0 = - I/2 + \frac{n I \angle \theta}{2}$$

Case 4. *Strands joined at the beginning and end of a whole coil of n turns. End connection not turned over on either side.*

$$I_0 = \frac{1}{2 n} \sum_1^n \left[(q - 1) I + n I \angle \theta + (q - 1) I \right]$$

$$= \frac{n - 1}{2} I + n/2 I \angle \theta$$

Case 5. *Strands joined at the beginning and end of a whole coil of n turns. End connections turned over on one side only.* The order of the strands in the first, or lowest, conductor of the upper coil side is direct,

that of the next half turn is reverse. The strands in the second conductor of the upper coil side are in the reverse order while those in the next half turn are in the direct order.

In general

$$I_0 = \frac{1}{2n} \left\{ (n \angle \theta - 1) + (-n \angle \theta - 1 - 1 + 1) + (n / \theta + 2 - 2 - 1) + (-n \angle \theta - 3 - 1 + 3) + \text{etc.} \right\} I$$

$$I_0 = \frac{1}{2n} \left\{ (n \angle \theta - 1) + (-n / \theta - 1) + (n / \theta - 1) + (-n / \theta - 1) \text{ etc.} \right\} I$$

(a) n an even number

$I_0 = - I/2$

(b) n an odd number

$I_0 = - I/2 + I/2 / \theta$

Case 6. Strands joined at the beginning and end of a whole coil of n turns. End connections turned over on both sides. In the upper coil side the strands are all in the direct order while in the lower coil side they are all in the reverse order.

$$I_0 = \frac{1}{2n} \sum_1^n (n \angle \theta + (q - 1) - (q - 1) - 1) I$$

$$= - I/2 + \frac{n I \angle \theta}{2}$$

Consider a solid conductor of the same width, w, and same net depth, d, but which has an angle β instead of α. The current density in this conductor is

$$c = A' \cosh \beta x + B' \sinh \beta x$$

Imagine that this solid conductor is divided into m equal parts, *i. e.*, strands, in the same manner that the actual conductor is divided. The difference between the currents in the $(p + 1)$ and p strands is

$$I'_{p+1} - I_p' = \frac{w\,d}{m} \frac{\sinh \frac{\beta\,d}{2\,m}}{\frac{\beta\,d}{2\,m}} \left(c'_{(p+1)c} - c_{pc}' \right)$$

(See equation 2)

$$\text{But} \quad c'_{(p+1)c} - c'_{pc} = \left(A' \cosh \frac{p + 1/2}{m} \beta\,d + B' \sinh \frac{p + 1/2}{m} \beta\,d \right) - \left(A' \cosh \frac{p - 1/2}{m} \beta\,d + B' \sinh \frac{p - 1/2}{m} \beta\,d \right)$$

Expand in terms of $p/m\ \beta\,d$ and $\frac{\beta\,d}{2\,m}$ giving

$$c'_{(p+1)c} - c'_{pc} = (A' \sinh p/m\ \beta\,d + B' \cosh p/m\ \beta\,d)\, 2 \sinh \frac{\beta\,d}{2\,m}$$

Thus:

$$I'_{p+1} - I'_p = \frac{w\,d}{m} \frac{2 \sinh^2 \frac{\beta\,d}{2\,m}}{\frac{\beta\,d}{2\,m}} (A' \sinh p/m\ \beta\,d + B' \cosh p/m\ \beta\,d)$$

The current in this conductor up to and including the p part is

$$\sum_1^p I'_p = \int_0^{\frac{p}{m}d} w\,c'\,d\,x = w/\beta\,(A' \sinh p/m\ \beta\,d + B' \cosh p/m\ \beta\,d) - w/\beta\,B'$$

We will now show that these values of current can be made to satisfy the relation that has been established between the currents in adjacent strands of the actual conductor. Substitute these values of $(I'_{p+1} - I'_p)$ and $\sum_1^p I_p'$ in equation (8). That is assume that the currents in the imaginary strands of the solid conductor are exactly equal to the currents in the corresponding strands of the actual conductor

$$\left(\frac{\frac{\alpha\,d}{m}}{\sinh \frac{\alpha\,d}{m}} + \frac{l_2}{l_1} \right) \frac{w\,d}{m} \frac{2 \sinh^2 \frac{\beta\,d}{2\,m}}{\frac{\beta\,d}{2\,m}} (A' \sinh p/m\ \beta\,d + B' \cosh p/m\ \beta\,d) - \frac{\alpha\,d}{m} \left(\alpha\,a + 2 \tanh \frac{\alpha\,d}{2\,m} \right) I_0 - \frac{\alpha\,d}{m} \left(\alpha\,a + 2 \tanh \frac{\alpha\,d}{2\,m} \right) w/\beta \left(A' \sinh p/m\,\beta\,d + B' \cosh p/m\,\beta\,d - B' \right) = 0 \quad \textbf{(8a)}$$

This equation (8a) is satisfied if:

$$\left(\frac{\frac{\alpha\,d}{m}}{\sinh \frac{\alpha\,d}{m}} + \frac{l_2}{l_1} \right) \frac{w\,d}{m} \frac{2 \sinh^2 \frac{\beta\,d}{2\,m}}{\frac{\beta\,d}{2\,m}} - \frac{\alpha\,d}{m} \left(\alpha\,a + 2 \tanh \frac{\alpha\,d}{2\,m} \right) w/\beta = 0 \quad \textbf{(9a)}$$

and:

$$- \frac{\alpha\,d}{m} \left(\alpha\,a + 2 \tanh \frac{\alpha\,d}{2\,m} \right) I_0 + \frac{\alpha\,d}{m} \left(\alpha\,a + 2 \tanh \frac{\alpha\,d}{2\,m} \right) w/\beta\,B' = 0 \quad \textbf{(9b)}$$

These conditions readily reduce to

$$\sinh^2 \frac{\beta d}{2m} = \frac{\dfrac{\alpha d}{2m}\left(\dfrac{\alpha a}{2} + \tanh \dfrac{\alpha d}{2m}\right)}{\dfrac{\dfrac{\alpha d}{m}}{\sinh \dfrac{\alpha d}{m}} + \dfrac{l_2}{l_1}} \qquad \text{(10a)}$$

and
$$B' = \beta / w \, I_0 \qquad \text{(10b)}$$

If the total current in the conductor, actual or equivalent, is I, the vector constant A' is determined as in the preceding paper.

$$A' = \beta / w \left(\frac{I}{\sinh \beta d} - I_0 \tanh \frac{\beta d}{2} \right) \qquad \text{(10c)}$$

By equation (3) the current in the p strand is

$$I_p = \frac{w d}{m} \frac{\sinh \dfrac{\beta d}{2m}}{\dfrac{\beta d}{2m}} c_{pc}$$

$$= \frac{w d}{m} \frac{\sinh \dfrac{\beta d}{2m}}{\dfrac{\beta d}{2m}} \cdot \left(A' \cosh \frac{p - 1/2}{m} \beta d + B' \sinh \frac{p - 1/2}{m} \beta d \right)$$

$$= 2 \sinh \frac{\beta d}{2m} \left(I \frac{\cosh \dfrac{p - 1/2}{m} \beta d}{\sinh \beta d} - I_0 \tanh \frac{\beta d}{2} \cosh \frac{p - 1/2}{m} \beta d + I_0 \sinh \frac{p - 1/2}{m} \beta d \right) \qquad \text{(11)}$$

The current in the conductor below the p strand is

$$\sum_1^{p-1} I_p = \int_0^{\frac{p-1}{m} d} w c' \, dx$$

$$= w / \beta \left(A' \sinh \frac{p-1}{m} \beta d + B' \cosh \frac{p-1}{m} \beta d - B_1 \right)$$

$$= \frac{\sinh \dfrac{p-1}{m} \beta d}{\sinh \beta d} - I_0 \tanh \frac{\beta d}{2} \sinh \frac{p-1}{m} \beta d + I_0 \cosh \frac{p-1}{m} \beta d - I_0 \qquad \text{(12)}$$

The total current below the $q\,p$ strand of the actual conductor is

$$I_{bq} + \sum_1^{p-1} I_{qp},$$

where I_{bq} is the current in the slot below the q conductor.

If the current in any conductor and all of that below it in the slot are given the copper loss in the conductor may be calculated as described in the preceding paper. We are thus able to calculate the copper loss in any strand of any conductor. This method of calculation is far too laborious and we shall content ourselves with calculating the loss for a half turn (Case 1), a single turn (Cases 2 and 3) or for a single coil (Cases 4, 5 and 6). To do this it is necessary to obtain expressions for the voltage drop per half turn in the top element[3] of the top strand, in the bottom element[3] of the bottom strand and the voltage drop due to flux within a single conductor in all conductors below it.

The voltage drop per half turn in the topmost element of the $q\,p$ strand due to resistance and leakage below the $q\,(p+1)$ element is,

$$l_1 \rho \, c_{q_{pt}} + l_2 \rho \frac{m}{w d} I_{qp} + l_1 \rho \frac{m}{w d} I_{bq\,(p+1)} \frac{\alpha d}{m} \alpha a$$

The third term in this expression is the voltage drop due to flux within the insulation—of thickness a—that is immediately above the $q\,p$ strand. It is necessary to include this term in order that the voltage expressions about to be derived will be similar in certain respects to the general equation (8) for the currents in the strands.

By equation (4a) this reduces to

$$\rho \frac{m}{w d} \left\{ \left(l_1 \frac{\dfrac{\alpha d}{m}}{\sinh \dfrac{\alpha d}{m}} + l_2 \right) I_{qp} + l_1 I_{bq\,(p+1)} \frac{\alpha d}{m} \left(\alpha a + \tanh \frac{\alpha d}{2m} \right) \right\}$$

The voltage drop per half turn in the topmost element of the top strand of the q conductor of the upper coil side due to resistance and leakage flux below this element is,

$$\text{drop} = \rho \frac{m}{w d} l_1 \left[\left(\frac{\dfrac{\alpha d}{m}}{\sinh \dfrac{\alpha d}{m}} + \frac{l_2}{l_1} \right) I_{qm} + (I_{bq_1} + I) \frac{\alpha d}{m} \left(\alpha a + \tanh \frac{\alpha d}{2m} \right) \right] \qquad \text{(13)}$$

This pressure is used when the strands are numbered in the direct order. The loss in pressure per half turn in the lowest element of the bottom strand of the $q\,p$ conductor due to resistance and leakage flux below this element is:

$$l_1 \rho \, c_{q_{pb}} + l_2 \rho \frac{m}{w d} I_{qp}$$

3. Due to resistance and flux below it.

By equation (2) this reduces to:

$$\text{drop} = \rho \frac{m}{w\,d}\, l_1 \left\{ \left(\frac{\frac{\alpha d}{m}}{\sinh \frac{\alpha d}{m}} + \frac{l_2}{l_1} \right) I_{q_p} - I_{b q_p} \frac{\alpha d}{m} \tanh \frac{\alpha d}{2m} \right\}$$

The loss in pressure per half turn in the lowest element of the bottom—*i. e.* the q_1—strand of the q conductor of the upper coil side due to resistance and leakage flux below this element is,

$$\text{drop} = \rho \frac{m}{w\,d}\, l_1 \left\{ \left(\frac{\frac{\alpha d}{m}}{\sinh \frac{\alpha d}{m}} + \frac{l_2}{l_1} \right) I_{q_1} - I_{b q_1} \frac{\alpha d}{m} \left(\alpha\, a + \tanh \frac{\alpha d}{2m} \right) + I_{b q_1} \frac{\alpha d}{m} \,.\, \alpha\, a \right\} \tag{14}$$

This pressure is used when the strands are numbered in the reverse order. The equation is written in this form so that it will be similar to equation (13). When the strands are continuous from one half turn to the next and the end connection is turned over between successive half turns the top strand of one half turn becomes the bottom strand of the next half turn. Thus in equations (13) and (14) the I_{q_m} is the same as I_{q_1}.

The flux in the q conductor is,

$$\phi_q = \sum_1^m (\phi_{q_p} + \phi_a)$$

By equations (5) and (5a) this is,

$$\phi_q = \frac{1}{j\,\omega}\, l_1\, \rho \frac{m}{w\,d} \frac{\alpha d}{m} \left\{ \tanh \frac{\alpha d}{2m} \sum_1^m (I_{q_p} + 2\, I_{b q_p}) + \alpha\, a \sum_1^m (I_{q_p} + I_{b q_p}) \right\}$$

$$= \frac{1}{j\,\omega}\, \rho \frac{m}{w\,d}\, l_1 \left\{ I \frac{\alpha d}{m} \left(\alpha\, a + \tanh \frac{\alpha d}{2m} \right) + \sum_1^m I_{b q_p} \frac{\alpha d}{m} \left(\alpha\, a + 2 \tanh \frac{\alpha d}{2m} \right) \right\}$$

The summation in the second term in this expression for the flux may be written,

$$\begin{aligned} \sum_1^m I_{b q_p} = \Big(& I_{b q_1} + 0 \\ & + I_{b q_1} + I_{q_1} \\ & + I_{b q_1} + I_{q_1} + I_{q_2} \\ & + I_{b q_1} + I_{q_1} + I_{q_2} + I_{q_3} \\ & \quad \cdots \\ & + I_{b q_1} + \sum_1^{p-1} I_{q_p} \\ & \quad \cdots \\ & + I_{b q_1} + \sum_1^{m-1} I_{q_p} \\ = {} & m\, I_{b q_1} + \sum_1^{m-1} \sum_1^{p-1} I_{q_p} \Big) \end{aligned}$$

From equation (8) we have,

$$\frac{\alpha d}{m} \left(\alpha\, a + 2 \tanh \frac{\alpha d}{2m} \right) \sum_1^{p-1} I_{q_p} = \left(\frac{\frac{\alpha d}{m}}{\sinh \frac{\alpha d}{m}} + \frac{l_2}{l_1} \right) (I_{q_p} - I_{q\,(p-1)}) - \frac{\alpha d}{m} \left(\alpha\, a + 2 \tanh \frac{\alpha d}{2m} \right) I_0$$

If the $(m-1)$ equations for the adjacent strands are added together we have,

$$\frac{\alpha d}{m} \left(\alpha\, a + 2 \tanh \frac{\alpha d}{2m} \right) \sum_1^{m-1} \sum_1^{p-1} I_{q_p} = \left(\frac{\frac{\alpha d}{m}}{\sinh \frac{\alpha d}{m}} + \frac{l_2}{l_1} \right) (I_{q_m} - I_{q_1}) - (m-1) \frac{\alpha d}{m} \left(\alpha\, a + 2 \tanh \frac{\alpha d}{m} \right) I_0$$

Therefore the flux in the q conductor when the strands are numbered in the direct order is,

$$\phi_q = \frac{1}{j\,\omega}\, \rho \frac{m}{w\,d}\, l_1 \left[I \frac{\alpha d}{m} \left(\alpha\, a + \tanh \frac{\alpha d}{2m} \right) + \frac{\alpha d}{m} \left(\alpha\, a + 2 \tanh \frac{\alpha d}{2m} \right) m\, I_{b q_1} + \left(\frac{\frac{\alpha d}{m}}{\sinh \frac{\alpha d}{m}} + \frac{l_2}{l_1} \right) (I_{q_m} - I_{q_1}) - (m-1) \frac{\alpha d}{m} \left(\alpha\, a + 2 \tanh \frac{\alpha d}{2m} \right) I_0 \right] \tag{15}$$

If the strands are numbered in the reverse order, so that the first strand is at the top and the mth strand is at the bottom, the current in the conductor below the $q\,p$ strand is $I - \sum_1^p I_{q_p}$, and the $\sum_1^m I_{b q_p}$ is now:

$$\begin{aligned} \sum_1^m I_{b q_p} = {} & I_{b q_m} + I - I_{q_1} \\ & + I_{b q_m} + I - (I_{q_1} + I_{q_2}) \\ & + I_{b q_m} + I - \sum_1^p I_{q_p} \\ & + \cdots \\ & + I_{b q_m} + I - I \\ = {} & m\, (I_{b q_m} + I) - \sum_1^{m-1} \sum_1^p I_{q_p} - I \\ = {} & m\, I_{b q_m} + (m-1)\, I - \sum_1^{m-1} \sum_1^p I_{q_p} \end{aligned}$$

Therefore the flux in the q conductor when the strands are numbered in the reverse order is

$$\phi_q = \frac{1}{j\,\omega}\,\rho\,\frac{m}{w\,d}\,l_1\Bigg[\,I\,\frac{\alpha\,d}{m}\left(\alpha\,a + \tanh\frac{\alpha\,d}{2\,m}\right)$$

$$+\,\frac{\alpha\,d}{m}\left(\alpha\,a + 2\tanh\frac{\alpha\,d}{2\,m}\right)(m\,I_{b\,q_m} + (m-1)\,I)$$

$$-\left(\frac{\dfrac{\alpha\,d}{m}}{\sinh\dfrac{\alpha\,d}{m}} + \frac{l_2}{l_1}\right)(I_{q_m} - I_{q_1})$$

$$+\,(m-1)\,\frac{\alpha\,d}{m}\left(\alpha\,a + 2\tanh\frac{\alpha\,d}{2\,m}\right)I_0\Bigg] \qquad (16)$$

The loss in pressure as derived in equations (13) and (14) and the flux within a conductor depend upon the current in the top strand and the difference between the currents in the top and bottom strands. The current in the p strand is determined by equation (11).

The current in the top strand numbered in direct order, is I_{q_m}.

$$I_{q_m} = 2\sinh\frac{\beta\,d}{2\,m}\Bigg(I\,\frac{\cosh\dfrac{m-1/2}{m}\,\beta\,d}{\sinh\,\beta\,d}$$

$$-\,I_0\tanh\frac{\beta\,d}{2}\cosh\frac{m-1/2}{m}\,\beta\,d$$

$$+\,I_0\sinh\frac{m-1/2}{m}\,\beta\,d\Bigg)$$

Expand in terms of $\beta\,d$ and $\dfrac{\beta\,d}{2\,m}$

$$I_{q_m} = 2\sinh^2\frac{\beta\,d}{2\,m}\Bigg[\,I\left(\coth\,\beta\,d\coth\frac{\beta\,d}{2\,m} - 1\right)$$

$$+\,I_0\left(\tanh\frac{\beta\,d}{2}\coth\frac{\beta\,d}{2\,m} - 1\right)\Bigg] \qquad (17)$$

Likewise:

$$I_{q_1} = 2\sinh^2\frac{\beta\,d}{2\,m}\Bigg[\,I\,\frac{\coth\dfrac{\beta\,d}{2\,m}}{\sinh\,\beta\,d}$$

$$-\,I_0\left(\tanh\frac{\beta\,d}{2}\coth\frac{\beta\,d}{2\,m} - 1\right)\Bigg]$$

Thus:

$$(I_{q_m} - I_{q_1}) = 2\sinh^2\frac{\beta\,d}{2\,m}\Bigg[\,(I + 2\,I_0)$$

$$\left(\tanh\frac{\beta\,d}{2}\coth\frac{\beta\,d}{2\,m} - 1\right)\Bigg] \qquad (18)$$

The pressure equations which determine the resistance and reactance drops, *viz.* equations (13) to (16) inclusive are in terms of these currents in the top and bottom strands in addition to the conductor current and the current I_0. We will rewrite these equations, making the substitutions given in equations (17) and (18), and remembering that the I_{q_m} in (17) is the same as I_{q_1} in (14). We will also make the substitution shown in equation (10a).

Equation (13) becomes:

$$\text{drop} = \frac{\rho}{w\,d}\,l_1\Bigg[\,I\,\alpha\,d\,\frac{\left(\dfrac{\alpha\,a}{2} + \tanh\dfrac{\alpha\,d}{2\,m}\right)}{\tanh\dfrac{\beta\,d}{2\,m}}\coth\,\beta\,d$$

$$+\,I_0\,\alpha\,d\,\frac{\left(\dfrac{\alpha\,a}{2} + \tanh\dfrac{\alpha\,d}{2\,m}\right)}{\tanh\dfrac{\beta d}{2\,m}}\tanh\frac{\beta\,d}{2}$$

$$+\,(I_b - I_0)\,\alpha\,d\left(\frac{\alpha\,a}{2} + \tanh\frac{\alpha\,d}{2\,m}\right)$$

$$+\,(I + I_b)\,\alpha\,d\,.\,\frac{\alpha\,a}{2}\Bigg] \qquad (13a)$$

Equation (14) becomes:

$$\text{drop} = \frac{\rho}{w\,d}\,l_1\Bigg[\,I\,\alpha\,d\,\frac{\left(\dfrac{\alpha\,a}{2} + \tanh\dfrac{\alpha\,d}{2\,m}\right)}{\tanh\dfrac{\beta\,d}{2\,m}}\coth\,\beta\,d$$

$$+\,I_0\,\alpha\,d\,\frac{\left(\dfrac{\alpha\,a}{2} + \tanh\dfrac{\alpha\,d}{2\,m}\right)}{\tanh\dfrac{\beta\,d}{2\,m}}\tanh\frac{\beta\,d}{2}$$

$$-\,(I_b + I_0 + I)\,\alpha\,d\left(\frac{\alpha\,a}{2} + \tanh\frac{\alpha\,d}{2\,m}\right)$$

$$+\,I_b\,\alpha\,d\,.\,\frac{\alpha\,a}{2}\Bigg] \qquad (14a)$$

Equation (15) becomes:

$$\phi_q = \frac{1}{j\,\omega}\,\frac{\rho}{w\,d}\,l_1\Bigg[\,(I + 2\,I_0)$$

$$\alpha\,d\,\frac{\left(\dfrac{\alpha\,a}{2} + \tanh\dfrac{\alpha\,d}{2\,m}\right)}{\tanh\dfrac{\beta\,d}{2\,m}}\tanh\frac{\beta\,d}{2}$$

$$+\,(I_b - I_0)\,2\,m\,\alpha\,d\left(\frac{\alpha\,a}{2} + \tanh\frac{\alpha\,d}{2\,m}\right)$$

$$+\,I\,\alpha\,d\,.\,\frac{\alpha\,a}{2}\Bigg] \qquad (15a)$$

Equation (16) becomes:

$$\phi_q = \frac{1}{j\,\omega}\,\frac{\rho}{w\,d}\,l_1\Bigg[-\,(I + 2\,I_0)$$

$$\alpha\,d\,\frac{\left(\dfrac{\alpha\,a}{2} + \tanh\dfrac{\alpha\,d}{2\,m}\right)}{\tanh\dfrac{\beta\,d}{2\,m}}\tanh\frac{\beta\,d}{2}$$

$$+ (I_b + I_0 + I)\,\alpha d\, 2m\left(\frac{\alpha a}{2} + \tanh\frac{\alpha d}{2m}\right)$$

$$+ I\,\alpha d \cdot \frac{\alpha a}{2}\Bigg] \qquad \textbf{(16a)}$$

In each of these four equations I_b is the current in the slot below the conductor in question.

The writing of these equations is much simplified if we let:

$$\frac{l_1}{l_1 + l_2}\,\alpha d\,\frac{\left(\frac{\alpha a}{2} + \tanh\frac{\alpha d}{2m}\right)}{\tanh\frac{\beta d}{2m}}\,\coth \beta d$$

$$= M' = M_r' + j\,M_x'$$

$$\frac{l_1}{l_1 + l_2}\,\alpha d\,\frac{\left(\frac{\alpha a}{2} + \tanh\frac{\alpha d}{2m}\right)}{\tanh\frac{\beta d}{2m}}\,2\tanh\frac{\beta d}{2}$$

$$= N' = N_r' + j\,N_x'$$

$$\frac{l_1}{l_1 + l_2}\,\alpha d\, 2m\left(\frac{\alpha a}{2} + \tanh\frac{\alpha d}{2m}\right)$$

$$= T' = T_r' + j\,T_x'$$

$$\frac{l_1}{l_1 + l_2}\,\alpha d\,\alpha a = S' = j\,\frac{8\pi^2\,\omega f}{\rho s}\,d a$$

and $\frac{\rho}{wd}(l_1 + l_2) = R$ (the d-c. resistance of a half turn)

These equations may now be rewritten in simplified form. The resistance drop per half turn in the top element of the top strand of a conductor **(13a)** becomes:

$$\text{drop} = R\left[I M' + \frac{I_0 N'}{2} + (I_b - I_0)\frac{T'}{2m} + (I + I_b)\,S'/2\right] \qquad \textbf{(13b)}$$

If the strands are turned over in the end connections the resistance drop per half turn in the bottom element of the foregoing strand, which is now the lowest in the conductor **(14a)** becomes:

$$\text{drop} = R\left[I M' + \frac{I_0 N'}{2} - (I_b + I_0 + I)\frac{T'}{2m} + I_b\,S'/2\right] \qquad \textbf{(14b)}$$

The average resistance drop per half turn for the six cases considered is obtained from these two equations. By definition I_0 has such a value that the term involving T' in this average resistance drop is zero in every case. In order to simplify the expression we will let I_s represent the coefficient of $S'/2$. The average resistance drop per half turn is:

$$\text{av. drop} = R\left(I M' + \frac{I_0 N'}{2} + \frac{I_s S'}{2}\right) \qquad \textbf{(19)}$$

I_s is the average sum of the $(I + I_b)$'s in equation **(13a)** and the I_b's in equation **(14a)** taken in the proper combination.

Case 1. $I_s = I + (q - 1 + n\,/\underline{\theta})\,I$ upper coil side
$= (q + n\,/\underline{\theta})\,I$ upper coil side
$= q\,I$ lower coil side

Case 2. $I_s = 1/2\,\{[I + (q - 1 + n\,/\underline{\theta})\,I] + [I + (q-1)\,I]\}$
$= (q + n/2\,/\underline{\theta})\,I$

Case 3. $I_s = 1/2\,\{[I + (q - 1 + n\,/\underline{\theta})\,I] + [(q-1)\,I]\}$
$= (q - 1/2 + n/2\,/\,\theta)\,I$

Case 4. $I_s = 1/n \sum_1^n (q + n/2\,/\,\theta)\,I$
$= \left(\frac{n+1}{2} + n/2\,/\underline{\theta}\right) I$

Case 5. $I_s = \frac{1}{2n}\Big[(1 + n\,/\underline{\theta}) + (O) + (1 + n\,/\underline{\theta}) + (1 + 1) + (1 + 2 + n\,/\underline{\theta}) + (2) + \text{etc.}\Big]\,I$

The first term within the parenthesis is the current in the conductor plus the current below the first conductor of the upper coil side **(13b)**. The second term is the current below the first conductor of the lower coil side **(14b)**. This is zero. The third term is the current below the second conductor of the upper coil side **(14b)**. The fourth term is the current in the conductor plus the current below the second conductor of the lower coil side **(13b)**. Notice that this expression for I_s may be written:

$$I_s = \frac{1}{2n}\Big[(1 + n\,/\,\theta) + (3 + n\,/\underline{\theta}) + (5 + n\,/\underline{\theta}) + \ldots + (2n - 1 + n\,/\,\theta)\Big)\,I$$

$$I_s = \frac{1}{2n}\sum_1^n (2q - 1 + n\,/\,\theta)\,I$$

$$I_s = n/2 + n/2\,/\,\theta\,I$$

Case 6. $I_s = 1/n \sum_1^n (q - 1/2 + n/2\,/\,\theta)\,I$
$= (n/2 + n/2\,/\underline{\theta})\,I$

The pressure acting in all conductors below the q conductor due to flux within the latter is $j\,\omega\,\phi_q$. Written in the simplified form this **(15a)** becomes:

$$\text{drop} = R\,[(I/2 + I_0)\,N' + (I_b - I_0)\,T' + I/2\,S'] \qquad \textbf{(15b)}$$

If the strands are turned over in the end connections, the pressure due to flux within the next succeeding half turn **(16a)** becomes:

$$\text{drop} = R\,[-(I/2 + I_0)\,N' + (I_b + I_0 + I)\,T' + I/2\,S' \qquad \textbf{(16b)}$$

Reference to the preceding paper shows that these pressure expressions are similar to those already derived for solid and finely laminated conductors except for the added terms involving S'. M' replaces M, N' replaces N and T' replaces $\alpha^2 d^2$. The expressions become identical in the limiting case of an infinite number of strands with no insulation between them.

Calculation of Copper Loss

The method of calculation is the same as that used in the preceding paper.

Case 1. When the strands are joined at the beginning and end of a half turn the copper loss in the half turn is symbolically:

$$\text{loss} = I \,.\, R\,(I\,M' + I_b/2\,N' + I_s\,2\,S') + I_b \,.\, R\,[\,(I/2 + I_s/2)\,N' + I/2\,S'\,]$$

In this case notice that $I_b = I_0$

The first term is the power loss due to the current in the conductor and the resistance drop in the topmost element of the topmost strand. The second term is the power due to the current in the slot below this conductor and to the pressure acting on it produced by the flux within the conductor. Expanding this expression gives:

$$\text{power} = I \,.\, R\,I\,M' + I \,.\, R\,\frac{I_b}{2}N' + I \,.\, R\,\frac{I_s}{2}S'$$

$$+ I_b \,.\, R\,\frac{I}{2}N' + I_b \,.\, R\,I_b\,N' + I_b \,.\, R\,\frac{I}{2}\,S'.$$

The first term is $R\,I^2\,M_r'$. The sum of the second and fourth terms is $R\,I\,I_b\,N_r'\,\cos\theta_b$. The fifth term is $R\,I_b^2\,N_r'$ and since S' is a pure imaginary the sum of the third and sixth terms is zero. The expression for the power may be written:

$$\text{loss} = R\,[I^2\,M_r' + (I \,.\, I_b \cos\theta_b + I_b^2)\,N_r']$$

The phase angle θ_b is between the current, I, in the conductor and the total current, I_b, in the slot below it. Here the letters I and I_b represent the numerical values of the currents.

If this copper loss due to alternating current is divided by the loss due to the same amount of direct current, we obtain the ratio of alternating to direct-current resistance.

(a) The ratio of alternating to direct current resistance for a single half turn is:

$$K = \{M_r' + [\,(I_b/I)^2 + I_b/I \cos\theta_b]\,N_r'\}$$

(b) The average resistance ratio for a one-coil-side-per-slot winding having n layers is:

$$K = 1/n \sum_1^n \{M_r' + [\,(q-1)^2 + (q-1)\,]\,N_r'\}$$

$$= \left(M_r' + \frac{n^2-1}{3}N_r'\right)$$

(c) The average resistance ratio for the upper coil side of a two-coil-side-per-slot winding having n layers per coil side reduces to

$$K = \left[\,M_r' + \left(\frac{4\,n^2-1}{3} + n^2\cos\theta\right)N_r'\,\right]$$

θ is the phase angle between the currents in the upper and lower coil sides.

If the strands are joined at the beginning and end of a whole turn the loss ratio is a little more difficult to calculate inasmuch as the losses in the two half turns are different. There are two cases to consider, one in which the end connections are not turned over and one in which they are turned over.

Case 2. Strands joined at the beginning and end of a single turn; end connections not turned over. The heating loss in the whole turn may be expressed symbolically as:

$$\text{loss} = 2\,I \,.\, R\,(I\,M' + I_0/2\,N' + I_s\,S'/2) + I_b' \,.\, R\,[\,(I/2 + I_0)\,N' + (I_b' - I_0)\,T' + I/2\,S'\,] + I_b'' \,.\, R\,[\,(I/2 + I_0)\,N' + (I_b'' - I_0, T' + I/2\,S'\,]$$

The first term is the power due to the current in the conductor and the resistance drop in the top element of the top strand of the turn. The second term is the power due to the current, I_b', below the upper half turn and the pressure produced by the flux within this half turn. Similarly the third term is the power due to the current, I_b'', below the lower half turn and the pressure produced by the flux within this half turn. For the q conductor, $I_b' = I\,(q - 1 + n\,\underline{/\theta})$ and $I_b'' = I\,(q-1)$. We have also shown that in this case (2) $I_s = I\,(q + n/2\,\underline{/\theta})$, and $I_0 = I\,(q - 1 + n/2\,\underline{/\theta})$.

As before θ is the phase angle between the currents in the upper and lower coil sides lying in the same slot. Making these substitutions and dividing by the direct-current resistance loss for a whole turn gives a resistance ratio per turn of

$$K = (M_r' + (q^2 - q + n^2/4 + (2\,q-1)\,n/2\cos\theta)\,N_r' + n^2/4\;T_r')$$

The average value of this resistance ratio for a whole coil of n turns is

$$K = \left[\,M_r' + \left(\frac{7\,n^2-4}{12} + n^2/2\cos\theta\right)N_r' + n^2/4\;T_r'\,\right]$$

Case 3. Strands joined at the beginning and end of a whole turn; end connections turned over. The heating loss for a whole turn is now:

$$\text{loss} = 2\,I \,.\, R\,(I\,M' + I_0/2\;N' + I_s\;S'/2) + I \,.\, R\,(-\,(I/2 + I_0)\,N' + (I_b'' + I_0 + I)\,T' + I\;S'/2 + I_b'\,R\,[\,(I/2 + I_0)\,N' + (I_b' - I_0)\,T' + I\,S'/2\,]$$

$$+ I_b'' \cdot R[-(I/2 + I_0) N' + (I_b'' + I_0 + I) T' + I S'/2]$$

The first term is the power due to the current in the turn and the resistance drop in the top strand of the turn in the upper coil side and the bottom strand of the turn in the lower coil side. Due to the turning over of the end connections these two half-turn strands are a part of the same strand. The second term is the power due to the current in the turn and the pressure produced by the flux within the half turn that is in the lower coil side. The third term is the power due to the current below the half turn in the upper coil side and the pressure acting on this current that is produced by the flux within this half turn. The fourth term is similarly the power due to the current below the half turn in the lower coil side and the pressure acting on this current that is produced by the flux within this half turn. In this case:

$$I_0 = (-1/2 + n/2 \angle\theta) I \quad I_b' = (q - 1 + n \angle\theta) I$$
$$I_s = (q - 1/2 + n/2 \angle\theta) I \quad I_b'' = (q - 1) I$$

Making these substitutions the resistance ratio for a whole turn reduces to:

$$K = \left\{ M_r' + \frac{n^2 - 1}{4} N_r' + [(2q - 1)^2 + n^2 + 2(2q - 1) n \cos\theta] T_r'/4 \right\}$$

The average resistance ratio for a whole coil of n turns is:

$$K = \left[M_r' + \frac{n^2 - 1}{4} N_r' + \left(\frac{7n^2 - 1}{12} + n^2/2 \cos\theta \right) T_r' \right]$$

The method of calculating the leakage impedance when the stranding is continuous throughout a whole coil is described in considerable detail in the preceding paper and need not be repeated here. With a finite number of strands, however, there are added terms involving S' which appear on account of the insulation between the strands. Fortunately their effect is not difficult to calculate.

The added resistance drop in a coil of n turns is (equation 19) $2 n R I_s/2 S'$. Values of I_s have already been calculated for the different cases. The added pressure acting in the coil side which lies in the bottom of the slot due to flux within the coil side above it is $n R (n \angle -\theta) I/2 S'$. The other added terms are those due to the pressure acting in the conductors of the coil produced by flux within the coil itself. There are three cases, *viz.*, 4, 5 and 6.

Case 4. When the end connections are not turned over the resistance drop taken is that in the upper element of the top strand of the conductors of both coil sides. The added drop is then:

$$\sum_1^n 2(q-1) R I/2 S' \quad \text{or} \quad \frac{n(n-1)}{2} R I S'$$

Case 5. When the end connections are turned over on one side only the resistance drop taken is that in the top element of the top strand of the first half turn plus that in the bottom element of the bottom strand of the next half turn plus that in the bottom element of the bottom strand of the next half turn plus that in the top element of the top strand of the next half turn plus, etc. In this case it is readily shown that the added drop is:

$$\sum_1^n (2q - 1) R I/2 S' \quad \text{or} \quad n^2/2 R I S'$$

Case 6. When the end connections are turned over on both sides the resistance drop taken is that in the top elements of the top strands of one coil side and the bottom elements of the bottom strands of the other coil side. The added pressure is thus

$$\sum_1^n (q-1) R I/2 S' + \sum_1^n q R I/2 S') \quad \text{or} \quad n^2/2 R I S'$$

The sum of these three component added terms is the same in each of the three cases. It is $(n^2 + n^2 \cos\theta) R I S'$.

The average value for a single half turn is $(n/2 + n/2 \cos\theta) R I S'$.

We may now write the expressions for the slot leakage impedance of a symmetrical pair of fractional pitch slots.

Refer to the preceding paper.

Case 4. End connections not turned over.

$$Z = R_c \left[M' + \left(\frac{2n^2 - 1}{4} + n^2/2 \cos\theta \right) N' + \frac{4n^2 - 1}{12} T' + (n/2 + n/2 \cos\theta) S' \right]$$

where R_c is the true resistance of a whole coil.

Case 5. End connections turned over on one side only. Even number of conductors per coil side.

$$Z = R_c \left[M' - N'/4 + \left(\frac{10n^2 - 1}{12} + n^2/2 \cos\theta \right) T' + (n/2 + n/2 \cos\theta) S' \right]$$

Case 5. Odd number of conductors per coil side.

$$Z = R_c \left[M' + \left(\frac{10n^2 - 1}{12} + n^2/2 \cos\theta \right) T' + (n/2 + n/2 \cos\theta) S' \right]$$

Case 6. End connections turned over on both sides.

$$Z = R_c \left[M' + \frac{n^2 - 1}{4} N' + \left(\frac{7n^2 - 1}{12} \right.\right.$$

$$+ n^2/2 \cos \theta \Big) T' + (n/2 + n/2 \cos \theta) S' \Big]$$

Since S' is pure imaginary, the terms involving it do not appear in the expressions for the alternating-current resistance. In the preceding paper $\alpha^2 d^2$ which is now replaced by T' was pure imaginary. T', however, has both real and imaginary parts, and thus adds to the value of the alternating-current resistance.

There follows a numerical calculation of the heat losses in a specified winding. The pitch of the coils is one and the dimensions of the slot and the conductors are:

Width of slot (s)	= 2.54	cm.
Width of conductor (w)	= 1.60	"
Length of armature core (l_1)	= 72.4	"
Length of end turn (l_2)	= 80.0	"
Depth of strand (d/m)	= 0.254	"
Thickness of insulation between strands (a)	= 0.0381	"
Number of strands per conductor (m)	= 7.0	
Number of conductors per coil side (n)	= 2.0	
Frequency (f)	= 60 cycles	
Average temperature of winding	= 100 deg.cent	

ρ = 2260 c. g. s. ohms at 100 deg. cent.

$$\alpha = 2\pi \sqrt{\frac{2 w f}{\rho s}} \,/\, \underline{45°} = 1.15 \,/\, \underline{45°}$$

$$\frac{\alpha d}{m} = 0.292 \,/\, \underline{45°}$$

$$\frac{\alpha d}{2m} = 0.146 \,/\, \underline{45°}$$

$$\frac{\alpha a}{2} = 0.0219 \,/\, \underline{45°}$$

$$\tanh \frac{\alpha d}{2m} = 0.146 \,/\, \underline{44° 36.5'}\ {}^{4}$$

$$\frac{\dfrac{\alpha d}{m}}{\sinh \dfrac{\alpha d}{m}} = 1.00 \,/\, \underline{-0.82}\ {}^{4}$$

$$\frac{T'}{4 m^2} = \frac{\alpha d}{2m} \cdot \left(\frac{\alpha a}{2} + \tanh \frac{\alpha d}{2m}\right)$$

$$= 0.0245 \,/\, \underline{89° 38.5'}$$

From equation (**10a**)

$$\sinh \frac{\beta d}{2m} = \sqrt{\frac{\dfrac{\alpha d}{2m}\left(\dfrac{\alpha a}{2} + \tanh \dfrac{\alpha d}{2m}\right)}{\dfrac{\dfrac{\alpha d}{m}}{\sinh \dfrac{\alpha d}{m}} + \dfrac{l_2}{l_1}}}$$

4. From Kennelly's "Tables of Complex Hyperbolic and Circular Functions."

$$\sinh \frac{\beta d}{2m} = \sqrt{\frac{0.0245 \,/\, \underline{89° 38.5'}}{1.0 \,/\, \underline{-0.82°} + 1.105}}$$

$$= \sqrt{0.01164 \,/\, \underline{45° 1.5'}}$$

$$= 0.07628 + j\, 0.07634$$

Let $\dfrac{\beta d}{2m} = g + j k$

$$\sinh (g + j k) = \sinh g \cos k + j \cosh g \sin k$$

$$= A + j B = C \,/\, \underline{\tanh^{-1} B/A}$$

That is $\sinh g \cos k = A$

$\cosh g \sin k = B$

Solving these two equations for g and k gives:

$$\sinh g = \sqrt{\frac{-(1 - C^2) + \sqrt{(1 - C^2)^2 + 4 A^2}}{2}}$$

and $$\sin k = \sqrt{\frac{1 + C^2 - \sqrt{(1 + C^2)^2 - 4 B^2}}{2}}$$

Substitution in these solutions shows that:

$\sinh g = 0.0766$ $\quad g = 0.0767$

$\sin k = 0.0761$ $\quad k = 0.0762$ radians

Therefore $$\frac{\beta d}{2m} = 0.108 \,/\, \underline{44° 50'}$$

$\tanh \dfrac{\beta d}{2m}$ is readily computed in this case from

$$\tanh \frac{\beta d}{2m} = \frac{\sinh \dfrac{\beta d}{2m}}{\sqrt{1 + \sinh^2 \dfrac{\beta d}{2m}}}$$

$$= \frac{0.1079 \,/\, \underline{45° 1.5'}}{\sqrt{1 + 0.01164 \,/\, \underline{90° 3'}}}$$

$$= 0.1079 \,/\, \underline{44° 21.5'}$$

$$\alpha d \, \frac{\dfrac{\alpha a}{2} + \tanh \dfrac{\alpha d}{2m}}{\tanh \dfrac{\beta d}{2m}} = 3.18 \,/\, \underline{45° 19'}$$

The values of $\coth \beta d$ and $2 \tanh \dfrac{\beta d}{2}$ can be computed from the formulas:

$\coth \beta d$

$$= \frac{\sinh 2 m g \cosh 2 m g - j \sin 2 m k \cos 2 m k}{\sinh^2 2 m g \cos^2 2 m k + \cosh^2 2 m g \sin^2 2 m k}$$

$2 \tanh \dfrac{\beta d}{2}$

$$= 2 \, \frac{\sinh m g \cosh m g + j \sin m k \cos m k}{\cosh^2 m g \cos^2 m k + \sinh^2 m g \sin^2 m k}$$

From which

$$\coth \beta d = 0.8835 \,/\, \underline{-11° 20'}$$

$$2 \tanh \frac{\beta d}{2} = 1.472 \,/\, \underline{34° 7'}$$

The complex quantities M', N' and T' may now be calculated

$$M' = 1.335\ \underline{/33°59} = 1.11 + j\,0.746$$
$$N' = 2.22\ \underline{/79°26'} = 0.408 + j\,2.19$$
$$T' = 2.28\ \underline{/89°38.5'} = 0.014 + j\,2.28$$

If the number of strands, m, is increased without limit while the depth of the conductor and the relative amount of insulation between the strands are unchanged we have:

$$\sinh \frac{\beta d}{2\,m} \doteq \frac{\beta\,d}{2\,m} \doteq \frac{\alpha\,d}{2\,m}\sqrt{\frac{a/d+1}{l_2/l_1+1}}$$

since $\tanh \dfrac{\alpha\,d}{2\,m} \doteq \dfrac{\alpha\,d}{2\,m}$

and $$\frac{\dfrac{\alpha\,d}{m}}{\sinh \dfrac{\alpha\,d}{m}} \doteq 1$$

$$M' \doteq \beta\,d \coth \beta\,d$$

$$N' \doteq \beta\,d\,2\tanh\frac{\beta\,d}{2}$$

For the winding we are considering,

$$\beta\,d \doteq 0.739\,\alpha\,d \doteq 1.51\ \underline{/45°}$$

For this value of $\beta\,d$; $M_r{}' = 1.11$ and $N_r{}' = 0.413$. In this case, since T' is pure imaginary, $T_r{}' = 0$.

A further calculation has been made for conductors of the same net cross-section, but consisting of three strands instead of seven. In this case:

$$M' = 1.295\ \underline{/33°9'} \qquad M_r{}' = 1.084$$
$$N' = 2.04\ \underline{/80°52'} \qquad N_r{}' = 0.324$$
$$T' = 2.086\ \underline{/87°52'} \qquad T_r{}' = 0.0776$$

The following is a table of the ratios of alternating to direct-current resistance for this winding for each of the six strand arrangements.

Strand Arrangement	Resistance Ratio		
	$m = \alpha$	$m = 7$	$m = 3$
Case 1	3.17	3.15	2.70
" 2	2.76	2.75	2.46
" 3	1.42	1.47	1.66
" 4	2.66	2.66	2.40
" 5	1.01	1.08	1.41
" 6	1.42	1.47	1.66

Discussion

W. V. Lyon (by letter): A series of curves has been plotted which, though they may not be of particular value themselves, indicate a line of investigation that should prove of considerable importance. Curves similar to them have been discussed by Rogowski and others.

The curves marked "I" are for the upper bar of a laminated bar winding, with two bars per slot.

The curves marked "II" are the average values for the slot. Laminated conductors with laminations joined at the beginning and end of each turn. Two turns per coil, two coil sides per slot.

The curves marked "III" are the average values for the slot. The winding is exactly like the preceding case but the end connections are turned over.

The curves marked "IV" are the average values for the slot. Laminated coil with laminations joined at the beginning and end of the coil. Two turns per coil, two coil sides per slot. End connections turned over.

All of these curves are plotted for full-pitch, finely laminated windings. The length of the armature core is assumed equal to the length of one end connection. The ordinates of these curves show relative values only. The abscissas, $\alpha\,d$, are roughly equal to the depth of the conductor in centimeters for a frequency of 60 cycles.

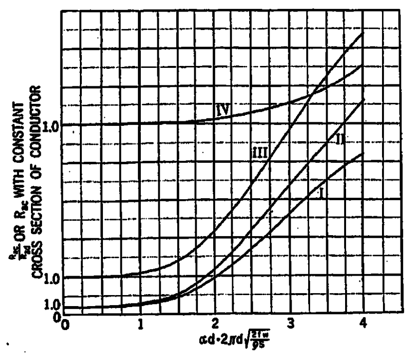

Fig. 1

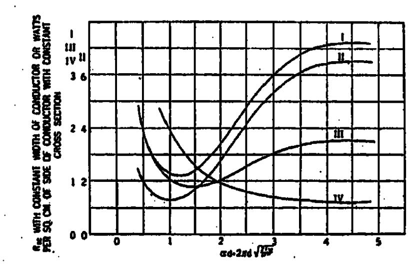

Fig. 2

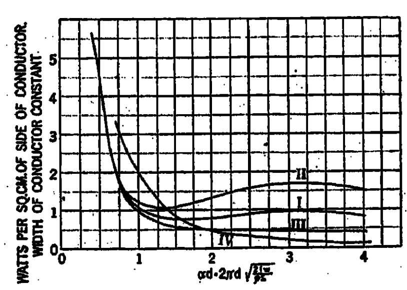

Fig. 3

Fig. 1 shows how entirely inappropriate laminated bar windings are when the conductors are deeper than about one centimeter. Fig. 2 shows that with conductors of constant width there is a depth which makes the alternating-current resistance a minimum. This has been called the critical depth. Notice that with the better types of windings, viz. III and IV, the critical depth is greater. The ordinates of those curves may also represent the watts per square centimeter of coil side for conductors of constant cross section. If all of the heat developed in the conductors passed through the *sides* of the coil, which of course it does not, these curves would show a truly critical depth.

If the width of the conductor is kept constant the watts per square centimeter of coil side do not reach as distinct a minimum value. In fact in the better windings, III and IV there is no minimum, *i. e.*, critical depth. Fig. 3.

Taking the surface through which the heat is conducted from the coil as the entire perimeter of the cross section of the coil the watts per square centimeter of insulation are plotted in Fig. 4. These curves were plotted for cases in which the cross section of the conductors was nine square centimeters and the thickness of the insulation was one-half a centimeter.

It seems that these curves only emphasize the need of a thorough investigation of the heat conduction through the insulation of embedded conductors. The problem is further complicated in that the best shape of conductor must be determined by considering not only the heat generated within it but also by the eddy current and hysteresis losses produced in the neighboring iron.

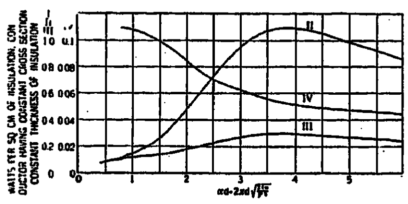

FIG. 4

M. S. Vallarta (by letter): Although a few resistance-ratio and temperature measurements have occasionally been reported, no thorough experimental investigation of the Field theory of skin-effect in embedded conductors has to our knowledge ever been undertaken. In order to fill this gap, such an investigation is now in progress at the Research Division of the Electrical Engineering Department, Massachusetts Institute of Technology. Its main purpose is to furnish experimental proof of the correctness of Field's assumptions, since the rest of the theory and its applications, as developed by Rogowski, Richter, Gilman and very recently by Professor Lyon, in his simple method involving the hyperbolic functions of a complex variable, follow from these assumptions by a process of mathematical deduction. Owing to experimental difficulties it has been found necessary, however, to test both the assumptions and the conclusions, as a check on the complete theory.

A piece of standard laminated slotted armature was kindly furnished for these tests by the Westinghouse Company, to which we acknowledge our indebtedness. This is mounted on a wooden framework, away from any magnetic material. So far as the magnetic circuit is concerned, conditions are in close agreement with the ideal demands of the theory.

For the purpose of obtaining the greatest possible resistance, the test coils are made of thin copper strip wound longitudinally in the slots, with its largest dimension parallel to the slot side and with paper-insulated turns. So far as one-dimensional skin-effect is concerned, which is the only one considered in the Field theory, these coils are the exact equivalent of a solid bar conductor of the same dimensions. Stranded conductors with twisted end connections have not been thus far experimentally investigated.

To test the assumption that an element of current in the slot produces no field below it, an exploring coil was placed longitudinally in the slot, with its plane parallel to the slot side, below a current carrying conductor. This exploring coil was connected through a shielded two-step vacuum tube amplifying circuit and thermocouple to a sensitive galvanometer. No deflection could in any case be obtained, thus confirming the assumption. No satisfactory proof of Field's assumption of no component of field strength parallel to the slot side has been found.

An experimental curve of cross-flux distribution was determined by winding five equi-distant exploring coils around the tooth and measuring the voltage induced in them when an alternating current flows through the slot conductors. This voltage was measured by connecting the exploring coils in turn to a sensitive galvanometer through a shielded two-step vacuum tube amplifying circuit and thermocouple. To eliminate tooth-tip leakage, an exploring coil at the top of the slot was always connected in series opposition with the coil through which the flux was measured.

The curve of cross-flux distribution is easily calculated from equation four of Professor Lyon's first paper. The flux linking an exploring coil distance x from the bottom of the upper conductor is

$$\phi_1 = \int_x^d \frac{4\pi l}{s}\left[\int_0^x w\,c\,dx + I_2\right] dx$$

where $c = f(x)$ is given by the equation quoted above, *i. e.*,

$$c = \alpha/w\left[I_1 \frac{\cosh \alpha x}{\sinh \alpha d} - I_2 \tanh \frac{\alpha d}{2} \cosh \alpha x + I_2 \sinh \alpha x\right]$$

It follows by integration, if $I_1 = I_2 = I$.

$$\phi_1 = \frac{4\pi l I}{\alpha s}\left[\coth \alpha d - \frac{\cosh \alpha x}{\sinh \alpha d} - \tanh \frac{\alpha d}{2} (\cosh \alpha d - \cosh \alpha x) + \sinh \alpha d - \sinh \alpha x\right]$$

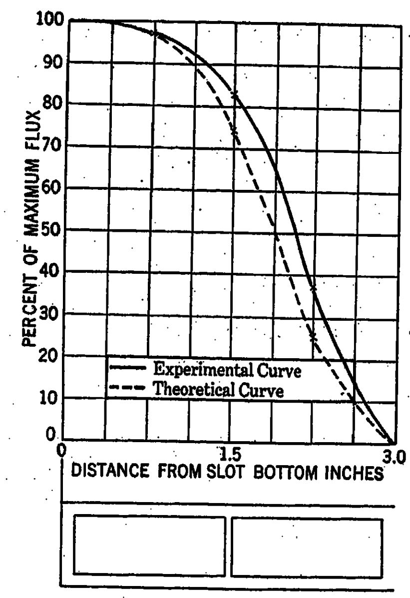

FIG. 5

For the lower conductor alone:

$$\phi_2 = \int_x^d \frac{4\pi l}{s}\left[\int_0^x w\,c\,dx\right] dx$$

with

$$c = \frac{\alpha I}{w} \quad \frac{\cosh \alpha x}{\sinh \alpha d}$$

whence

$$\phi_2 = \frac{4\pi l I}{\alpha s}\left[\coth \alpha d - \frac{\cosh \alpha x}{\sinh \alpha d}\right]$$

Let ϕ_{10} be the total flux linking an exploring coil at the bottom

of the upper conductor. The total flux linking an exploring coil distance x from the bottom of the slot is:

$$\phi = \phi_{10} + \phi_2$$

From which the flux at any point along the lower conductor can be calculated.

The experimental and calculated curves of cross-flux distribution are given in Fig. 5. The agreement is considered satisfactory, within the limits of experimental error.

Resistance-ratio measurements have also been made. Power is measured by the three-voltmeter method, especial precautions being taken to have a sinusoidal voltage wave. Oscillographic records show that this condition was in every case closely fulfilled. The disturbing effect of uneven temperature distribution is largely eliminated by operating only after a steady uniform temperature, such as caused by a direct current, has been reached, then making all a-c. measurements within a short interval. To correct for iron loss, a coil of fine magnet wire was wound around the teeth, the excitation being distributed so as to correspond as closely as possible with conditions in the slot conductors. Phase difference effects of course cannot be imitated with this arrangement. The skin effect of such a winding is assumed to be negligible.

Results of resistance-ratio measurements and computation data are given below. Each power measurement given is the average of at least five runs. The precision of individual measurements is estimated at one per cent or better.

COMPUTATION DATA

Dimensions of slot: Width	1.905	cm.
Length	40.6	cm.
Depth	7.62	cm.
Effective width of conductor	1.418	cm.
Effective height of conductor	3.58	cm.
Frequency	60.0	cycles
Temperature	65	deg. cent.

TABLE I

Measured power watts	Measurements for two conductors in series: Current amperes	Correction for end turns watts [1]	Correction for iron loss watts	Net power watts	A-C. resistance ohms
204.9	9.14	3.84	6.05	195.0	2.34
68.0	5.21	1.22	2.21	64.6	2.38
11.53	2.131	0.20	0.50	10.83	2.39
3.32	1.136	0.05	0.22	3.05	2.38
				Average	2.37 ohms
	Embedded portion d-c. resistance				0.2251 ohms
	Resistance ratio				10.52
	Calculated resistance ratio				10.26
	Difference				2.5%

TABLE II [2]

Measured power watts	Measurements for lower conductor: Current amperes	Correction for end turns watts [1]	Correction for iron loss watts	Net power watts	A-C. resistance ohms
95.8	15.16	5.25	3.14	87.4	0.382
34.9	9.16	1.92	1.21	31.7	0.378
11.81	5.32	0.65	0.37	10.79	0.381
1.98	2.21	0.09	0.05	1.84	0.377
	Average				0.3795 ohms
	Embedded portion d-c. resistance				0.1148 ohms
	Resistance ratio				3.30
	Calculated resistance ratio				3.25
	Difference				2.0%

1. Length of end turns is 20 per cent of total length. Correction assumes that skin effect in air for the coils is negligible, which is borne out by experiment.

2. Lower conductor alone in slot.

TABLE III [3]

Measured power watts	Measurements for upper conductor: Current amperes	Correction for end turns watts [1]	Correction for iron loss watts	Net power watts	A-C. resistance ohms
181.5	9.36	2.15	2.36	177.0	2.04
62.7	5.47	0.74	1.54	60.4	2.01
10.17	2.145	0.11	0.46	9.60	1.98
2.70	1.140	0.03	0.07	2.60	2.00
	Average				2.01 ohms
	Embedded portion d-c. resistance				0.1110 ohms
	Resistance ratio				18.1
	Calculated resistance ratio				17.27
	Difference				4.8%

3. Both conductors carrying the same current.

It is seen from the above that, as far as can be judged from our present evidence, the complex hyperbolic method developed by Prof. Lyon correctly describes the cross-flux distribution and gives simple means of computing the resistance ratio of ideal bar windings with engineering accuracy.

In connection with this investigation, the following bibliography has been prepared:

V. Karapetoff: Prof. Lyon deserves much credit for having worked out in detail various expressions for heat losses in armature conductors, with a non-uniform distribution of current. I wish only to point out some possible improvements in the fundamental mathematical treatment, and to indicate the next steps that might be taken in the solution of this important problem.

1. *Gilman's Work.* In June 1920 Mr. R. E. Gilman presented before the Institute a highly mathematical paper on the same subject (TRANS. Vol 39, p. 997), and it is to be regretted that in Prof. Lyon's paper, presented a year and a half later, before the same body, no attempt is made to correlate his work with that of Gilman's, and to point out identical results, discrepancies, if any, advantages and disadvantages of the two different methods of mathematical analysis. It remains for a future investigator to finish this part of the work.

2. *Exponential Notation.* In my discussion of Gilman's paper (*ibid*, p. 1054) the advantages of exponential notation are pointed out, and it is shown that several pages of long tedious formulas may be done away with, and that a solution of certain simultaneous equations is obviated. It now remains to compare the method of exponential notation with the use of hyperbolic functions of a complex variable, as used in Prof. Lyon's paper. In making this comparison, it is necessary to keep in mind that at the present time we have only Kennelly's tables of such functions, with steps of such magnitude that the two-directional interpolation is quite tedious. The building up of hyperbolic functions of a complex variable out of those of real variables also takes considerable time.

3. *The fundamental differential equation.* The fundamental differential equation of distribution of alternating-current density in a long conductor, subjected to a transverse magnetic flux, is not original either with Mr. Gilman or with Prof. Lyon. See, for example, A. Russell, Alternating Currents, Vol. I, index under "eddy currents." This equation can now be derived much more directly from Heaviside's laws of circuitation which are familiar to the younger generation of engineers. We want as wide a circle of readers for our Institute papers as possible, and any simplification in mathematics, any deduction directly from a general physical law, rather than by a special "follow me" method, is a step in the right direction.

4. *Some mathematical simplifications.* Prof. Lyon's paper being based on a well-known fundamental equation, the value of the contribution lies mainly in the application of the solution to certain specific cases. The solution must be in the simplest possible form for numerical computations. An inspection of his formulas shows the possibility of considerable further simplification. The formulas used in the present paper are based on equation (3) in his first paper (TRANS., 1921, Vol. 40, p. 1361). and it is therefore necessary to go back to that paper in order to indicate an alternative treatment.

The objections to Prof. Lyon's formulas are (a) that they are involved and unsymmetrical, and (b) that the variable x enters in the same formula in two or more places. What seems to be a simpler form of solution both for a general development and for numerical work, is indicated below; the equations numbers **1**, **2** and **3**, refer to Lyon's first paper:

Let the general solution of equation (2) be written in the form of

$$\dot{c} = (\alpha/w)\ \dot{D} \operatorname{Sinh} (\alpha\, y + \beta) \qquad \textbf{(10)}$$

This solution differs from equation (3) in the following respects: (a) the expression (α/w) is written out explicitly in order to simplify further transformations; (b) the variable distance, y, is assumed to be measured from the center of the conductor, in order to make the equations more symmetrical. In the original paper the corresponding variable, x, is measured from the lower edge; (c) the variable y enters in the equation only once, while equation (3) contains x twice; (d) The two constants of integration are D and β, that is, directly the amplitude and the phase, instead of the components A and B.

To determine $\dot{D}$ and β, we substitute expression (**10**) in equation (**1**), and in the formula for $\dot{I}_1$*. After simplification we find:

$$\tanh \beta = [I_1/(I_1 + 2\, I_0)] \quad \operatorname{Coth} \alpha\, d/2 \qquad \textbf{(11)}$$

$$\dot{D} = \frac{1}{2}\, I_1/(\operatorname{Sinh} \beta \operatorname{Sinh} \alpha\, d/2) \qquad \textbf{(12)}$$

Equation (**10**), with the auxiliary expressions (**11**) and (**12**) leads to simpler formulas and computations than the formulas used in both of Prof. Lyon's papers. For the current density at the center of the conductor we have, putting $y = 0$,

$$\dot{c} = (\alpha/w)\ \dot{D} \operatorname{Sinh} \beta \qquad \textbf{(13)}$$

or, substituting for $\dot{D}$ its value from eq. (**12**),

$$\dot{c} = \alpha\, I_1/(2\, w \operatorname{Sinh} \alpha\, d/2) \qquad \textbf{(14)}$$

which checks with Prof. Lyon's expression.†

5. *Future Work.* There is no reason why this problem should not be brought now to a final solution, at least in application to standard turbo-alternators. By this I mean a set of curves, charts, tables, etc. with which a designer could safely compute the armature copper loss for an assumed arrangement of conductors. At the present stage the designer would have to study one or two highly mathematical articles and then perform rather long computations before he could get a specific result. Should he then decide to change his winding, much of the numerical work would have to be repeated.

Current Locus of Single-Phase Induction Motors

BY J. K. KOSTKO
Associate A. I. E. E.
Wagner Electric Manufacturing Company, St. Louis, Mo.

***Review of the Subject.**—The principal applications of the current locus of single-phase induction motors are the predetermination of the performance of a projected motor on the basis of its constants, and the determination of the performance and constants of an existing motor on the basis of a few simple tests. The first question is particularly attractive to a mathematically trained mind, because, with constants considered as known, it is simply a problem of mathematics; a great amount of work has been done to find and perfect its solution. The second problem is, perhaps, more difficult than the first. Its thorough treatment requires not only the knowledge of the solution of the first problem, but also the ability to make use of more or less complicated combinations of constants given by tests instead of the constants themselves; moreover, the exact solution usually cannot be obtained, and one is obliged to make certain incorrect assumptions, drawing upon the practical experience to set proper limits to these inaccuracies; for this reason, perhaps, the second problem has always been less popular with investigators than the first, and the available results still leave room for improvement, especially in connection with the "tilted" diagram.*

In what follows this problem is treated by a method which is believed to combine the accuracy with comparative simplicity of the final results—the latter, at least, to the extent which can reasonably be expected when dealing with an apparatus of such inherent complexity as the single-phase induction motor.

CONTENTS

Current Locus Diagram

The diagram will be based on the circuit of Fig. 1 which expresses the equivalence of the single-phase motor to two polyphase motors with primary windings connected in series.[1] The exciting impedance consists of a reactance X divided between the two stators; the core loss circuit g is connected across the line; no specific assumption is made as to the nature of the loss in an elliptical field, the current

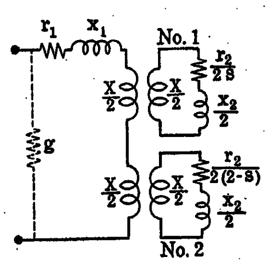

FIG. 1

covering this loss being always too small to have an appreciable influence on the phase relation and the magnitude of the vectors of the diagram.

In Fig. 2 let $O\,I$ be the current I' in the motor branch $r_1 - x_1 - X/2 - X/2$; the line voltage V' is the sum of $O\,R' = r_1 I'$, $R'\,S' = x_1 I'$, $S'\,M' = X/2\, I'$, $M'\,N' = X/2\, I'$, and of the e. m. fs. $M'\,P' = X/2\, I_2'$ and $N'\,Q' = X/2\, I_2''$ due to the reaction of the currents I_2' and I_2'' set up in the rotor circuits No. 1 and No. 2 by the e. m. fs. $S'\,M'$ and $M'\,N'$. Electromotive forces $M'\,P'$ and $N'\,Q'$ result from the diagram of Fig. 2 in which

$$S'\,F' = \frac{r_2\, I_2'}{2\, s}\,,\ F'\,M' = \frac{X + x_2}{2}\, I_2'\,,$$

$$M'\,H' = \frac{r_2\, I_2''}{2\,(2 - s)}\,,\ H'\,N' = \frac{X + x_2}{2}\, I_2''\,.$$

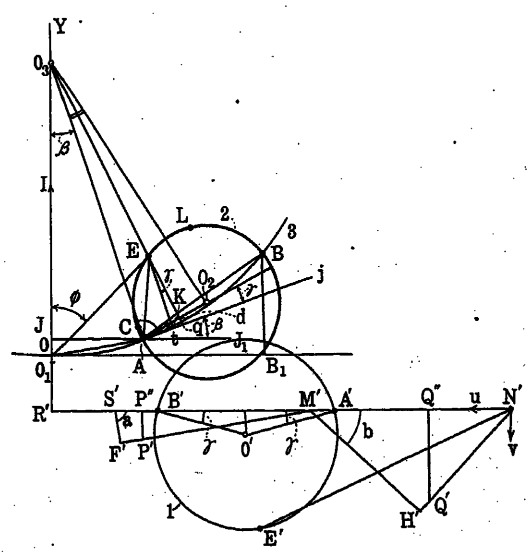

FIG. 2

Let
$$z_1^2 = \frac{r_2^2}{4\, s^2} + \left(\frac{X + x_2}{2}\right)^2$$

and
$$z_2^2 = \frac{r_2^2}{4\,(2 - s)^2} + \left(\frac{X + x_2}{2}\right)^2;$$

then (Fig. 2) $\sin a = \dfrac{X + x_2}{2\, z_1}$, $\cos a = \dfrac{r_2}{2\, s\, z_1}$,

1. The cross field theory leads to the same circuit. See V. Karapetoff, JOURNAL A. I. E. E., August, 1921, p. 640. The primary and secondary windings are usually combined in a divided circuit instead of being left in inductive relation by means of 1 to 1 ratio transformers, as in Fig. 1.

Presented by title only at the 10th Midwinter Convention of the A. I. E. E., New York, N.Y., February 15-17, 1922.

$$\sin b = \frac{X + x_2}{2\, z_2}\,, \cos b = \frac{r_2}{2\,(2 - s)\, z_2}\,.$$

If the current I' remains constant, the point N' is fixed, and the locus of the line voltage is described by the sum $N'E'$ of the vectors $M'P'$ and $N'Q'$. Let N' be the origin of coordinates u and v, with axes directed to the left and downwards, as shown; projections of $M'P'$ on these axes are:

$$M'P'' = M'P' \sin a = M'F' \frac{X}{X + x_2} \sin a$$

$$= S'M' \frac{X}{X + x_2} \sin^2 a = \frac{X}{2} \times \frac{X}{X + x_2} I' \sin^2 a\,;$$

and $M'P' \cos a = \dfrac{X}{2} \times \dfrac{X}{X + x_2} I' \sin a \times \cos a$

respectively; the e. m. f. $N'Q'$ gives for its projections similar expressions with the angle b instead of a; therefore, denoting

$$\frac{X^2 I'}{2\,(X + x_2)} \text{ by } m,$$

the coordinates of E' are $u = m(\sin^2 a + \sin^2 b) = m(2 - \cos^2 a - \cos^2 b)$ and $v = m(\sin a \cos a + \sin b \cos b)$. The equation of the locus of E' is obtained by eliminating a and b between these expressions and the following relation:

$$\tan a + \tan b = \frac{(X + x_2)\, s}{r_2} + \frac{(X + x_2)\,(2 - s)}{r_2}$$

$$= \frac{2\,(X + x_2)}{r_2}\,;$$

denoting $\dfrac{2\,(X + x_2)}{r_2}$ by n,

it is found: $u^2 + v^2 = m^2 (4 + \cos^4 a + \cos^4 b - 4 \cos^2 a - 4 \cos^2 b + 2 \cos^2 a \cos^2 b + \sin^2 a \cos^2 a + \sin^2 b \cos^2 b + 2 \sin a \cos a \times \sin b \cos b) = m^2 [4 - 3 \cos^2 a - 3 \cos^2 b + 2 \cos a \cos b \cos (a - b)\,] = m^2 \Big[- 2 + 3 \sin^2 a + 3 \sin^2 b + \dfrac{2 \sin (a + b) \cos (a - b)}{\tan a + \tan b} \Big] = -\,2\, m^2 + 3\, m\, u + m^2/n\, (\sin 2\,a + \sin 2\,b) = -\,2\, m^2 + 3\, m\, u + \dfrac{2\, m}{n}\, v$, which can be written:

$\left(u - \dfrac{3\, m}{2}\right)^2 + (v - m/n)^2 = m^2\,(1/4 + 1/n^2)$, and shows that the locus is a circle 1 with the point O' of coordinates $u_0 = \dfrac{3\, m}{2}$, $v_0 = m/n$ as center. For $v = 0$ the equation gives $u = \dfrac{3\, m}{2} \pm m/2$, i. e. $N'A' = m$, $N'B' = 2\, m$. At B', $u = m(\sin^2 a + \sin^2 b) = 2\, m$, i. e. $\sin a = \sin b = 1$, which is possible only if $s = \infty$ at this point.

The current locus at constant voltage V is derived from the circle 1 by inversion with O as center and $V I'$ as constant of inversion, followed by the substitution for the inverse figure of its image with respect to $O\,Y$; this gives a circle 2 of center O_2. If the core loss is constant, the locus of the entire circuit of Fig. 1 is the circle 2 referred to an origin O_1 such that $O_1 O$ = current in the branch g.

The inverse of the line $R'N'$ is a circle 3 of diameter $= \dfrac{V I'}{O R'} = \dfrac{V}{r_1}$, having its center O_3 on $O\,Y$; let γ be the angle which the radius $A\,O_2$ at A (corresponding to A') makes with the tangent $A\,j$ to the circle 3; this angle is equal to the angle $B'A'O'$; therefore,

$$\tan \gamma = v_0 : \frac{A'B'}{2} = \frac{2}{n} = \frac{r_2}{X + x_2} \tag{1}$$

INPUT TO THE ROTOR[2]

At a point E of the circle 2 let $E\,q$ be $\perp$ to $A\,O_2$ and $E\,t \perp$ to $A\,j$; the triangles $O\,O_3\,E$ and $A\,O_3\,E$ having a common side $O_3\,E$ give $2\,A\,O_3 \times E\,t - A\,E^2 = 2\,O\,O_3 \times O\,E \times \cos \phi - O\,E^2 = \dfrac{V\,I \cos \phi}{r_1} - I^2$

$$= \frac{\text{rotor input}}{r_1}\,.$$

If R is the radius of the circle 2, then $A\,E^2 = 2\,R \times A\,d = 2\,R \times A\,q \cos \gamma$; the similar triangles $A\,O_3\,O_2$ and $A\,K\,q$ give $R \times A\,q = A\,O_3 \times K\,q$, hence,

$$\frac{\text{rotor input}}{r_1} = 2\,A\,O_3 \times E\,t - 2\,A\,O_3 \times K\,q \cos \gamma$$

$$= 2\,A\,O_3\,(E\,q \cos \gamma - K\,q \cos \gamma) = V/r_1 \times E\,K \cos \gamma, \text{ i. e.}$$

$$\textit{Rotor input} = E\,K \times V \cos \gamma \tag{2}$$

or, since γ is always very small:

$$\textit{Rotor input} = \sim E\,K \times V \tag{2a}$$

As will be seen, the graphical expressions of the performance elements are very simple in the constant current diagram (denoted "c. c. d."); they will be used for the derivation of the much less obvious relations in the constant voltage diagram ("c. v. d."). Since the current I' is arbitrary, it is convenient to simplify the figures by giving it such a value that the inverse of the circle 1 is equal to the circle 1 itself, which may then be considered both as the voltage locus at constant current, and—disregarding its incorrect location with respect to $O\,Y$—as the current locus

2. It is known that the primary and secondary outputs at a point E are proportional to the distances of E from the lines passing through the points of zero outputs (lines $A\,B$ and $C\,L$ in the figures). The purpose of the demonstration given below is to determine the coefficients of proportionality in equations (2) and (3) and to establish equations (2a) and (3a) whose simplicity facilitates the use of the tilted diagram.

at constant voltage. Plain capitals A, B, etc., will refer to the points of the c. v. d.; the same capitals with an accent, A', B', etc., will be used for the corresponding points of the c. c. d.; two corresponding points of the circle, such as A and A' are on the same line passing through O. The voltage and the current will be denoted by V and I in the c. v. d., and by V' and I' in the c. c. d.; it is clear that at the corresponding points $V'/V = I'/I$.

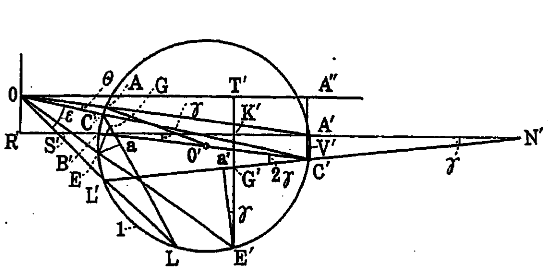

FIG. 3

In the triangles $M' F' S'$ and $M' P' P''$, Fig. 2, $M' P' \times M' F' = M' S' \times M' P''$; but $M' F' = \dfrac{X + x_2}{X} \times M' P'$, $M' P' = X/2\, I_2'$, and $M' S' = X/2\, I'$, therefore, $I_2'^2 = \dfrac{2 I' \times M' P''}{X + x_2}$;

similarly, $I_2''^2 = \dfrac{2\, I' \times N' Q''}{X + x_2}$;

hence $r_2/2\,(I_2'^2 + I_2''^2) =$ rotor copper loss

$$= \frac{r_2\, I'}{X + x_2} \times u = I' u \tan \gamma \;(u = \text{abscissa of } E').$$

In Fig. 3 let $E' T'$ be ⊥ to $R' N'$, and $N' C' L'$ a line such that $\angle A' N' C' = \gamma$; then $G' K' = N' K' \tan \gamma = u \tan \gamma$, i. e. in the c. c. d. the rotor copper loss is $G' K' \times I'$. Since the input to the motor is $T' E' \times I'$, and the stator loss $= T' K' \times I'$, the rotor input is $K' E' \times I'$, and the rotor output $= G' E' \times I'$. At L' and C', $G' E' = O$; these points are the locked[3] and the no-load points (= zero − torque points) respectively. $A' C'$ is ⊥ to $R' N'$ because $B' A' = A' N'$; therefore, in the c. c. d. the rotor loss is the same at A' and C'; but at C' the stator supplies both its own loss $A' A'' \times I'$ and the rotor loss; at A' the latter must be supplied externally, as mechanical power. At synchronism (point U') $s = O$, $\cos a = O$, and v/u

$$= \frac{m \sin b \times \cos b}{m \sin^2 b} = \frac{r_2}{2\,(X + x_2)} = 1/2 \tan \gamma,$$

i. e. U' is the middle of the vertical segment (not shown) passing through U' and representing the rotor loss at U'; this expresses the well-known fact that at synchronous speed the stator supplies one-half of the rotor loss; the other half must be supplied externally.

3. This can also be proved by making $s = 1$ in the expressions of u and v, which gives $\dfrac{v}{u} = \dfrac{r_2}{X + x_2} = \tan \gamma$.

ROTOR OUTPUT

Let (Fig. 3) $E' a'$ be ⊥ to $C' L'$ and $E a$ ⊥ to $C L$; in Fig. 3a (giving details of Fig. 3) the inscribed triangles $C E L$ and $C' E' L'$ give:

$$\frac{E' a'}{E a} = \frac{E' C' \times E' L'}{E C \times E L}\,;\quad \text{but}\quad \frac{E' C'}{E C} = \frac{O E'}{O C}\,;$$

$$\frac{E' L'}{E L} = \frac{O L'}{O E}\,;\quad \text{and}\quad \frac{O L'}{O C} = \frac{L' C'}{L C}\,;$$

$$\text{hence}\quad \frac{E' a'}{E a} = \frac{O E'}{O E} \times \frac{L' C'}{L C} = \frac{V'}{I} \times \frac{L' C'}{L C}.$$

The rotor output at E' is

$$E' G' \times I' = \frac{E' a' \times I'}{\cos \gamma}\,;$$

therefore, the rotor output at E in the c. v. d. is

$$\left(\frac{E' a' \times I'}{\cos \gamma}\right) \times \left(\frac{V}{V'}\right)^2 = \frac{E a \times V}{\cos \gamma} \times \frac{L' C'}{L C}.$$

In Fig. 3 let $\epsilon = \angle C O L$; the arc $B' E L'$ is measured by 4γ; the arc $L' E' C' = B' E' C' - B' E L' = \pi - 4\gamma$; therefore, the arc $C E L =$ arc $C L'$ + arc $L' L$ $= (C' E' L - 2\epsilon) + (L' E' C' - C' E' L) = -2\epsilon + L' E' C' = \pi - 4\gamma - 2\epsilon$;

$$\text{hence,}\quad \frac{L' C'}{L C} = \frac{\sin {}^1/_2\,(\pi - 4\gamma)}{\sin {}^1/_2\,(\pi - 4\gamma - 2\epsilon)}$$

$$= \frac{\cos 2\gamma}{\cos(\epsilon + 2\gamma)}.$$

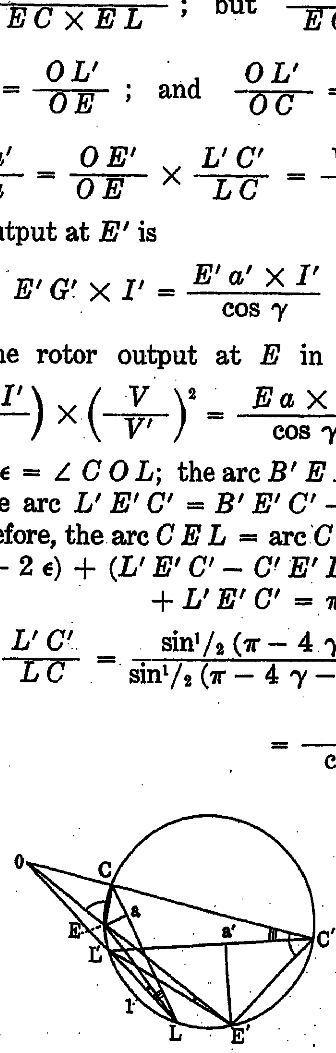

FIG. 3A

Let $\theta = \angle A O C$; the arc $A' C' = 2\gamma$, therefore, the arc $A C = 2\gamma - 2\theta$. The angle which $C L$ makes with the diameter $A O'$ is

$$\frac{\pi - \text{arc}\, A C L}{2} - \frac{\text{arc}\, A C}{2} = \frac{\pi - \text{arc}\, C E L}{2}$$

$$- \text{arc}\, A C = \frac{\pi - (\pi - 4\gamma - 2\epsilon)}{2} - (2\gamma - 2\theta)$$

$$= \epsilon + 2\theta;$$

if $E G$ is drawn ⊥ to $A O'$, then $E a = E G \times \cos(\epsilon + 2\theta)$; substituting:

$$\textit{Rotor output} = E G \times V \times \frac{\cos 2\gamma}{\cos \gamma} \times \frac{\cos(\epsilon + 2\theta)}{\cos(\epsilon + 2\gamma)} \qquad (3)$$

The angles θ and γ are very small; moreover, θ

differs from γ only by one = half of the negligibly small arc $A\,C$; both fractions in (3) are very close to unity (and differ from it in the opposite senses), therefore,

$$\textit{Rotor output} = \sim E\,G \times V \qquad \text{(3a)}$$

If the rotor resistance is very high, it may be advisable to measure γ, ϵ and θ on the diagram and use equation (3), but this is seldom necessary.

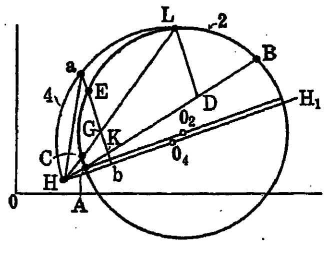

FIG. 4

ROTOR COPPER LOSS

When equations (2a) and (3a) are applicable,[4] they give (Fig. 4)

$$\textit{Rotor copper loss} = E\,K \times V - E\,G \times V = G\,K \times V \qquad \text{(4a)}$$

In Fig. 4 let H be the intersection of $L\,C$ with $B\,A$, and 4 = a circle through H and L, with its center O_4 on $H\,H_1$ parallel to $A\,O_2$. Since $G\,K$ is proportional to $H\,b$ and therefore proportional to $H\,a^2$, the rotor loss $G\,K \times V$ is proportional to $H\,a^2$. Let $L\,D$ be $\perp$

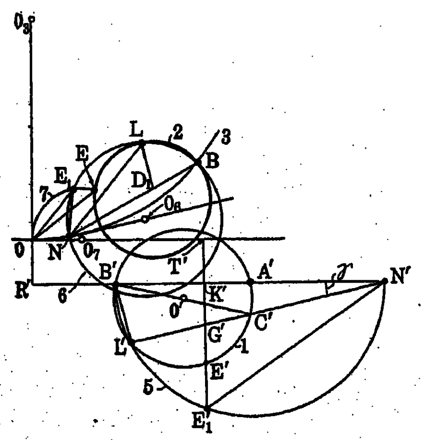

FIG. 4A

to $A\,O_2$; at L the rotor loss = rotor input = $\sim L\,D \times V$; therefore, the coefficient of proportionality is

$$V \times \frac{L\,D}{H\,L^2}:$$

$$\textit{Rotor copper loss} = \sim H\,a^2 \times \left(V \times \frac{L\,D}{H\,L^2} \right) \qquad \text{(4b)}$$

Expressions (2a), (3a) and (4a) show that *if representative segments of the rotor input, output and loss are drawn perpendicular to the diameter passing through the point of zero stator output, they can be read directly in amperes, as in the current locus of a polyphase motor.*[5] The expressions are, however, only approximate in the single-phase motor, although the accuracy is sufficient in most cases occurring in practise.

SPEED

Let $a\,a$ (c. v. d. in Fig. 5) be an arbitrary line parallel to the tangent at B ($s = \infty$), and f, g, h, the points of intersection of this line with $B\,L$, $B\,E$ and $B\,U$ respectively (U = point of synchronous speed); then, if S is the speed with synchronism as unity:

$$S = \frac{f\,g}{f\,h} \qquad \text{(5)}$$

This expression is well-known; a brief outline of its derivation will be sufficient. In the c. c. d. of Fig. 5 let f' be the intersection of $B'\,L'$ and $A'\,C'$ produced; using the same axes of coordinates u, v, (to the left and downwards from N') as in Fig. 2, let p and q be coordinates of a point E'; the equation of $N'\,f'$ is $v = u$

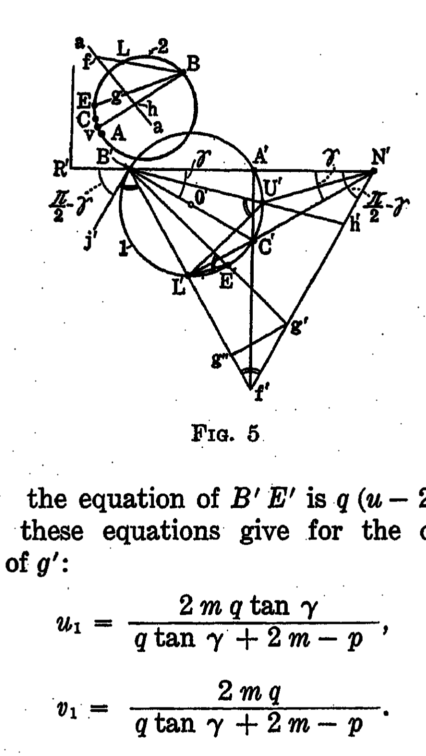

FIG. 5

$\times \cot \gamma$; the equation of $B'\,E'$ is $q\,(u - 2\,m) = v\,(p - 2\,m)$; these equations give for the coordinates u_1 and v_1 of g':

$$u_1 = \frac{2\,m\,q \tan \gamma}{q \tan \gamma + 2\,m - p},$$

$$v_1 = \frac{2\,m\,q}{q \tan \gamma + 2\,m - p}.$$

The equation of $B'\,f'$ is $u + v \times \tan \gamma - 2\,m = 0$; therefore, the distance $g''\,g'$ of g' from $B'\,f'$ is proportional to $u_1 + v_1 \tan \gamma - 2\,m$; but, in connection with Fig. 2 it was found: $p = m\,(\sin^2 a + \sin^2 b)$; $q = m\,(\sin a \cos a + \sin b \cos b)$ hence, substituting, $g''\,g'$ is proportional to

$$\frac{\tan \gamma\,(\sin a \cos a + \sin b \cos b) - \cos^2 a - \cos^2 b}{\tan \gamma\,(\sin a \cos a + \sin b \cos b) + \cos^2 a + \cos^2 b}$$

substituting for $\tan \gamma$, $\sin a$, etc. their expressions as functions of the slip and the constants of the motor gives, after some transformations: $g''\,g'$ is proportional to $(1 - s)^2$ and to S^2; therefore, $f'\,g'$ is proportional to S^2, and, if U' is the point of synchronous speed,

4. See Appendix 1 for the exact expression of the rotor copper loss.

5. JOURNAL A. I. E. E., April 1921, p. 329.

$$S^2 = \frac{f'\,g'}{f'\,h'}\,.$$

It can easily be seen that $N'\,f'$ is parallel to the tangent $B'\,j'$ at B'; the triangles $B'\,L'\,E'$ and $B'\,L'\,U'$ are, therefore, similar to $B'\,f'\,g'$ and $B'\,f'\,h'$ respectively;

hence, $\dfrac{f'\,g'}{L'\,E'} = \dfrac{B'\,f'}{B'\,E'}$ and $\dfrac{f'\,h'}{L'\,U'} = \dfrac{B'\,f'}{B'\,U'}$,

which gives $\dfrac{f'\,g'}{f'\,h'} = \dfrac{L'\,E'}{L'\,U'} \times \dfrac{B'\,U'}{B'\,E'}$.

It is, generally, $L'\,E' = L\,E$

$$\times \frac{\text{constant of inversion between c. c. d. and c. v. d.}}{O\,L \times O\,E},$$

and similar relations for $L'\,U'$, $B'\,U'$, and $B'\,E'$; substitution shows that

$$\frac{L'\,E'}{L'\,U'} \times \frac{B'\,U'}{B'\,E'} = \frac{L\,E}{L\,U} \times \frac{B\,U}{B\,E}\,;$$

but $\dfrac{L\,E}{L\,U} \times \dfrac{B\,U}{B\,E} = \dfrac{f\,g}{f\,h}$,

therefore, $\dfrac{f\,g}{f\,h} = \dfrac{f'\,g'}{f'\,h'} = S^2$.

It was found that

$$\tan \angle\, A'\,N'\,U' = 1/2 \tan \angle\, A'\,N'\,C',$$

i. e. U' is nearly equidistant from A' and C'; since $A'\,C'$ is $\perp$ to $B'\,N'$ and far from the center of inversion the point U in the c. v. d. is nearly equidistant from A and C, and can be located by the eye. Usually, however, the no-load point C can be used instead of U; eq. (5) gives then the speed with the no-load speed as unity.

Torque

The torque in synchronous watts is

$$= \frac{\text{rotor output}}{S} = \frac{E\,G \times V}{S}\,.$$

The following approximate expression can also be used; it can be shown that S^2 is approximately equal to the efficiency of the rotor:[6]

$$S^2 = \sim \frac{E\,G}{E\,K} \text{ (Fig. 4)} \tag{5a}$$

Therefore, approximately:

$$\textit{Torque in synchronous watts} = \frac{E\,G \times V}{S}$$

$$= V \sqrt{E\,G \times E\,K}$$

$$= \sqrt{(\textit{rotor output})\ (\textit{rotor input})} \tag{6a}$$

It remains now to establish a few analytical relations useful for the construction of the locus from the test data. The branch $r_1 - x_1 - X$ of the circuit of Fig. 1 is equivalent to an impedance whose elements can conveniently be determined from the c. c. d. of Figs. 2 and 3 by observing that a point E' of coordinates u and v the equivalent resistance is

$$\frac{E'\,T'}{I'} = r_1 + \frac{v}{I'}\,,$$

and the equivalent reactance

$$= \frac{R'\,K'}{I'} = x_1 + \frac{S'\,N' - u}{I'} = x_1 + X - u/I'\,.$$

Substituting for u and v their values as functions of $\sin a$, $\sin b$ etc. and denoting $1 + x_2/X$ by k (with $k = \sim 1$), it is found:

At the locked point L', $s = 1$:

Equivalent resistance $= r_1$

$$+ \frac{r_2}{k^2 + (r_2/X)^2} = \sim r_1 + r_2/k^2 \tag{7}$$

Equivalent reactance $= x_1$

$$+ \frac{X\,[r_2^2 + x_2\,(X + x_2)]}{r_2^2 + (X + x_2)^2}$$

$$= x_1 + \frac{x_2 + \dfrac{r_2^2}{(X+x_2)}}{k + \dfrac{r_2^2}{X\,(X + x_2)}} = \sim x_1 + x_2/k \tag{8}$$

At the no-load point C':

$$\text{Equivalent resistance} = r_1 + \frac{r_2}{2\,k^2} \tag{9}$$

$$\text{Equivalent reactance} = x_1 + X - \frac{X^2}{2\,(X + x_2)}$$

$$\doteq x_1 + X\,\frac{2\,k - 1}{2\,k} \tag{10}$$

At the point A': (11)

Equivalent resistance $= r_1$

$$\text{Equivalent reactance} = x_1 + X\,\frac{2\,k - 1}{2\,k} \tag{12}$$

At the point B' ($s = \propto$);

Equivalent resistance $= r_1$ (13)

$$\text{Equivalent reactance} = x_1 + X - \frac{X^2}{X + x_2}$$

$$\doteq x_1 + x_2/k \tag{14}$$

Construction of the Diagram from Test Data

The necessary tests are: 1. Resistance r_1; 2. Locked point L: I_s amperes, W_s watts, $\cos \phi_s$ = power factor; 3. No-load point C: I_0 ampere, W_0 watts. The open rotor circuit point test should also be made, whenever possible (slip ring motors, repulsion-induction motors).[7] One of the difficulties of the problem is the fact that the point A is not given by the test; in the majority of methods of constructing the diagram

6. A. S. McAllister, "Simple Circle Diagram of the Single-Phase Induction Motor" *Electrical World*, June 30, 1906. See also Appendix 2.

7. The no-load test point corresponds to a small friction torque; experience shows that a correction for this torque, theoretically simple, is not necessary.

A is considered as coinciding with C; when this is permissible, as in large motors, it greatly simplifies the construction; but in small motors the arc $A\,C$ is not always negligible, and it is necessary to find the point A, which involves certain complications.

The small chord $A\,C$, Fig. 2, is nearly $\perp$ to the diameter $A\,O_2$ and (equation **4a**) nearly equal to

$$\frac{\text{rotor loss at } C}{V};$$

moreover, with γ very small, $A\,C$ nearly coincides in direction with $O_3\,A$; therefore,

$$O_3\,C = \sim O_3\,A - \frac{\text{rotor loss at } C}{V} = \frac{V}{2\,r_1} - I_0^2 \times \frac{r_2}{2\,k^2} \times \frac{1}{V},$$

(equation **9**); equation (**7**) shows that

$$\frac{r_2}{k^2} = \frac{W_s}{I_s^2} - r_1;$$

with this value $O_3\,C$ can be calculated and O_3 located on $O\,Y$; the circle 3 of radius $\frac{V}{2\,r_1}$ is then drawn and determines the points O and A, the latter as the intersection of the circle 3 with $O_3\,C$ produced (or, more accurately, with the inverse of $A'\,C'$, *i. e.* with a circle passing through O and C and having its center on the line $O\,B_1 \perp$ to $O\,Y$).

The next step is to calculate the angle γ; it is always so small that the following method is sufficiently accurate: x_1 and x_2 are calculated from equation (**8**) which gives: $x_1 + x_2/k = \sim (x_1 + x_2) = V/I_s \times \sin \phi_s$; it may be assumed that $x_1 = \sim 0.6$ to 0.7 of $(x_1 + x_2)$; X is calculated from equation (**10**) as follows:[8]

$$x_1 + X\,\frac{2\,k - 1}{2\,k} = \sim x_1 + X/2 = V/I_0\,;$$

equation (**7**) gives r_2/k^2 as above; with these data

$$\tan \gamma = \frac{r_2}{X + x_2} = r_2/k^2 \times \frac{X + x_2}{X^2}$$

can be calculated. The center O_2 of the locus is the intersection of the perpendicular bisector of $C\,L$ with a line passing through A and making an angle $90 - \gamma$ with $O_3\,A$. As a check, it will be found that the point A found above is either on the locus or at a negligible distance from it.

If the object of the test is the determination of the constants of the motor, more accurate values of $x_1 + x_2/k$ and X can be found from the diagram as follows: If $\phi\,\infty$ is the angle of lag at B, then equations (**13**) and (**14**) give:

$$x_1 + x_2/k = r_1 \tan \phi\,\infty = r_1 \times \frac{O\,B_1}{B\,B_1} \qquad (\mathbf{15})$$

On the basis of equation (**11**) and (**12**) X is calculated from the equation

$$\left(x_1 + X\,\frac{2\,k - 1}{2\,k}\right)^2 + r_1^2 = \left(\frac{V}{O\,A}\right)^2 \qquad (\mathbf{16})$$

with k calculated with the previously found preliminary value of X.

If it is desired to calculate the rotor loss by the exact method (App. 1), the point N on the circle 3 can be located by observing that

$$O\,N = \frac{V}{\sqrt{r_1^2 + (X + x_1)^2}} = \sim \frac{V}{X + x_1}.$$

If O_3 is at an inconveniently great distance from the locus, the necessity of drawing the circle 3 can be avoided as follows: The angle β (Fig. 2) of the horizontal $A\,J$ with the tangent $A\,j$ to the circle 3 is given by

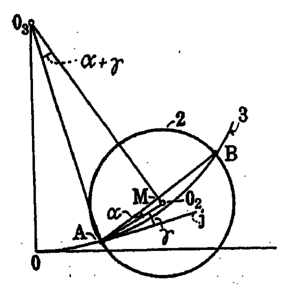

FIG. 6

$$\sin \beta = \frac{A\,J}{A\,O_3} = \sim \frac{2\,r_1\,I_0}{V}.$$

$A\,C$ is nearly $\perp$ to the diameter $A\,O_2$, which makes an angle γ with $A\,j$, i. e. $A\,C$ makes an angle $= \sim \beta + \gamma$ with $O\,Y$; γ is calculated as shown above; the direction and length of

$$A\,C = \sim I_0^2\,\frac{r_2}{2\,k^2\,V}$$

determine the point A and the locus 2. It can easily be seen that

$$\angle\,J\,A\,O = \frac{\angle\,A\,O_3\,J}{2} = \beta/2,$$

i. e. the point O is the intersection of $O\,Y$ with the bisector of the angle $J_1\,A\,j$; this bisector can be drawn by the eye. Finally, the point B ($s = \infty$) is determined by the angle $O_2\,A\,B$ as follows: In Fig. 6 let R be the radius of the locus and $A\,j$ = the tangent to the circle 3; then,

$$\sin \angle\,A\,O_3\,M = \sin(\alpha + \gamma) = \frac{A\,M}{A\,O_3} = \frac{R \cos \alpha \times 2\,r_1}{V};$$

8. If the open rotor circuit test is available, it gives directly $x_1 + x = \sim \frac{V}{\text{current}}$ it may be observed, however, that this test, made with the rotor at rest, cannot be considered as giving the point N and used for the determination of the circle 3, because, unlike N, it does not correspond to the same conditions of the core loss and friction as the point C.

hence, developing,

$$\tan \alpha = \frac{2\, r_1 R}{V \cos \gamma} - \tan \gamma = \sim \frac{2\, r_1 R}{V} - \tan \gamma \quad \textbf{(17)}$$

Fig. 7 gives an example of the diagram applied to a 1/4-h. p., four-pole, 60-cycle motor. Resistance $r_1 = 6.8$ ohms; no-load test: 220 volts, 2.04 amperes, 116 watts; locked test: 220 volts, 8.46 amperes, 1300 watts. For this motor $\gamma = 3$ deg. 37 min., $\epsilon = 36$ deg. 33 min., $\theta = 3$ deg. 6 min. The coefficients in equations (2) and (3) are 0.998 and 1.011 respectively. Brake test points are shown in the diagram.

Appendix I

In Fig. 4A let 5 be a circle described on $B' N'$ as diameter. This circle is the voltage locus of a polyphase motor of exciting reactance X and of constants r_1, x_1, r_2, x_2;[9] it passes through L' because $\angle\, B' L' C' = \pi/2$. At a point E_1' the rotor current is $\dfrac{N' E_1'}{X}$,

and the rotor loss

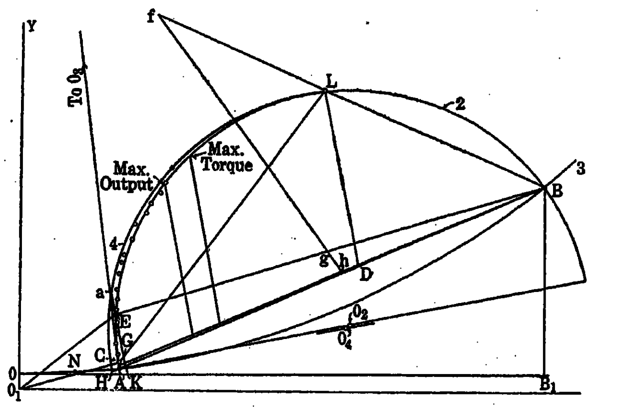

FIG. 7

$$= \frac{N' E_1'^2}{X^2} \times r_2 = \frac{N' B' \times N' K' \times r_2}{X^2}$$

$$= \frac{X^2 I'}{X + x_2} \times \frac{K' G' \times \cot \gamma \times r_2}{X^2} = K' G' \times I',$$

i. e. the same as for the single-phase motor at E'. The current locus corresponding to 5 is a circle 6 of center O_6 passing through N, L and B and normal to the circle 3 at N,[9] the points E_1 and E lie on the inverse of the line $E_1' E'$, i. e. on a circle 7 passing through O and having its center O_7 on $O\,T'$. Since E_1' and E' correspond to different voltages $O\,E_1'$ and $O\,E'$, the rotor losses in the c. v. d. are in the ratio

$$\left(\frac{O\,E_1'}{O\,E'}\right)^2 = \left(\frac{O\,E}{O\,E_1}\right)^2.$$

The polyphase motor rotor loss is proportional to $N\,E_1^2$, therefore, the single-phase motor loss is proportional to

$$N\,E_1^2 \times \left(\frac{O\,E}{O\,E_1}\right)^2,$$

9. See JOURNAL A. I. E. E., April, 1921, pp. 326-332.

and the coefficient of proportionality is found by reference to the point L where the loss is[9] $D_1 L \times V$ (with $D_1 L \perp$ to $N\,O_6$) which gives

$$\textit{Rotor copper loss} = O\,E^2 \times \left(\frac{N\,E_1}{O\,E_1}\right)^2 \times V \times \frac{D_1 L}{N\,L^2} \quad \textbf{(4)}$$

Appendix II

At a point E' (Fig. 3) of coordinates u and v, the rotor input $= E' K' \times I' = v \times I'$; the rotor output $= (E'K' - G' K')\, I' = (v - u \tan \gamma)\, I'$; rotor efficiency

$$= \frac{v - u \tan \gamma}{v}$$

$$= \frac{\sin a \times \cos a + \sin b \times \cos b - (\sin^2 a + \sin^2 b) \tan \gamma}{\sin a \times \cos a + \sin b \times \cos b};$$

substituting for $\sin a$ etc. their values and transforming, it is found:

$$\textit{Rotor efficiency} = (1 - s)^2 \times \frac{2\,s - s^2 - \tan^2 \gamma}{2\,s - s^2 + \tan^2 \gamma} \quad \textbf{(5b)}$$

If $\tan^2 \gamma$ is small relative to $2\,s - s^2$, as at the point of maximum torque, then

Rotor efficiency $= \sim (1 - s)^2 = \sim S^2$.

Discussion

V. Karapetoff: Mr. Kostko deserves much credit for having consistently followed what may be called a graphico-analytical method of solution of the single-phase induction motor, without the use of complex quantities. He is somewhat in the position of an arctic explorer who went to verify indefinite rumors about a favorable passage, and proved concisely that there was none. Someone had to do it, but few will appreciate the real value of a contribution consisting of a negative result. To me Mr. Kostko has proved only that by the method which he adopted no particularly useful results can be obtained either for a designer, an operating man, an experimenter, or a theoretical investigator. In order to use his results intelligently, one has to study carefully about twelve columns of weary mathematics and several complicated geometric figures. And when one finally arrives at the end, one finds the familiar old fact that the no-load and short-circuit tests alone do not determine the circular locus. It is necessary to use approximate relationships and empirical coefficients as given in his paper.[1] The limits of validity of these assumptions, or the magnitude of error committed, would be difficult to estimate, especially with a new motor of unusual constants.

To me the present situation and the possible future progress in the quantitative theory of the single-phase induction motor seem to be as follows:

(a) *The "one variable" diagram.* The difficulty with either the rotating-field or the cross-field theory of the single-phase induction motor is that both lead to equivalent diagrams with two variable branches. Thus, in Mr. Kostko's Fig. 1 one branch has the variable quantity $r_2/2\,s$, and the other has $r_2/2\,(2 - s)$, where s is the variable slip. It has been shown some time ago that the single-phase motor may be replaced by an equivalent

1. A. I. E. E., JOURNAL Jan. 1922, p. 35, first column.

diagram with one variable branch only (see V. Karapetoff, JOURNAL of the A. I. E. E., Vol 40, 1921, Aug., p. 641. Fig. 3). This diagram admits of a much simpler analytical or graphical treatment than either of the two usual diagrams, and should be used in the future.

(b) *The circular locus.* In the "one variable" diagram mentioned above, the admittance of the variable branch is $s\,(2 - s)\;Y_c$, where s is the slip and Y_c is a constant admittance which characterizes a given motor. Thus, the locus of the variable admittance is a straight line in the direction of the vector Y_c. A constant admittance, $(X + Z + r)^{-1}$, is added in parallel to this admittance, still leaving the straight-line locus. The first inversion gives a circular locus for the equivalent impedance. Two more inversions are necessary to account for the remaining constant parts of the circuit, but the inverse of a circle is also a circle so that the final result is a circular locus. This is the simplest exact proof of the circular locus of the single-phase induction motor that I know of. No complicated analytical or graphical proof is necessary.

I have shown on another occasion that it is not necessary to change the circle at each successive inversion, but that the first circle and the last circle can be made to coincide by properly changing the scale (See Sibley *Journal of Eng'g* Vol. 32, 1921, p.42). Therefore, for a single-phase induction motor of given constants it is now possible to construct a circle diagram of a current, with hardly any computations, except for measuring a few lengths and taking their reciprocals. This diagram also inherently contains slip values. Knowing the primary current, its phase angle, and the corresponding slip, it is not difficult to compute the remaining characteristics.

(c) *The analytical method.* The same new equivalent diagram, mentioned above, leads to the following expression for the equivalent impedance of a single-phase induction motor:

$$Z_{eq} = Z_1 + \left[Y + \{ X + [(X + Z + r)^{-1} + Y_c\, s\,(2-s)]^{-1} \}^{-1} \right] \qquad (1)$$

In this formula all the quantities are motor constants, expressed as complex numbers, and the only variable is the slips s, By giving different values to s, the values of Z_{eq} can be computed, and the corresponding values of current vector found by dividing the applied voltage by Z_{eq}. It is true that at the present time numerical computations with complex quantities are somewhat tedious, but then one has the advantage of using a formula which contains only standard operations of addition of impedance in series and admittances in parallel. One does not have to study a complicated analytical theory with special vector diagrams, several angles, simplifying assumptions, etc.

Formula (1) probably represents the simplest analytical expression for the motor in question, since it corresponds to a diagram with but one variable branch. Our next problem is not so much to simplify this expression as to devise a simpler method of computing complex quantities. At the present time the most convenient method seems to be to use the trigonometric or exponential form for multiplication, division, and reciprocals; and to use the orthogonal form for addition and subtraction. The writer has constructed a chart and a device (vectrometer) by means of which changes from one form to the other takes less time. The final solution of the difficulty should be a computing machine made to add and to multiply complex quantities directly. Such a machine would be very useful in many computations relating to a-c. machinery and circuits.

(d) *The circular locus from a test.* It is a well known fact that the no-load and short-circuit tests alone are not sufficient to determine the circular locus of either a polyphase or a single-phase induction motor, since a circle has to be determined by three points. In large and medium-size polyphase induction motors of usual proportions the center of the circle usually lies on a certain horizontal line determined by the no-load losses, but for small single-phase motors this assumption is not permissible (See for example, Mr. Kostko's Fig. 7).

The tangent from the origin to the circle determines the point at which the power factor is a maximum and this may be a convenient additional datum to make the circle definite. I know from experience that this method works well on a small polyphase motor. To obtain this value, a reliable power-factor meter is connected in the motor circuit and watched while the motor is coming up to speed, or while it is being loaded. It is easy then to read the maximum value which the power factor reaches. The speed or the slip may also be read at the same time. This test gives the direction of the tangent from the origin to the circle, and together with the no-load and short-circuit point determines the circle itself, and the ampere-speed characteristic.

If a power factor meter is not available, a wattmeter may be used and read at its maximum indication, as the machine is loaded. This will give the horizontal tangent to the circle, and thus furnish the necessary additional information for drawing the circle itself.

J. L. Hamilton: Mr. Kostko attempts to get a little more accurate analysis of the single-phase induction motor. It is doubtful if there is any electrical problem more difficult of solution than this one.

The "Tilted Diagram" gives slightly more accurate results on very small single-phase motor of one-half h. p. and smaller. For larger size motors the accuracy is not improved very much, by using the diagram.

The present writer has used a number of refinements in applying the circle diagram to the small single-phase motor, and has always found that it is questionable if increased accuracy is obtained. We believe, therefore, that it is better to use the simplified diagram as slight variations in the construction of the motor and slight differences in the temperature of the motor will effect the performance, to such an extent as to make too many refinements in calculation useless.

The present writer has for a number of years used the simplified diagram for single-phase motors as is covered in a paper presented before the A. I. E. E.[2]

It is important, however, to have a clear understanding of the assumptions, and approximations used in making calculation. Mr. Kostko's paper deals with some of these approximations in a very definite manner.

J. K. Kostko: In my preface I stated explicitly that my object was the construction of the current locus from test data. Prof. Karapetoff's note deals almost exclusively with a question which is entirely outside of the scope of the paper—the construction of the diagram and the predetermination of the performance from the design data of the motor. My paper is mentioned only in the first paragraph, and the mention consists of a number of statements of such general nature that, unfounded as they are, it would be a hopeless task to try to refute them in their present form, especially in the short time given to me for reply. For certain reasons I must abandon the attempt to obtain some light on the meaning of these statements, and confine myself to a short discussion of the only definite statement, which is, apparently, the key to the rest of Prof. Karapetoff's criticism. I refer to the statement: "one finds the familiar old fact that the no-load and short-circuit tests alone do not determine the circular locus."

The fact is, indeed, old and familiar—and has nothing to do with the method of the paper, which is based on three tests, not on two, as clearly stated in the paper.

The problem of constructing the circle diagram from the no-load and locked tests alone has been completely solved in the classical works on this subject; they show the necessity of certain simplifying assumptions and prove the futility of all methods such as the one imputed to me by Prof. Karapetoff, *i. e.*, where it is sought to make further progress without additional physical data. Prof. Karapetoff suggests that these data be obtained from certain tests involving the use of mechani-

2. A. I. E. E. TRANS., Vol. XXXIV, 1915, Part II, p. 2443.

cal power; but this drastic remedy, which would greatly impair the practical value of the circle diagram, is entirely unnecessary, because by the method of the paper the accuracy can be extended beyond the most exacting requirements of practical work without the complication of unusual and difficult tests. In this method I take advantage of the fact that, while we speak of the no-load and locked tests alone, we always make one more test: We measure the primary resistance r_1, without which the circle is of no value for the applications; I use this resistance not only for the study of the performance, but for the construction of the diagram itself, by proving that the current circle is in a simple angular relation to another circle, of radius determined by the primary resistance alone (circle 3 of the paper, of radius $V/2\,r_1$). The principle is quite general; I found it applicable to many types of machines; its advantages are very well illustrated in the case of a polyphase motor[3], where the circle of radius $V/2\,r_1$ is determined in magnitude and in position, and is normal to the current locus; by this condition the latter is completely determined without any simplifying assumptions or additional tests. The diagram of the single-phase motor is not so simple; but even in this case the results are far more accurate than with the two tests only, as follows from the following considerations:

The inherent errors of the method are (1) the exact location of the point A (which determines the position of the circle 3) is not known; (2) the angle of tilt $\beta + \gamma$ can be determined only approximately; β = angle between the horizontal and the tangent to the circle 3 at A; γ = angle between this tangent and the line $A\,O_2$ through the center of the locus; it can easily be seen that

$$\tan \beta/2 = \frac{r_1}{X\,\dfrac{2\,\kappa - 1}{2\,\kappa} + x_1}, \quad \tan \gamma = \frac{r_2}{X + x_2}.$$

As to (1): The point A is determined by its (directed) distance $A\,C$ from the no-load point C; this distance (which is the measure of the rotor copper loss at no-load) is so small, that it is simply neglected in all methods known to me, *i. e.*, the point A is considered as given directly by the no-load test; but even when it is desired to take $A\,C$ into account, the error committed on it is very small (= error of the approximate formula 7 of the paper), so that the point A can be located without an appreciable error, thus accurately determining the circle 3, its tangent at A and the angle β; in other words, the introduction of the circle of radius $V/2\,r_1$ practically eliminates the error of the tilt due to the primary resistance and reduces the error of the method substantially to that committed on the small angle γ. In small motors γ is usually of the order of magnitude of 1/3 to 1/4 of the total angle of tilt, so that the error of the method can be described as a small error committed on a fraction of a small quantity.

Taking, for instance, such abnormal values as 20 per cent error on γ and 15 to 20 degrees angle of tilt, the error is of the order of one degree; it is certainly not greater than the error due to the unavoidable assumptions, such as non-saturated magnetic circuit and sine wave currents.

3. Journal A. I. E. E., April 1921, p. 326.
The circle of radius $V/2\,r_1$, is a familiar feature in the theory of synchronous motors (circle of zero power).

A numerical estimate of this error would be very difficult; but a graphical study of any individual case can very simply be made as follows: With the constants of the motor (either given or approximately determined from the diagram) the exact diagram is drawn by any of the numerous available methods;[4] then, assuming that only the primary resistance the no-load and locked points C and L are known another diagram is drawn by the method of the paper; the comparison of the two diagrams shows at a glance the order of magnitude of the error due to the method itself, *i. e.*, excluding the influence of errors common to all diagrams such as saturation, etc. In Fig. A this comparison is made for a 1/20 h. p. motor whose constants are derived from the diagram of Fig. B constructed from test data; the numbers with accents refer to the exact diagram. As seen even in such

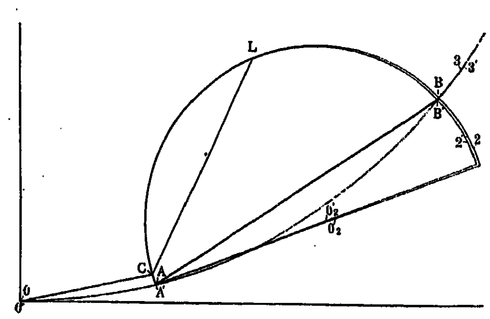

FIG. A

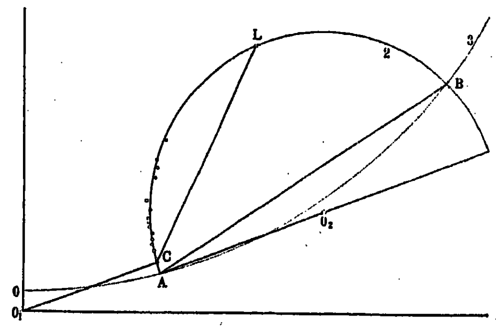

FIG. B

a small motor the error of the method has no appreciable influence on the diagram within its working range, where both circles practically coincide. No additional test could give better results.

I agree with Mr. Hamilton that there is little advantage in the use of the exact diagram above 1/2 h. p. (4 pole). The use of the tilted diagram can be facilitated by a gradual extension of simplifying assumptions as follows: (1) exact diagram; (2) point A coincides with the no-load point; (3) same as (2) and negligible rotor resistance, angle $\gamma = 0$; (4) same as (3) and negligible stator resistance, *i. e.* non-tilted diagram.

4. For instance, the admittances of the points A, C, L and B can be calculated from the impedances given by the (exact) formulaes (7) to (14) of the paper; these admittances determine the points A, C, L and B, *i. e.*, the circle as well as the power lines $C\,L$ and $A\,B$.

Polyphase Commutator Machines

BY A. B. FIELD
Assoc. A. I. E. E.
Metropolitain Vickers Electrical Co., Manchester, Eng.

In a certain type of frequency-changer which consists of an armature similar to that of a synchronous converter, viz., a type of direct-current armature with slip rings on one side and a commutator on the other, the energy loss due to the currents flowing in these conductors is here analyzed.

The energy loss appearing as heat depends upon the degree to which the currents which flow in or out at the commutator end or the slip rings compensate one another. In the case of the synchronous converter the former are direct currents while the latter are alternating currents.

In the case of the frequency-changer, they are alternating currents of different frequency.

This paper analyzes the losses taking account of the time and space overlapping of the currents and gives the results for different numbers of phases and for different power factors.

$I^2 R$ Losses in Frequency-Changers

If we have an induction motor stator connected to a polyphase source, and a commutator rotor of the same number of poles provided with, say, three-phase stationary brushes, then as we start to rotate the rotor in the same direction as the air gap field is rotating, the frequency at the brushes remains the same as that fed into the stator, but the voltage between brush studs gradually drops as the speed rises towards synchronism. Upon passing through synchronism the voltages reverse; but the direction of phase rotation remains the same, as this depends upon the sequence with which the air gap field cuts the phase bands of conductors on the rotor, and these phase bands are stationary. The frequency at the brushes also remains constant, of course.

Below synchronism, if power is drawn from the rotor the machine will be acting as a motor; that is to say the kilowatts input to the stator will be greater than the electrical output from the rotor. The rotor action itself, however, is that of a generator, and if the current drawn from the rotor is a lagging one, a demagnetizing action will be produced.

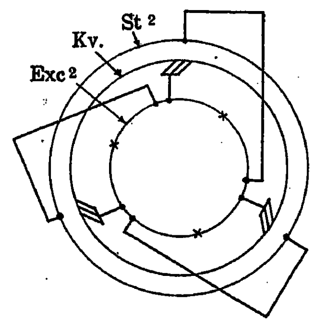
After passing through synchronism mechanical power will have to be put into the shaft when power is withdrawn from the rotor and then power will be simultaneously delivered by the stator. The relative direction of motion of any one rotor conductor and the field will have become reversed and consequently also the direction of generator current in such conductor; but the direction of the field relatively to any one phase band of rotor conductors remain as before; hence a lagging current in the circuit supplied by the rotor, which previously produced a demagnetizing action, now produces a magnetizing one, and we have so far as the rotor alone is concerned an a-c. generator whose voltage increases upon an inductive load and drops upon a capacity load. The corresponding case without a-c. excitation of the stator, would be that of a salient pole stator with the commutator brushes rotating in a direction opposite to that of the rotor. Such a generator ought to self excite when connected to an inductance; or if excited by direct current on the stator, would have a negative regulation upon an inductive load.

Coming back to the first case and making the number of conductors the same on the Δ-connected stator and rotor, as also the coil throw, but the direction of coil progression different, we have a curious combination, when this machine is driven at twice synchronous speed. If, say, an a-c. supply be connected to the stator only, a magnetizing current will be drawn from the supply, having the usual 90 deg. lag. If instead, the rotor be connected to this supply, the same amperes of magnetizing current will be drawn, but the current will be leading by 90 deg. Consequently, if both stator and rotor be connected in parallel to the supply, the magnetizing current can circulate between the stator and the rotor without any being supplied from the outside system. To obtain this circulation of magnetizing current, the small voltage required for IR and leakage reactance purposes must be obtained; the former would be immediately provided by a slight shift of the brushes, causing the phase bands on the rotor to be slightly displaced from those on the stator. In this case the voltage of the machine, being controlled by the excitation current circulating between stator and rotor, would be adjusted by slight movements of the brush ring backwards or forwards. In such a machine the field rotates in the same direction as the rotor at half the speed of the rotor and consequently a rotor conductor is cutting the field in a direction opposite to that in which the stator conductor, immediately opposed to it, cuts the field, the two speeds of cutting being the same. Hence we have in the case of such a machine acting as a generator, complete compensation of the stator ampere conductors by the rotor ampere conductors immediately opposite to them. Such a machine should prove self-regulating.

In addition to the IR voltage required to circulate the magnetizing current, there will be required on account of the slight magnetic leakage of stator and rotor conductors, a small component voltage in the same phase direction as that of the voltage produced by the air gap field—in phase for the rotor, out of phase for the stator. If this were not taken care of, the

Presented by title only at the 10th Midwinter Convention of the A. I. E. E., New York, N. Y., February 15-17, 1922.

load current would divide unequally between stator and rotor. Probably a small a-c. excitation of variable voltage and field phase, will have to be inserted, the line terminals being located at centers of phases of exciter windings.



The type of machine here dealt with is that in which a commutator and set of slip-rings are connected to a common winding, the rotor thus being similar to that of a synchronous converter.

In the case of a synchronous converter, a field structure with separate excitation windings is used, but it would be possible to produce the requisite magnetizing force by alternating currents introduced at the slip-rings, or by direct current at the commutator. In fact converters have been proposed in which the whole mechanical structure remains at rest except the system of brushes which plays upon the commutator. In this case the magnetic field rotates in space synchronously with the brushes, and the external structure has neither salient poles nor windings but serves merely to close the magnetic circuit of the rotor. Although both elements, corresponding to the stator and rotor of the synchronous converter, remain at rest here, it is still necessary to employ a considerable air gap in view of the fact that the distribution of three-phase or six-phase currents in the armature winding, while nearly cancelling the distribution of direct currents over each pole pitch, do so only *on the average*, leaving relatively large uncompensated positive or negative ampere turns of armature reaction locally, which fluctuate both in time and in position relatively to the tap points and to the brushes. This feature which similarly becomes objectionable in the frequency changer discussed below, can be mitigated by chording the winding.

Now if in the above type of machine, the brushes should be rotated at a speed other than that at which the air gap field rotates, alternating current would clearly be drawn from the machine instead of direct current, and the frequency of the commutator current would correspond to the speed difference. Further, should three sets of brushes per pair of poles be evenly disposed upon the commutator instead of two, three-phase currents would be withdrawn. For mechanical convenience we may evidently bring the brushes to rest, maintaining the same relative velocities by rotating the remainder of the structure, or by rotating the wound armature only. We then have the frequency changer about to be discussed here. The proper chording of the coils to minimize the irregularities of resultant armature reaction has been specified by Lamme[1] to be approximately half the angle between consecutive brushes on the commutator; for instance, if we had six brushes on a two pole commutator the coil span would be made 150 deg. or 210 deg. instead of 180 deg.

Before considering the I^2R losses in this machine it will be well to obtain a clear picture of the conditions arising by noting a few salient features.

Fig. 1 represents diagrammatically the rotor of the machine.

Let us represent by

p the number of pairs of poles.

f_1 the frequency at the slip-rings.

f_2 the frequency at the commutator.

Then we note that

1. The magnetic field must rotate relatively to the rotor with a speed in revolutions per second of

$$n_1 = f_1/p$$

2. It must rotate in space, or relatively to the brushes on the commutator, with a speed of

$$n_2 = f_2/p$$

3. The rotor therefore has a speed of

$$(f_2 - f_1)/p$$

4. It is to be noted that (3) gives us the choice of two speeds; for f_2 may be positive, in which case the phase rotation at the commutator is the same as at the slip-rings, *A B C*, or it may be negative corresponding to a reversed direction of phase rotation on the commutator; f_1 is taken as positive always.

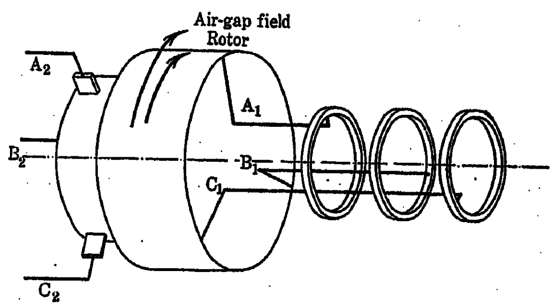


Fig. 1

5. The direction of rotation of the rotor is the same as that of the field relatively to the stator, if f_2 is greater than f_1, or if f_2 has any negative value. It is the reverse of the direction of rotation of the field relatively to the stator if f_2 is positive and less than f_1.

6. The generated voltage of the first frequency, measured from one slip-ring tap point to the next, corresponds directly to the number of armature

1. U. S. Patent No. 1318775, 1919.

conductors, the field strength, and the relative speed of field and conductors, or to f_1/p.

7. The generated voltage of the second frequency, measured between consecutive brushes on the commutator, corresponds similarly to the number of conductors, the field strength and the *same* velocity.

8. Thus if we have the armature tapped for six phase slip-rings, and brushes on the commutator for six phases also, the generated voltage of frequency f_1, between slip-rings connected to consecutive taps, will be the same as that of frequency f_2 between consecutive brushes; the currents also will be equal, barring magnetizing current and a small component which provides part of the power lost in the conversion.

9. The commutator frequency f_2 may be either higher or lower than the slip-ring frequency f_1. But if one of the two frequencies is to be a very low one, it is advisable to adopt the lower for the commutator, and this becomes essential if the lower frequency is to be subject to variation passing through zero, that is, changing its direction of phase rotation. In deciding which frequency to assign to the commutator, it will be noted that:

a. The mechanical speed is the same in either case.

b. The core loss is not greatly affected by the choice, since the field rotates at a speed corresponding to the one frequency, relatively to the stator, and the other frequency relatively to the rotor.

c. The relative speed of *rotor* and field should be high, for minimum size of machine; *i. e.*, the slip-ring frequency should be high.

d. With reference to commutation, the transformer action in the coils connected to the segments under the brush will be the smaller the lower is the frequency on the commutator side.

e. The frequency can be brought down to zero at the commutator, but not at the slip-rings.

On the whole it is usual to assign the higher frequency to the slip-rings, but no assumption on this point will be made, and the results will apply equally either way. As regards the two possible rotor speeds, we shall find that by adopting a suitable convention with regard to the sine of ϕ, the angle of displacement of current on the commutator side, the results obtained apply equally for either speed, *i. e.*, for f_2 positive or negative.

Now the currents in the rotor will result from the combination of the slip-ring currents at frequency f_1, and the commutator currents at frequency f_2.

Generally, in the case of superposed currents of two frequencies, the determination of the mean I^2R loss averaged over a few cycles, is simple, as each set of currents involves its own loss, and the net resultant loss is merely the sum of the two separate ones, irrespective of their relative magnitude or phase. In the present case, these simple relations do not hold, for although in any one conductor we have merely current of the first frequency introduced via the slip-rings, and for brief periods, we similarly have the actual current of the second frequency superposed in the same conductor, yet before one cycle is complete, the relative movement of commutator and brush has transferred this conductor into another phase group of the f_2 system.

It becomes necessary to view the cycle of events for atypical conductor, and then by a system of averages— or simple integrations— to arrive at the resultant loss.

We may start from the basis that should power be mechanically transmitted to or from the rotor, enabling the one system to operate alone, then the distribution among the arms of the delta-connected rotor of the Y-currents introduced at the slip-ring taps, or at the equivalent taps corresponding to the instantaneous positions of the brushes, will necessarily follow the ordinary $Y-\Delta$ courses; and by the symmetry of the system, the voltage upon the idle taps or brushes, as the case may be, will form a symmetrical three-phase or six-phase system. As this applies to the case of operation with power being supplied either via the commutator or via the slip-rings, the result of superposing the two will leave balanced conditions and we may therefore consider that each set of currents upon entering the rotor divides up among the delta arms in the orthodox way, so that at any instant the actual current in any conductor is the sum of the two corresponding instantaneous currents. The same reasoning may, of course, be applied to other numbers of phases than three or six on either or both sides.

We now require a simple way of viewing the life history of a typical conductor, determining for any one instantaneous value of the f_1 current the range of values of the f_2 current. We can most readily do this by reference to the only feature which is common to the two frequencies, viz.: the armature reaction. To render this process more clear, we shall on paper bring the air-gap field to rest in space by rotating the brushes on the commutator, and by readjusting the rotor speed suitably.

Assume the field to be rotating clockwise, viewed from a given side of the machine. Superpose upon the whole machine a counter clockwise rotation of f_2/p revolutions per second, thus bringing the field to rest in space while the brushes rotate counterclockwise at this speed. Note that f_2 may be negative.

We can now readily picture the current distribution in the rotor, since the armature reaction of the f_1 currents, and again that of the f_2 currents, will be represented each by a diagram fixed in space (although slightly pulsating or varying). Although produced by currents of different frequencies, these two diagrams will have the same number of poles, and on the average will cancel one another, the one being, at every instant, nearly superposable upon the reverse of the other— if for the moment we ignore the magnetizing current.

We have two methods open to us of investigating the I^2R loss; we may do so (1) by considering the loss

occurring, from moment to moment, in the succession of conductors which occupy a point fixed in space, upon the rotor periphery; then averaging this up with respect to time, and again with respect to angular position.

Or (2) we may consider a marked conductor upon the rotor; average the loss occurring in it; and again average this up for all positions on the rotor. This latter method enables us to discriminate between conductors near to, and far from the slip-ring taps, and thus has an advantage. We shall adopt this procedure, and we shall first omit the magnetizing current, in order to make the procedure more clear.

With this omission, we have the same power factor on the two sides of the machine. That this must be so, can be seen by considerations along the following lines: The same air-gap field is responsible for causing the generated voltage of each frequency, and it is stationary in space. The armature reaction diagram of the currents of frequency f_1 must be generally similar to that of the currents of frequency f_2, except for sign since the sum of the two produces the working field and we are neglecting the magnetizing current for the present. But the armature reaction of the watt component of current of either frequency has its polar center lines at right angles to those of the air gap field. Therefore, these two component armature reactions, for the two frequencies, have their polar center lines coincident; the watt component of current of frequency f_1 must be equal to the watt component of current of frequency f_2, in order to effect balance of mechanical torque; and therefore the armature reactions of these two watt components balance one another; hence the

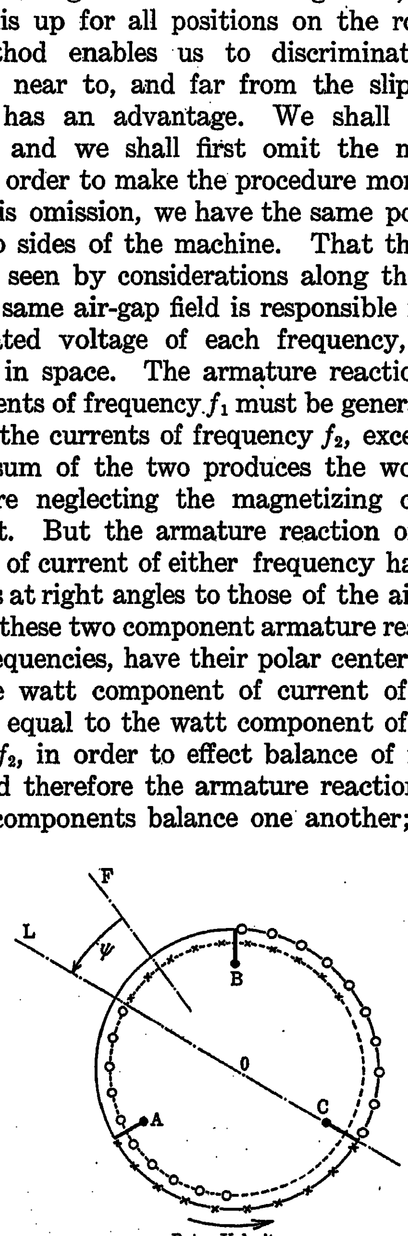

FIG. 2

armature reactions of the two remaining components must balance one another, *i. e.*, the two wattless current components must be equal and therefore the power factor must be the same on the two sides.

We shall now show, still neglecting the magnetizing currents, that for positive values of f_2 not only is the power factor the same on the two sides, but the sine of ϕ, which determine whether the current is leading or lagging, is the same; while for negative values of f_2 the power factor is the same on the two sides, but a lagging current on the slip ring side is associated with a leading one on the commutator side, and vice versa.

Fig. 2 indicates diagrammatically a two-pole rotor tapped at $A\ B\ C$ for three-phase slip rings; the line $O\ F$ represents the stationary polar center line. Assume the rotor to be driven in a counter-clockwise direction

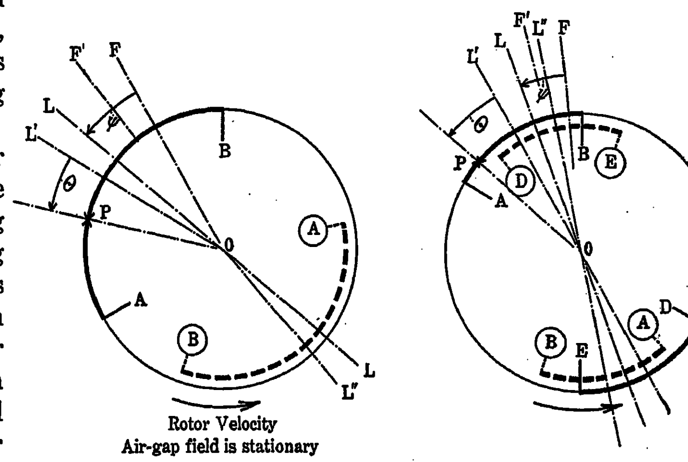

FIG. 3

mechanically and to be acting as an a-c. generator, then the current in every conductor of the $A\ B$ phase band will reach its maximum when the center line $O\ L$ of the phase band has some definite angular position, say ψ in advance of $O\ F$, where ψ may be positive or negative. If the load be noninductive ψ will be zero and the current will be a maximum in all conductors of the phase band at the moment when $O\ L$ coincides with $O\ F$. If the load be inductive and the current be lagging by an angle α, then when the current reaches its maximum in the conductors of the $A\ B$ phase band, the center line $O\ L$ will have advanced beyond $O\ F$ by the angle α, and in the well recognized manner, the conductors of the phase band will occupy such a position that the reaction of the currents in them has a component along $O\ F$ opposing the main field.

If now the points $A\ B\ C$, instead of being fixed tap points rotating with the rotor, should correspond to the momentary positions of brushes on the commutator which are rotating in a direction the reverse of that of the rotor, then the movement of the center line $O\ L$ by the angle α will be in a clockwise direction in the figure. But as the voltage induced in the conductor is due to the motion of the conductor, and not that of $O\ L$, it will remain in the same direction as before, and hence also the current in the conductor if the machine is still acting as a generator via $A\ B\ C$. In this case, therefore, a lagging current will produce a reaction having a component along $O\ F$, tending to *increase* the field strength although the machine is acting as a generator and not a motor.

Hence we have the condition already outlined for

the relative phase displacement on the two sides, *viz.*, that when f_2 is positive $\phi_1 = \phi_2$, but when f_2 is negative $\phi_1 = -\phi_2$.

We have seen that the power factor is the same on each side of the machine; it follows that the amperes per slip ring equal the amperes per brush stud, assuming the same number of phases each side, for the voltage between rings equals that between brush studs.

Fig. 3 shows a two pole rotor with chorded windings; the right hand diagram shows six phase taps brought out, and the left hand three phase taps. The region occupied by conductors of one phase, which we may call a phase band, is shown by heavy lines, dotted for the inner layer conductors and full for the outer. The tap is shown as though located opposite the slot containing the outer layer conductor to which it is connected, but the inner layer conductor to which it is also connected is indicated by a similar letter with a circle around it; this is displaced from the outer layer conductor by one coil span. $O\,L'$ represents the center line of the outer layer phase band, and $O\,L''$ the center line of the inner. The effective center line for determining the phase relations is $O\,L$ which is displaced from $O\,L'$ by half the angle of chording. It will be understood that the tap points shown may be either actual fixed taps connected to slip rings, or may represent the momentary position of brushes on the commutator; in either case the voltage generated in the phase band is the same, being produced by the movement of the conductors in the field and not by the movement of the center line of the phase band. If we are dealing with a commutator phase band the center line $O\,L$ may be rotating oppositely to the rotation of the rotor itself; *viz.*, when f_2 has a negative value.

In the figure, $O\,F$ represents the polar center line of the main field and ψ the angle, measured counter clockwise, of $O\,L$ from $O\,F$. We take the component of current in the phase band which has frequency f, to have a root-mean-square value of unity and we define its phase angle as follows:

If f is positive, $+\phi$ represents the angle by which the current *leads* with respect to conditions for unity power factor.

If f is negative, $+\phi$ represents the angle by which the current *lags* with respect to conditions for unity power factor.

In either case the power factor is $\cos\phi$ and a magnetizing armature reaction is associated with generator conditions when ϕ is positive.

It will be found that with this definition the current component of frequency f in every conductor of the phase band $A\,B$ is represented by

$$\pm\sqrt{2}\cos(\psi + \phi) \tag{1}$$

for either direction of rotation of $O\,L$. Note that ψ is always to be measured in a counter-clockwise direction.

When we are dealing with a specific conductor P in say the outer layer, it becomes convenient to specify this by its co-ordinate measured from the center line of its phase band in the layer in question, or $O\,L'$ for the outer layer, instead of from $O\,L$, and consequently it becomes convenient to deal with the angular co-ordinate of $O\,L'$, rather than $O\,L$, with respect to the fixed field axes. It will be noted that we may still use expression (1), and define ψ therein as the angle measured counter clockwise from some suitable zero line $O\,F'$ fixed in space, to the phase band center line $O\,L'$; further the datum line $O\,F'$ will be the same whether $O\,L'$ is a center line of a slip ring phase band and therefore is fixed in the rotor, or whether it represents the momentary position of the center line of a commutator phase band and is rotating in the same direction as the rotor or the reverse. In other words, the chording angle does not enter into consideration in dealing with the difference of phase of the currents of the two frequencies in a conductor, either for positive or negative values of f_2.

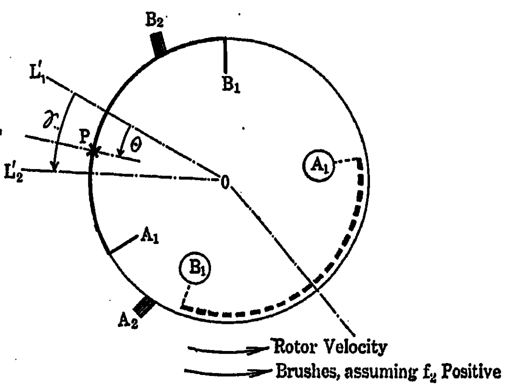

FIG. 4

THREE-PHASE CASE

Consider now the case of three-phase slip ring taps and commutator brushes 120 deg. apart, Fig. 4, and omit magnetizing current for the present. P in the figure represents a definite conductor of the rotor; it is shown as occurring in phase band $A_1\,B_1$ of the slip ring side, and in $A_2\,B_2$ on the commutator side. It remains permanently in the $A_1\,B_1$ phase band, but passes successively through the various phase bands of the second frequency (commutator).

Currents then arise in the conductor P having values which have already been discussed and represented by (1). They have respectively the values:

$\sqrt{2}\cos(\psi_1 + \phi)$ of frequency f_1

and $\sqrt{2}\cos(\pi + \psi_2 + \phi)$ of frequency f_2

The difference $(\psi_2 - \psi_1)$ may clearly have any value between $\pi/3 + \theta$ and $-\pi/3 + \theta$. Further, every value within this range is an equally probable one and will occur for the same number of seconds per hour of operation, on the average. We therefore require the average value of

$$2\,[\cos\psi - \cos(\psi + \gamma)\,]^2 \tag{2}$$

for all values of γ within the range $(\theta \pm \pi/3)$, giving equal weight to each value. We shall next require

the average value of this result for all values of ψ over a range of 2π. This will give us the loss in a specific conductor; to obtain the entire rotor loss we shall have to again average for all possible values of θ, *i. e.*, between $\pm \pi/3$ in our present three-phase case.

For the loss in conductor P we have therefore:

$$\frac{3}{2\pi^2}\int_{\gamma_1}^{\gamma_2} d\gamma \int_0^{2\pi} [\cos\psi - \cos(\psi+\gamma)]^2\, d\psi$$

where

$$\gamma_2 = \theta + \pi/3$$
$$\gamma_1 = \theta - \pi/3$$

which is equal to

$$3/\pi \int_{\gamma_1}^{\gamma_2} d\gamma\,(1-\cos\gamma) \qquad (4)$$

or to

$$2 - 1.653\cos\theta \qquad (5)$$

If we had current of the one frequency only in the conductor, the corresponding loss would be unity, as we have taken the current to have an r. m. s. value of unity. Hence the loss, in terms of that due to current of one frequency only, is given by the above expression (5). This is clearly least for the mid conductor of the phase band, *i. e.* for $\theta = 0$ while it is a maximum for the two tap conductors for which $\theta = \pm\pi/3$. For these two positions the relative losses are, respectively:

Mid conductor 34.7 per cent
Tap conductors 117 per cent

Finally, averaging expression (5) for values of θ over its range $\pm\pi/3$ we have for the relative total rotor loss

$$2 - 1.367 \qquad (6)$$

or 63 per cent of that corresponding to the current of one frequency only.

SIX-PHASE CASE

In the case in which six-phase provision is made on each side of the machine, the expressions become slightly modified to suit a range of θ of $\pm\pi/6$, and a range of the difference $(\psi_2 - \psi_1)$ amounting to $\theta \pm \pi/6$. Consequently expression (5) for the conductor loss becomes

$$2 - 6/\pi\cos\theta \qquad (7)$$

and expression (6) for the rotor loss becomes

$$2 - 18/\pi^2 \quad \text{or} \quad 0.176$$

so that the losses, in terms of those corresponding to the current of one frequency only, amount to

For mid conductor of phase band (min.) 9 per cent
For tap conductor (max.)............ 35 per cent
For whole rotor..................... 17.6 per cent

LOSSES ALLOWING FOR MAGNETIZING CURRENT

We may have the magnetizing current introduced at the slip rings or at the commutator, or partly at each; and either side may be the motor side. As a matter of fact we may arbitrarily say at which side we consider the magnetizing current to be introduced, as this affects only our definition of load current in which we already have a variable phase angle ϕ at our disposal. The case will therefore remain general if we consider the magnetizing current to be introduced at the slip rings and define the load current as being the current at the commutator side, no matter at which side power enters the machine, nor which of the two currents is the greater. We later give expressions enabling the loss to be written down in terms of the current on each side of the machine and the known magnetizing current, and so avoid the necessity of considering how or where the magnetizing current is supplied.

Take, then, the magnetizing current to be introduced at the slip rings, and let the angle ϕ refer to the conditions on the commutator side and be subject to the definition already given on page 54. Take the root-mean-square value of current on the commutator side as unity, and define:

m = ratio of amperes magnetizing current to amperes load current, *i. e.* to amperes on the commutator side.

The expression to be averaged, corresponding to (2), is then:

$$2\,[\cos(\psi_1+\phi) + m\cos(\psi_1 \pm \pi/2) - \cos(\psi_2+\phi)\,]^2 \qquad (8)$$

where the upper sign is to be taken if the slip ring side is the motor side, and the lower if the generator side. Or, we may average:

$$2\,[\,\cos\psi \pm m\sin(\psi-\phi) - \cos(\psi+\gamma)\,]^2$$

between limits zero and 2π as regards ψ and the limits for γ already used for three-phase and six-phase respectively.

The result is easily found to be:

$$[m^2 + 2a] + \text{Average value over the } \gamma \text{ range of } 2\,[\,b\sin\gamma - a\cos\gamma] \qquad (9)$$

where

$$b = \pm m\,.\cos\phi$$
$$a = 1 \pm m\,.\sin\phi$$

the signs being subject to the conditions stated above in connection with (8).

For the three-phase case the limits for γ are $\theta \pm \pi/3$ and the relative conductor loss becomes:

$$[m^2 + 2a] + 1.655\,[b\sin\theta - a\cos\theta] \qquad (10)$$

while for six-phase, γ varies between $\theta \pm \pi/6$ and the relative conductor loss becomes:

$$[m^2 + 2a] + 1.91\,[b\sin\theta - a\cos\theta] \qquad (11)$$

Now a may be taken as positive except when the magnetizing current exceeds the load current being considered; and b may be positive or negative; the maximum value of (10) will therefore occur for $\theta = \pm\pi/3$ according as b is positive or negative; and the maximum value of (11) will occur for $\theta = \pm\pi/6$ according to the same conditions. Inserting these values we find for the worst conductor:

Three phase

$$1.172 + m^2 + 1.433\,m\,.\cos\phi \pm 1.172\,m\,.\sin\phi \qquad (12)$$

Six phase

$$0.347 + m^2 + 0.955\,m\,.\cos\phi \pm 0.347\,m\,.\sin\phi \qquad (13)$$

Finally, averaging (**10**) and (**11**) for variations of θ we have:

Three phase rotor loss

$$m^2 + 0.63\,[1 \pm m\,.\sin\phi] \tag{14}$$

Six phase rotor loss

$$m^2 + 0.175\,[1 \pm m\,.\sin\phi] \tag{15}$$

this frequency in the conductor. For any different brush stud current, I_2, we shall have a correspondingly altered slip ring current; also m will be changed, since the actual amperes of magnetizing current remain independent of I_2. However, by multiplying the previous expressions by $I_2^2\,r$ or by $I_2^2\,r'$ as the case may require, we shall have the correct loss expression

Item	Phases	Power Factor on Com.[2]	Power Factor on Slp. Rs.	ϕ (degrees)	Motor side	Amperes on Com.[2]	Amperes on Slp. Rs.	Rotor speed higher or lower	Percentage Losses Worst Cond.	Percentage Losses Rotor
Excluding magnetizing current.

6	Six	1	0.956	0	Either	1	1.045	Either	43.5	26.6
7	"	0.8 lag	0.66 lag	− 36.9	Slp. Rs.	1	1.21	Lower	73.5	29.8
8	"	0.8 lead	0.66 lag	− 36.9	"	1	1.21	Higher	73.5	29.8
9	"	0.8 lead	0.935 lead	+ 36.9	"	1	0.855	Lower	60	23.4
10	"	0.8 lag	0.935 lead	+ 36.9	"	1	0.855	Higher	60	23.4

For the purpose of illustration, we give in the tabulation herewith some numerical values for the different cases discussed. We take a magnetizing current equal to 30 per cent of the current on the commutator side, or $m = 0.3$, and we give the losses as percentages, in terms of the losses due to the current at the commutator side only.

It will be found that the expressions given later, in a different form, see (**16**) to (**19**), allow a clearer appreciation of the manner in which the loss is influenced by the conditions of operation than those set down above.

The previous results may be put into a different form which will sometimes be more convenient of application. In the case of an actual machine we shall know what figure to use as an equivalent resistance r such that if I_2 is the (r. m. s.) current per commutator brush stud, $I_2^2\,r$ will be the total loss, W_2, in the armature winding due to the commutator currents alone flowing. Similarly the same value r in $I_1^2\,r$ will give us the loss W_1 due to the slip ring currents alone flowing in the armature winding, the current into each slip ring having a (r. m. s.) value equal to I_1. The magnetizing current, for which our symbol is $m\,I_2$ will similarly cause a loss, if flowing alone, denoted by W_0 and given by $(m\,I_2)^2\,r$. Further, in an actual case we shall know what value to take for r', *viz.*, an equivalent resistance such that the loss in "the worst conductor" due to the several currents taken separately is given respectively by the expressions $I_2^2\,r'$, $I_1^2\,r'$, $(I_2\,m)^2\,r'$. These losses we shall also denote by W_2', W_1', W_0' respectively.

Now the various expressions we have deduced for the mean value of the net current squared, in a conductor, or for the average value of this throughout the rotor, were based upon a commutator brush stud current such as to give unit (r. m. s.) value to the current of

for a brush stud current of I_2 amperes, and we can rewrite them in terms of W_1, W_2, W_0 etc., since we have:

$$W_0 = (m\,I_2)^2\,r \quad W_1 = (a^2 + b^2)\,I_2^2\,r \quad W_2 = I_2^2\,r$$

and corresponding equations in W' and r'; and by means of these we can replace m, a, b, etc. Thus, from the definition of a, b, we have:

$$(1 - a)^2 + b^2 = m^2$$

and therefore:

$$2\,a\,I_2^2\,r = W_1 + W_2 - W_0$$

Expression (**14**) which, upon multiplication by $I_2^2\,r$ is equivalent to $[m^2 + 0.63\,a]\,I_2^2\,r$, becomes when re-written:

$$0.315\,(W_1 + W_2) + 0.685\,W_0 \tag{16}$$

and represents the three-phase rotor loss; while the six-phase rotor loss is similarly found from (**15**) to be:

$$0.088\,(W_1 + W_2) + 0.912\,W_0 \tag{17}$$

In precisely the same way the loss in any one conductor at position θ can be written down in the new terms, from expression (**10**) and (**11**), *viz.*

For three-phase;

$$W_0' + 1.655\cot\phi\,\sin\theta\,W_2' + [1 - 0.827\cos\theta - 0.827\cot\phi\,\sin\theta]\,[W_1' + W_2' - W_0'] \tag{18}$$

For six-phase;

$$W_0' + 1.91\cot\phi\,\sin\theta\,W_2' + [1 - 0.955\cos\theta - 0.955\cot\phi\,\sin\theta]\,[W_1' + W_2' - W_0'] \tag{19}$$

In expressions (**18**) and (**19**), ϕ is introduced as well as the W' s. The conditions of operation are really completely defined when we are given the values of the three W' s, a statement as to which side is the motor side, and the two frequencies (including their relative signs); hence the presence of ϕ might be avoided. In fact an inspection of the vector diagram for the three current components (f_1 load, f_2 and f_1 magnetizing) will reveal that

$$\sin \phi = \pm \frac{W_2 + W_0 - W_1}{2 \sqrt{W_2 W_0}}$$

the upper or lower sign being taken according as the slip ring side is acting as the motor or generator side. Hence ϕ might be eliminated by means of this equation; or alternatively, in an actual case it may be determined from this equation, if not independently known, and the value used in the expressions given.

The reference numbers of the expressions derived in this chapter for the conductor and rotor losses under various conditions and allowing for magnetizing current are collected below for convenience of reference;

CORRESPONDENCE

POLYPHASE COMMUTATOR MACHINES

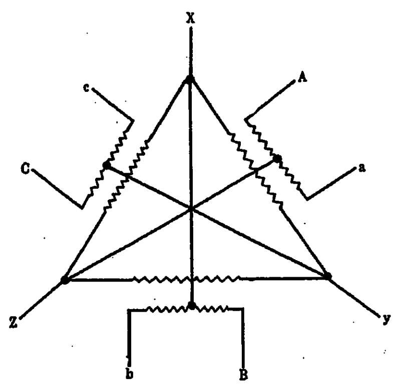
To the Editor:

An article under this heading appears in the January issue of the JOURNAL, attributed to myself. In spite of the title the Article itself deals with only one type of frequency changer, and even for that machine only discusses some of the I^2R losses, but the broad titles which appears above the article has no doubt arisen by reason of the inclusion, through some inadvertence, of the matter contained in a hastily compiled memorandum dealing with another subject, and not intended for publication; this composes the first five paragraphs and the first (unnumbered) figure of the article in question.

The error would have been avoided had proofs been submitted to me, but in the circumstances perhaps you will allow me to make some necessary corections now, in the part referred to.

On page 50 of the JOURNAL in the fourth paragraph of the article, reference is made to the characteristics which may be expected from a machine comprising an induction motor stator and a rotor having a commutator, both stator and rotor having closed windings with the same number of conductors. The rotor is supposed to be running at twice synchronous speed in the same direction as the air-gap field, and the three phase brushes to be in line with the three phase tapping points of the stator winding, or at 180 deg. to the same, according as the coil progression of the rotor winding is the reverse of, or the same as that of the stator winding. It is suggested that as the same air-gap field would be produced by a lagging magnetizing current in the stator winding as by a leading current in the rotor winding, the requisite magnetizing current might be induced to circulate between stator and rotor connected in parallel to the bus bars without the necessity of any magnetizing current being introduced from outside; also that the small $I\,R$ voltage required to cause this circulation might be produced by a slight shift of the brushes, while the small $I\,X$ voltage component at right angles to this, corresponding to the stator and rotor leakage fluxes associated with the magnetizing current only, might be introduced by an a-c. exciter, interposed between the line and the machine.

The statement needs a little modification in as much as the shift of brushes which provides the requisite $I\,R$ voltage for the circulation of magnetizing current produces at the same time a compounding effect, and would therefore have to be determined by the amount of such compounding desired; the balance one way or the other would have to be obtained otherwise, for instance by the transformer connection referred to later. Further, the $I\,X$ voltage required would automatically appear by a slight slip arising, that is, by the air-gap field taking up a speed of rotation slightly different from half the rotor speed; therefore no a-c. exciter need



be postulated. For operation with shunt characteristics the brushes would be left in the normal position, and a small quadrature voltage would be injected between the stator and rotor to overcome the $I\,R$ drops corresponding to the circulation of magnetizing current only; this quadrature voltage might be introduced by the delta-connected transformer arrangement shown in the appended figure, the lines $A\ B\ C$ going to the stator and $a\ b\ c$ to the rotor, while $X\ Y\ Z$ pass to the busbars. The transformer might advantageously have a moderate magnetic leakage.

The last two statements of the fourth paragraph substantially stand, to the effect that in a machine such as here described the field rotates in the same direction as the rotor at approximately half the speed of the rotor so that a rotor conductor cuts the field in a direction opposite to that in which the stator conductor, immediately confronting it, cuts the same field, the two speeds of cutting being nearly the same; and that therefore, whether the machine be running as a generator or motor, almost complete compensation takes place of the stator ampere conductors by the rotor ampere conductors immediately confronting them and the machine becomes closely self-regulating.

It will be seen further that although the machine

operates with some slip, it behaves more like a synchronous generator or motor than an induction machine inasmuch as there is one combination of frequency speed and voltage which forms a consistent set of conditions, and the only natural flexibility in the relation between the frequency and speed is that introduced by saturation which causes a variation in the ratio between the IR and IX components of voltage requisite for circulating the magnetizing current. The slip will not change sign between generator and motor conditions of operation, in fact it arises only to provide voltage for circulating magnetizing current and not for load current. A slight variation in frequency with speed fixed can be artificially secured however by introducing an external inductance in the path of the circulating magnetizing current; such inductances may, if desired, be so arranged as to be substantially non-inductive to the passage of load current, although inductive to the circulation of magnetizing current. Similarly the voltage can be varied with speed fixed, or with frequency fixed, by varying the ratio of the transformer shown in the figure, or by introducing an external resistance in the path of the magnetizing current, but unlike the inductance the resistance can only be introduced in a manner such that it opposes the load current as well as the magnetizing current.

For parallel operation or for stable running as a motor, a certain amount of effective reactance will be necessary either internal to the machine or accessory. In this respect also the conditions are similar to those which arise with synchronous machines.

These features of operation are detailed here, not with the intention of claiming practical utility for the arrangement, but merely to correct the somewhat erroneous view of the matter which has already been printed in the article in question.

While upon this subject it may be of interest to consider the conditions arising at twice synchronous speed in the frequency changer dealt with in the main part of the article. If we assume the rotor of say a three-phase frequency changer of this type to be independently driven at twice synchronous speed in such direction that the frequency is the same on the commutator as on the slip rings, we have two three-phase systems of equal frequency and voltage associated with the machine. The phase rotation on the commutator is the reverse of that on the slip rings considering corresponding brushes but nevertheless the two three-phase systems can be paired and brought into phase with one another and then there would seem to be no objection to paralleling them on to common bus bars. The machine will then be running on the bus bars without distress with commutator brushes solidly connected to slip ring brushes, a somewhat paradoxical condition. Here again the arrangement is of theoretical interest only and has no practical utility, it acts neither as generator, motor nor converter; it might serve as a filter to short-circuit all effects other than those of fundamental frequency.

Glancing over the main part of the article I note that ambiguous signs are invariably printed with the plus as the upper and the minus as the lower sign, whereas they should be reversed in the case of the expressions numbered 8, 12, 13, 14, 15 and in the definition of a on page 55. Without these corrections the tabulation would appear to be wrong and the matter troublesome to follow.

A. B. FIELD.

The Electric Hammer.

BY P. TROMBETTA

Associate, A. I. E. E.

General Electric Company, Schenectady, N. Y.

Review of the Subject.—*The power hammer has been in use for a long time and there are now on the market many types of power-operated hammers which may be roughly classed according to the nature of the power as follows:*

Pneumatic, steam, motor and pulley; cam or crank, and electro-pneumatic drives. The pneumatic drive includes all riveting hammers; the steam drive includes practically all forge hammers, some drop hammers, pile drivers and steam drills; the motor and pulley drive class, includes the greater part of drop hammers; the electro-pneumatic drive includes only small forge hammers. The pneumatic hammer, due to its lightness, holds the field of hand-operated riveting hammers and it is hardly possible that any other means will ever surpass air for driving hand-operated riveting hammers; the steam hammer holds its own in very large forging and drop hammers and it is doubtful whether any other kind of hammer can remove it from that place. The field for very large forging or drop hammers is however rather limited; they are used only in very large plants in which all sorts of power prevail.

There is an immense field, however, for medium and small forging and drop hammers which are used to produce all the small automobile and other similar parts as well as name plates, jewelry apparel, etc. It is this field which the electric hammer is supposed to cover. The present methods of driving these hammers are cumbersome, complicated, costly and very unsafe for the workman.

The electric hammer has been studied and developed by the writer to a point where it seems to show superiority to the present used hammers, in simplicity, safety, running expenses, cost of installation, cost of upkeep and in many cases in the original cost.

The development shown herein is of the induction motor type. Instead of the usual arrangement of concentric armature and field, the slots are punched on long strips of iron in a straight line which makes the field and armature parallel. The armature and field still face each other but every part of the aramture is not always active under th influence of the field as is the case in the ordinary motor. In other words in a straight-line motor the armature or runner is continuously entering the field of action at one end and leaving it at the opposite end. This constitutes the main difference between the straight-line and the rotary motor. The rotating fields of an induction motor are here replaced by magnetic fields moving in a straight line. The principal elements of this straight-line induction motor hammer are shown in Fig. 3. The actual hammer as finally constructed is shown in Fig. 5 (back view) and Fig. 6 (front view.)

CONTENTS

Definitions

An electric hammer as described in this paper constitutes a hammer in which the reciprocating part is moved solely by the direct action of the electromagnetic forces without interposition of any other mechanism, such as belts, gears, compressed air, etc.

The electrical portion of the reciprocating part, which is analogous to the rotor of a motor, will be called the runner while the die holder which is attached to the runner is called the ram.

Electric hammers may be divided into four classes: Direct-current, semisynchronous induction, nonsynchronous induction and purely synchronous. A direct-current hammer consists of two symmetrical straight armatures mounted facing each other between which moves the field carrying with it the brushes; it may also be made with two stationary fields and one moving aramature. A semisynchronous induction hammer is made by setting two polyphase straight-line stators facing each other with a squirrel-cage runner moving between them; the reversal of the current is made by a switch rigidly connected to the generator shaft so that the phases are reversed at zero potential and at predetermined intervals. A two-phase hammer fed with two phases of different frequency in which the reversal comes at the nodes of the two frequencies may also be classed as a semisynchronous hammer.

A nonsynchronous induction hammer is made exactly as a semisynchronous induction one with the exception that the reversing of the phases at each end of the stroke is done by the runner itself. A purely synchronous hammer may be defined as a hammer

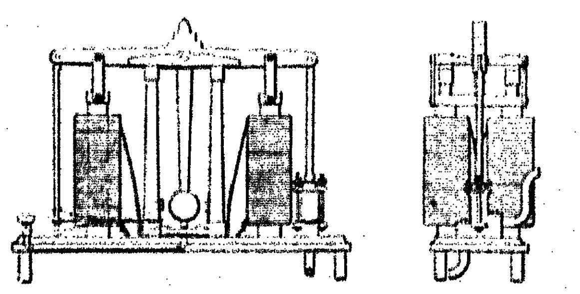


FIG. 1—FIRST PATENT ON RECIPROCATING MOTOR
Issued in 1852.

which gives one stroke per cycle. This type of hammer may be made of the simple plunger type or of the excited plunger type.

Historical

The writer invented the electric hammer early in 1915, when still in school. After coming out of school, the war was in full swing and it was thought inadvisable to start developments of any kind. The studies were

Presented at the Spring Convention of the A. I. E. E., Chicago, Ill., April 19-21, 1922.

made independently but the following historical treatment will show that it was not an invention but a reinvention.

The subject of the reciprocating motor in general is practically as old as that of rotary motors; this fact is shown by the records in the Patent Office from which it is seen that the earliest attempts to make electric motors were mainly along the lines of imitating the reciprocating steam engine and the first patent for a reciprocating motor to be applied to a pump was issued in 1852; a picture of this device is reproduced in Fig. 1. In 1870, there were some attempts made to operate sewing machines with reciprocating electric motors. In 1880 appear two patents on a solenoid rock drill. In 1885, the Van Depoele patent appears. This patent is reproduced in Fig. 2 from which it may be seen that engineering was, at that time, being applied to this line of inventions, for it is quite a well developed machine which may easily be made practical by

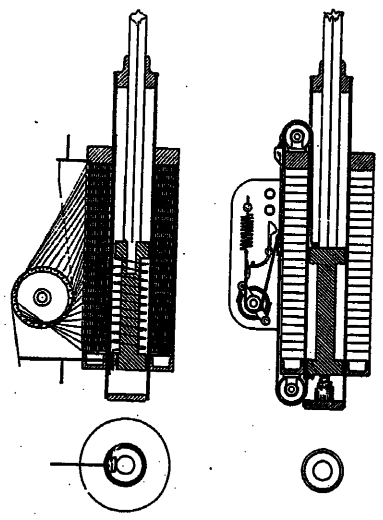

FIG. 2—A WELL DEVELOPED IDEA ON STRAIGHT-LINE MOTORS Patented in 1885.

properly proportioning it. It is a d-c. machine in which the armature is stationary and the field moves. An important feature of this machine is that the plunger is excited while machines of previous dates were made with a nonexcited plunger, that is, they were mere electromagnets and with this machine we pass from electromagnets to straight-line motors. The idea of plunger reciprocating motors and straight-line d-c. motors prevails until the present time and it would be useless to recount here the innumberable patents that have been issued on the subject. It may be said, however, that the idea remains unchanged and the only thing that changes is the inventor.

In August, 1901, a patent was issued to R. D. Mershon on a straight-line nonsynchronous polyphase induction motor for a rock drill. He mentions in his specifications that prior to that time polyphase rectilinear motors have been proposed in which the reversing of the fields was done by a switch connected to the generator; that system he condemns because the vibratory period of the motor would have to be of certain value in order to be in synchronism with the generator, and consequently it would not start from rest unless those conditions were fulfilled. His system has a reversing switch operated by the moving part of the motor and consequently makes the latter completely independent of the generator. As far as the writer can find, this is the first record of a practical polyphase rectilinear motor.

In 1905, a patent was issued to P. Centener. This machine is based on an entirely new principle. In this machine, each stator is fed with two separate sources of alternating current of different frequencies and in this way the motion of the field is reversed at the beats occurring in the two frequencies so that the moving part would reverse its motion without the necessity of reversing the currents by means of contactors or switches. While this machine is built on different principles from those criticised by Mershon, its faults are the same, namely: It has a constant period and it requires special generators to operate it.

In 1909, a patent was issued to T. F. Bailey in which the same invention as is shown in Mershon's patent was described with the exception that the application is made directly to a forge hammer instead of to rock drills.

The success of these inventions in rectilinear motors is apparent from the fact that none of them are at the present time on the market. Of the semisynchronous hammers, the only successful machine that the writer knows of is that made by Professor Leo Schüler of Berlin, Germany, described in U. S. Patent No. 1115251. He actually made a small chipping plunger hammer that would work successfully. From his account in the *Elektrotechnische Zeitschrift*, it is hard to understand why the machine has not been put on the market unless it is for the reason that it requires special generators for the supply of power. It is not known to the writer whether or not there have been built any polyphase rectilinear motors operating on the principle brought out by Mershon, that is, in which the reversing is done by the motor itself. Mr. Charles Fair, who was employed by the G. E. Co. at the time this work was started, said that he had seen a model of the d-c. plunger-type hammers which he described as not being "lively" enough for forging purposes. The machine, as he described it, was made up of a series of solenoids in which moved a plunger. The plunger was first attracted by one solenoid, the current was then switched to the next one and the plunger moved with the current. Irrespective of whether this machine was "lively" or not it is easy to see what difficulties would be encountered in shifting the current from one solenoid to another at the time of maximum inductance. In other words, it may be said that this machine was a very badly designed direct-current motor.

The reasons why the electric hammer was not developed appear to be the following: In the early days of electrical development the demand for hammers was rather small; rotary motors could be used for many more applications than the special uses for which the straight-line motors were proposed; hence it became much more remunerative to develop rotary motors than to develop straight-line ones. Once a rotary motor was available in its perfect form it became much easier simply to take a standard motor and apply it to the particular use for which it was needed than it would have been to develop a new special motor.

It may be said further that in the early stage of electrical development, the total demand for motors was very small and of this total demand the percentage which required an ordinary standard motor was far greater than that which required a special straight-line motor, so that it was altogether out of question for any manufacturer to undertake the development of as many special motors as there were special cases to be taken care of. At the present stage of electrical industries, the conditions are precisely reversed in that there are now many special cases which require a much larger number of motors than was required for the total electrical industry in the earlier days of the art and certainly anybody who is acquainted with the industry will agree that many manufacturing enterprises are now existing, and in fact prospering in the manufacture of only one or two special appliances. It is for this reason that it is felt justifiable to state that the application of standard rotary motors to special cases has gone beyond its limits.

The above is, it is hoped, the answer to the many questions that are continually being asked as to why it is that nobody else has ever tried to develop an electric hammer before this if it is as simple as it looks. It is also an explanation of the arguments which led to the undertaking of this development.

As a matter of fact, it is felt that the development of a new special machine will always be justified as long as the demand for it is large enough to build up a reasonable amount of business and its qualities are such as to guarantee its preference to existing systems.

Preliminary Studies of the Electric Hammer

When the study of the electric hammer was undertaken, the subject was so new from an engineering view point that a preliminary study was required in order to decide which system of those mentioned would be the best to use, also to determine fully the advantages of an electric hammer over those hammers which it was to replace.

In studying the problem in general, it is found that an electric hammer is essentially an apparatus which is continually starting and stopping; electrically, therefore the apparatus best fitted for this purpose would be an apparatus which gives the best efficiency during the starting period. A d-c. series motor is evidently the best apparatus to use for such purposes. On the other hand, a power hammer must be so constructed as to withstand shocks without limit either in number or in size and it was doubtful whether any commutating apparatus would be capable of withstanding such rough usage as that even though the armature and commutator may be made the stationary part and the field allowed to move. The problem therefore, resolves itself into three branches; one consists of the study of the properties of the electric hammer to predetermine its advantages over the hammers which it shall replace; the second consists of a study of its mechanical stability and durability under repeated and violent shocks; and the third is a study of the electrical properties of the machine as affecting an apparatus which is continually starting and stopping.

The problem of determining the advantages of an electric hammer over a board hammer had to be resolved from fundamental considerations rather than from existing facts because there were no facts available. The main points of merit of the electric hammer were the following:

In cases where it replaces board hammers, it consumes no power while not working, there are no moving parts while it is not operating, it is neater in appearance, it occupies a minimum of floor as well as overhead space. There are no parts to wear out, outside of the runner, and the contactors (which in the final design will be made so easy to replace that it is expected will give no more difficulties than an ordinary board hammer). It is very easy to move it from place to place. The most prominent feature of an electric "board" hammer is its great variety of the size of blow that it can give, ranging from zero to four or five times as large a blow as it could give by merely falling under the action of gravity.

When the electric hammer is made to replace a steam hammer its advantages are as follows: It is a well-known fact that a steam hammer is the most accomplished waster of energy ever made by the human hand, considering all condensation on the lines, which are sometimes of great length, all the steam used to keep it warm while not in operation, and the fact that sometimes a special boiler plant must be installed to operate a steam hammer. All these losses are eliminated with an electric hammer; there can be an electric hammer wherever there is an alternating-current supply, it can be moved from place to place without much difficulty; since it can be tied to any supply system, the small manufacturer can have it, in other words anybody may have a power hammer. These qualities are what could be foreseen before any test was made or even before any hammer was ever designed.

Mechanical Stability and Durability of an Electric Hammer

Here again it was a case of predetermining these qualities from facts which were more or less self evident,

because no actual apparatus had ever been built. The facts which were very apparent were the following: Compared with the board drop hammer it may be said that the runner of the electric hammer replaces the board of the board hammer, hence the electric hammer has nothing to get out of order except its "board;" against the elimination of all those parts must be set the introduction of at least two pairs of contactors (in case the third one is introduced, electrically it is possible for only two to work since two of the three are in series and either of these two must open the circuit). Also the question came up as to whether the runner of the electric hammer would withstand the severe shocks to which it must be subjected. This question may be considered from two standpoints, first if it is made of laminated steel with copper bars for the squirrel cage, the construction is apparently weak but on the other hand, it has that elasticity which absorbs the shocks much better than any solid construction can absorb them and prevents breakages.

A laminated runner is a rather costly construction but it is believed that it would last longer than a solid one and certainly much longer than boards last in ordinary board hammers. The other alternative was to make the runner of solid steel which would, by reason of its simplicity, cost so little that the replacement of it would not be at all expensive nor would it be any more difficult to renew a solid steel runner in an electric hammer than it would be to renew a board in a board hammer.

Compared with the steam hammer, it may be said that the troubles given by the steam hammer by the breaking of the piston rods on account of the crystalization which occurs where the rod connects to the ram of the hammer might be eliminated to a great extent by a laminated construction which is perfectly possible with the electric hammer, but I do not think it would be feasible in case of a piston rod which has to fit steam tight in the cylinder head (it must be remembered that outside of the ways which guide the runner in a vertical direction, it may be said that the latter hangs almost free in the air). In short, it was thought that the worst expectation that we could have was that we might have as much breakage from an electric hammer as from a steam hammer and certainly all the rest of the conveniences obtained by an electric hammer were thought to be enough to justify the change.

Field of Application of the Electric Hammer

If we consider the replacement of all steam hammers, board hammers, pile drivers and all like apparatus, the field is certainly sufficient to justify the development and marketing of such an apparatus.

The Electrical Problem

From the electrical standpoint and from the long study previously made on d-c. motors (especially the series motors), it appeared always preferable, ever since the problem was undertaken, to build a direct-current series machine; therefore proceeding on this belief, a direct-current reciprocating motor was designed and its main characteristics calculated. The runner of this machine was to be the field and was to be made of solid steel in which there were slots for the distributed field windings. The field coils were to be retained in the slots by nonmagnetic materials such as brass or bronze, and the brushes were to be carried by this moving part. The armature was to consist of two straight-line armatures, one on each side of the field, each having its own commutator so that the two might be connected either in series or in parallel with each other. (The double armature was of course necessary to balance the electromagnetic forces as well as to utilize the field metal to its fullest extent). The

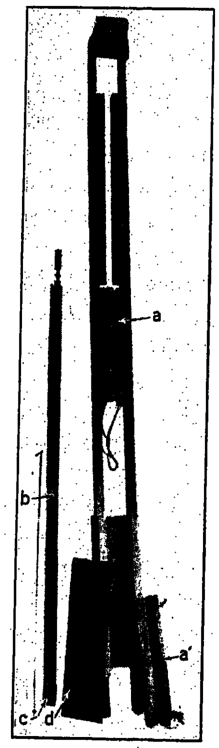

Fig. 3—First Experimental Electric Hammer

a—one of the stators mounted on the wooden frame, *a'*—the other stator dismounted, *b*—the armature or runner (a piece of brass $^1/_8$ in. by $2\frac{1}{2}$ in.) removed, *c*—the ram, *d*—a guarding plate making a part of the framework.

electromagnetic properties of this machine were found to be very excellent; the starting current was rather small and the torque per watt very large; it can be designed for very low speeds. In general, it showed the superiority of d-c. to a-c. in case of motors which have to start and stop continually under heavy load. The electromagnetic force per pound of the active metal of the runner was very high as compared to that of the induction motor. In power hammers, and especially in the so called drop hammers where the ram must be heavy enough to hold the die, it is very important that the electromagnetic force per pound of active metal be as large as possible so that most of the metal con-

stituting the total weight of the moving part may be placed on the ram. In electric hammers, this point is of even greater importance since the power may be applied downward and the total weight of the moving part must be decreased very much to obtain the proper rating.

In spite of the preference which the writer had for the direct-current machine, it was repeatedly pointed out that it would not withstand the shocks of a hammer and it was finally recommended that the polyphase induction type be looked into before definite plans were made for building any hammers at all.

Under these suggestions, a very small model of polyphase straight-line motor, in which the moving part was made of a piece of brass 1/8 in. thick by 2 1/2 in. wide, was built and tested. This hammer was equipped with a heavy piece of cast iron on the bottom end and also with an automatic reversing switch so that when power was applied it would reciprocate up and down like an ordinary hammer. An illustration of this crude model is shown in Fig. 3. It should be understood that this model was not made to obtain engineering data nor was it designed to give any definite result. The object of building it was merely to show the several people interested that such a hammer would work. The model proved very satisfactorily how much simpler a polyphase hammer is than a direct-current one.

After several lengthy discussions with engineers who were well acquainted with the power hammer problems, it was concluded that it would be best to start the development by building a polyphase induction hammer.

In accordance with this decision, a hammer was designed to operate a 200-pound ram, in other words, a hammer which would be equivalent to a so-called 200-pound board hammer, this comparison of course being made in a case when the electric hammer lifts a 200-pound ram, and lets it fall by gravity; in case power is added on the downward stroke its capacity would be greatly increased as will be shown in the results of the tests. For the purpose of obtaining engineering data, the runner was made of laminated steel.

It was apparent from the character of the working cycle of this machine that the runner should be made of high resistance in order to obtain high starting torques, high power factors and at the same time draw a small starting current from the circuit. This was done by using brass bars in the squirrel cage; in addition to that, both for convenience in building it and to diminish leakage reactance, the secondary slots were made open and the bars made even with the surface of the steel laminations. Making the bars even with the surface also eliminates all that portion of the primary leakage flux which passes from one tooth to the other above the secondary conductor.

About the worst thing to contend with, at least during the discussions of this apparatus, was the so-called end effect that occurs when a conductor of the rotor passes out of the stator field into the air. This difficulty, as pointed out by Dr. Steinmetz, had been one of the main difficulties which led to the abandonment of the induction railroads. To the end-effect problem, as related to this hammer, there was at least one solution and that was to be found from the fact that the efficiencies of the present hammers are so small that it was thought almost impossible to make a straight-line motor bad enough to compare with the present hammers, in other words, one solution of the problem was not to solve it at all.

Accordingly, the hammer was built with the following dimensions: Length of stator, 39 inches, length of runner 5 feet, and width of the cores, 2 1/2 inches, or in other words, the motor was very nearly "square." It was assembled in a box made of boards 2 1/2 inches thick, which was provided with brackets for mounting it on the uprights of an ordinary 200-lb. board hammer. The construction was made so crude because it was still

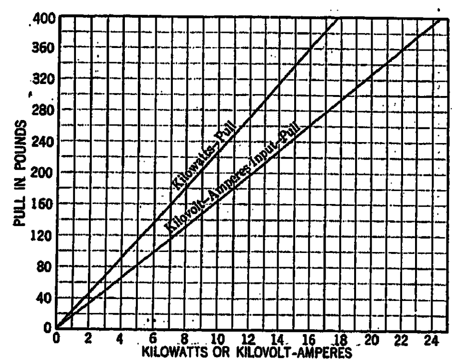

FIG. 4

Curves showing the relations between the total kilowatts input and the total pull exerted on the runner; also the relation between the total kilovolt-amperes input and the total pull exerted on the runner.

doubtful in the minds of a good many of those concerned in the development as to whether it would be successful or not. The standstill characteristics were then obtained and the most important curves are shown in Fig. 4.

It was finally mounted on the uprights and since the 5-ft. runner was too short to reach to the anvil, it was found necessary to make a wooden block high enough so that it could be operated with the given runner. The switch mechanism consisted merely of a reversing knife switch automatically operated by the moving part and no connection was made between the switch mechanism and the treadle, so that to start the hammer it was necessary to close the main switch. Once it was closed the hammer kept on going up and down at the rate of about three strokes per second.

This model, as crude as it was, was sufficient to show that the electric hammer was a success. In addition to that, we obtained starting currents, and power factor, and cleared in this way all those questions which were up to that date a stumbling block for the develop-

ment; it was shown, in other words, that operating an electric hammer did not wreck the supply system, as was thought by many. No photographs were taken of this model when it was mounted, but outside of the wooden anvil, it was exactly the same as that shown in Fig. 6. Having cleared all these difficulties, it was decided to build a real model capable of performing the same functions as an ordinary 200-lb. board hammer.

In the new model, the same stators were used and the work of the new design consisted merely of designing

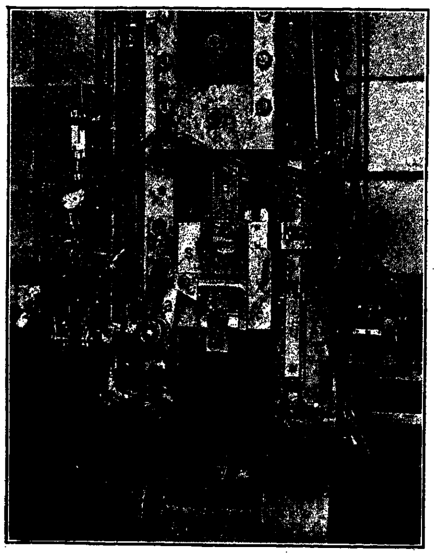

FIG. 5—EXPERIMENTAL ELECTRIC HAMMER (BACK VIEW)

Main parts: *p*—armature or runner, *q*—stator casing, *x*—ram, *u*—upper half of die, *v*—lower half of die, *w*—anvil.

Auxiliary parts: *a*—holding dog, *b*—holding block, *s*—spring which actuates both the dog *a* and the lever *c*, *e*—a lever crank, *f*—cut-out contactor operated by dog *a* through lever *c*, *r*—switch for controlling power on downward stroke.

a pair of uprights together with the proper automatic switching mechanism necessary to have the electric hammer operate analogously to the board hammer.

At this point Mr. D. C. Garroway, an engineering draftsman, began to assist me in the development of the present model.

The cycle of operation of an ordinary drop hammer is as follows: Ordinarily, a hammer hangs up in place and when the treadle is pressed, it falls down and automatically returns up to its original position and keeps on going up and down as long as the foot is kept on the treadle. As soon as the latter is released no matter where the hammer is it continues its operation until it gets up to the upper position and hangs itself there ready for the next operation. It was necessary, therefore, that an electric hammer be capable of performing the same cycle. To do this, it is essentially necessary to have a cut-out contactor and a pair of reversing contactors. The cut-out contactor must be operated automatically by the moving part so that when the hammer hangs itself on the upper position the circuit is open. The reversing contactors are for the purpose of reversing two of the three phases at each end of the stroke. The opening and closing of contactors must be done at a constant speed irrespective of the speed of the moving part of the hammer.

In addition to these three contactors, it was decided to add a fourth one for the purpose of cutting off the current on the upward stroke before it had actually reached the end of the stroke in order to save power and also avoid the necessity of reversing at full speed.

Fig. 5 shows a back view of the hammer with the ram in its upper position. At *b* is shown a block fastened to the ram which engages with the dog *a* fastened to the uprights. The dog has an elliptical hole at its fulcrum so that when the ram comes down on it, it moves downward a half inch before it gets to the bearing. On the same dog is fastened the lever *d*, which is connected to the treadle and also a vertical flat piece of steel *c*, free to move up and down a half inch with the dog *a*. This piece of steel operates a lever *e* which in turn operates the cut-out contactor *f*. Therefore, when the hammer comes down on dog *a*, it hangs itself and also cuts out the main circuit.

The spring *s* has two functions, one is to keep the dog *a* in its upper position and in that way keep the contactor *s* closed, and the second function is to keep the dog *a* always turned to the right under the block *b*. The vertical motion of *a* and therefore that of *c* is always quick and consequently no additional mechanism was needed to make the opening of the contactor fast enough to eliminate burning.

FIG. 6—EXPERIMENTAL ELECTRIC HAMMER (FRONT VIEW)

Main parts: *Q*—motor casing in which stators are mounted, *P*—armature or runner, *X*—ram, *U*—upper half of die, *V*—lower half of die, *W*—anvil.

Auxiliary parts: *R R'*—follower rods, *f f'*—followers, *TT'*—cams, *C'*—cut-off contactor, *C*—one of reversing contactors, *A A'*—switching arms operated by *R R'*, *S S'*—switching springs, *K K'*—contactor cranks. Arm *A* moves spring *S* to one or the other side of *K* and the spring does the switching.

Fig. 6 shows a front view of the hammer also with the ram in its upper position. The two rods *R* and *R'*

carry the cams and levers to operate respectively reversing contactors C and the "cut-off" contactors C'. These rods are made long enough to be able to get the stroke of any desired length from zero to the length of the uprights. The cams that are fastened on these rods are operated by two studs T and T' fastened to the ram. The arms A and A' also connected to these rods operate the reversing contactors and the "cut-off" contactors respectively. In order to assure a constant opening and closing speed of the contactors, the opening is done through springs S and S'. All that arms A and A' have to do is to move one end of the spring S and S' on one side or on the other of the center of the contactor cranks K and K' and the opening and closing after that is performed by the springs independently of the cams or the moving part of the hammer and hence it is done always at practically the same speed, which can be adjusted by adjusting the tension of the spring and its eccentricity.

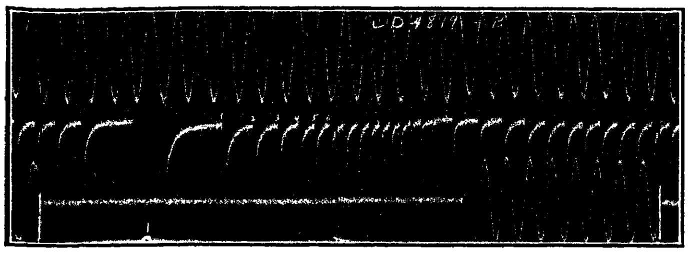

FIG. 7—OSCILLOGRAM OF ELECTRIC HAMMER OPERATING WITH ELECTRIC POWER ON UPWARD PART OF STROKE ONLY, GRAVITY PRODUCING THE HAMMER BLOW.

The upper vibrator gives a smooth wave of a 40-cycle voltage which is used for measuring time. The middle vibrator shows the deflection of a direct current obtained from a dry cell which has its circuit momentarily closed at every inch of movement of the armature or runner. The time taken for the runner to move through one inch is measured by the distance between "making" points which are marked 1, 2, 3, etc. on the record of the approximate zero of the middle vibrator.

The lower vibrator shows the current of one of the three phases.

The distance between the vertical lines A and B indicates the time of one complete stroke (or cycle of operation).

Starting from the point A when the alternating current ceases the runner continues on its upward stroke until it uses up its momentum at some point about the position marked C. It then begins to fall slowly by gravity, as shown by the distance between the vertical lines of the middle vibrator, and gradually accelerates until the hammer strikes. Shortly after, the current to lift the runner comes on again for eight and a half cycles to point B where the cycle of operation starts to repeat.

Since this hammer is provided with reversing mechanisms, it is evidently possible to apply power on the upward as well as on the downward stroke and here is where the electric hammer differs from the board hammer. In order to cut off the power in downward stroke, it is necessary to have also an ordinary knife switch in series with the circuit for the downward stroke. This switch may be seen at r in Fig. 5. By changing the position of the cam F', it is possible to regulate the length of "admission" and by changing the position of F, it is possible to regulate the point of reversal. The length of the stroke can be changed only by changing the position of a in Fig. 5 and that can be done only by moving the steel block m upon which a is fixed. Holes are provided on the upright and also on the steel piece c for changing the length of strokes.

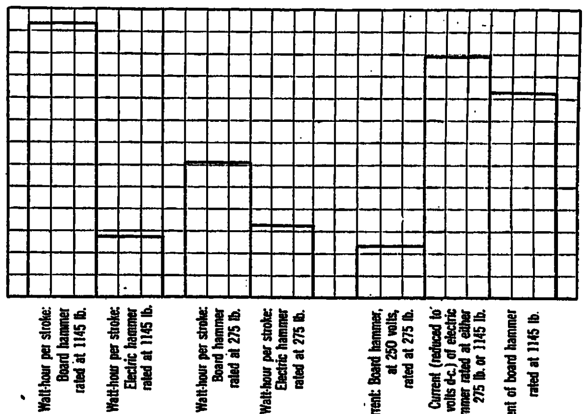

FIG. 8—CHART GIVING COMPARISON BETWEEN ELECTRIC HAMMER AND BOARD HAMMER WHICH IT IS TO REPLACE

Comparison of efficiency is made in watt-hour per stroke. Current efficiency is given in amperes. The hammers are compared both at a rating of 275 lb. and at a rating of 1145 lb.

It is evident that by inserting resistances in series with the downward circuit, we may apply any amount of power ranging from zero to full value on the down-

TABLE I.
Working Characteristics of Hammer Already Existing

Steam	37	1000	6.0	9075	2107	1512	351	3000	881

ward part of the stroke. Also by making the switch r a reversing switch, we may apply upward power on the downward stroke also from zero to full value. This gives a range of blows from zero to a blow given when full power is applied downwards.

Tests of the Hammer

In order to test the hammer it was necessary to obtain the speed at the time of impact, the upward and downward accelerations, current at starting and on running, energy input per stroke etc. The oscillograph method was the only method available to do all this. The hammer was therefore equipped with a sliding contact mounted on the ram and made to slide against a long piece of fiber in which there was a strip of copper imbedded at intervals of one inch. In Fig. 5, h is the fiber block and k is the sliding contact. A watt-hour meter was also installed and the energy input per stroke obtained by measuring the total input for a given number of strokes. It was also necessary to

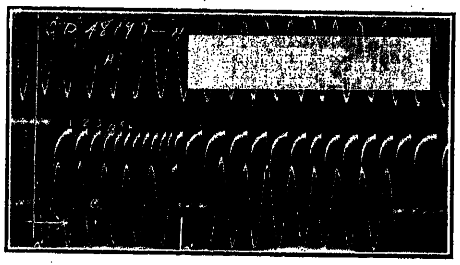

Fig. 9—Oscillogram of Electric Hammer Operating with Full Electric Power on Upward and Downward Parts of Stroke

The upper vibrator gives a smooth wave of a 40-cycle voltage which is used for measuring time. The middle vibrator shows the deflection of a direct current obtained from a dry cell which has its circuit momentarily closed at every inch of movement of the armature or runner. The time taken by the runner to move through one inch is measured by the distance between "making" points which are marked 1, 2, 3, etc. on the record of the approximate zero of the middle vibrator.

The lower vibrator shows the current of one of the three phases.

The distance between the vertical lines A' and B' indicates the time of one complete stroke (or cycle of operation).

Starting at the point A' when alternating current is switched on for the downward stroke the runner starts to fall under the joint action of gravity and electricity accelerating quite rapidly, as shown by the successively decreasing distance between the vertical lines of the middle vibrator, until after six cycles the hammer strikes at about the position marked C'. Shortly after the current to lift the runner is again switched on for a period of eight cycles after which the hammer keeps on moving upward until it practically uses up its momentum and the reversing mechanism operates to switch on the downward power at point B' when the cycle of operation starts to repeat.

study other hammers in order to make a clear comparison between the electric hammer and the ordinary types.

In the oscillogram of Fig. 7 is shown (between the two vertical lines) the current per phase, a 40-cycle timing wave, and in the middle line is shown the timer. In this oscillogram it is found that the total time required for one complete stroke when the hammer falls down by gravity is $\frac{26}{40} = 0.65$ sec. The time during which power is being admitted is $\frac{8.5}{40} = 0.21$ sec. The average current per phase is 109 amperes.

The energy input per stroke, when falling down by gravity, as found by the watt-hour meter is 1.6 watt-hours. The total height to which the ram and runner were lifted was 1.21 ft. giving therefore a total amount of work, done on the hammer by the motor, of $1.21 \times 275 = 333$ foot-pounds. 1.6 watt-hour $= \frac{1.6 \times 3600}{9.8} \times 7.2$ ft-lb. $= 4240$ ft-lb. giving an efficiency $= \frac{330}{4240} = 7.8$ per cent. In calculating this efficiency no account is taken of the friction as it was not measured at the time the tests were made. It is very probable that if the friction were considered, an efficiency of about 10 per cent would result. Under the same conditions, the board hammer gives an efficiency of $7.8 \frac{1.6}{3.09} = 4.05$ per cent.

In Table I are given data which were collected in the drop forge shop of the General Electric Company at Schenectady. From this table we may obtain an idea of what we may expect to be the efficiency of a steam hammer. For instance, hammer No. 32 gave 21,800 strokes in 6.5 hours and only 2971 or approximately 13.7 per cent of the total number of strokes were of use. With an electric hammer this percentage may be raised to 100 per cent and the total efficiency again becomes equal to that of the machine itself as if it were working continuously.

The chart of Fig. 8 gives an idea of the magnitudes of the different quantities involved in the comparison of the two hammers. The weights of the moving part of each of the two hammers are very nearly equal and therefore the comparisons may be made directly. In this chart one assumption is made, that if the board hammer were rated at 1145 lb. it would take four times as much current to lift it as it does at 275 lb. From the oscillograph of Fig. 9 we find that when the electric hammer works with power up and down the total time in which power is being admitted equals 14.5 waves and therefore the power per stroke equals

$$\frac{14.5}{8.5} \times 1.6 = 2.72 \text{ watt-hours.}$$

The comparison between the amounts of energy taken per stroke must necessarily be very rough because the energy per stroke taken by the board hammer is a variable quantity depending upon the amount of useful work it does in a given time that it is running, since it consumes energy while running idle, while the energy

per stroke consumed by the electric hammer is constant. The efficiency of the electric hammer therefore is also a constant quantity while that of the board hammer is variable and may reach zero in case the hammer runs idle for a long period of time. It may be pointed out here that since the static condensers are now available at a reasonable price, the total kilovolt amperes drawn from the line may be much reduced by the use of such condensers. Outside of energy consideration, the following qualities have been found very favorable for the electric hammer.

Since there are no moving parts when it is not in operation, it is very much safer than a board hammer. Lately it has been equipped with a reversing knife switch shown at *r* (Fig. 5) and in this way it is possible to obtain any size of blow from zero to 1145 lb. It is obvious that for the small customer, this type of hammer will prove much more satisfactory than an ordinary board hammer which is capable of giving only one size of blow for a given length of stroke. This principle has already been made use of during the period it has been in production work. Therefore the electric hammer is more flexible, is handier, cheaper to operate, probably cheaper in first cost; and while the board hammer has the advantages of the flywheel, the electrical hammer has the advantages of the power on the downward stroke.

Conclusions

To recapitulate, the straight-line motor has proved inefficient for driving railroads, due in part to causes inherent to this type of motors and in part to lack of detailed study relating to the proper construction and to the proper class of railroads to which it should be applied. The motor will, however, prove to be very useful in cases where it is best adapted. The electric hammer is only one of these cases, many others will soon be found and in fact, several of them are already under consideration. I hope in the near future to publish, besides the results of a new hammer now under test, a treatment of this subject under a much broader title in which the electric hammer will appear as a special case of a particular branch of the subject, "The General Motor."

Discussion

R. E. Hellmund: There is in such a hammer air gaps on the two sides of the moving parts. Have any difficulties been experienced, such as bending of the moving parts, or getting excessive friction on one side?

P. Trombetta: We have not experienced any difficulty in that line, and from the fact that they are pretty well balanced, the difficulties, if there should be any, will be minimized almost to nothing by putting the two stators in parallel, in which case as the air gap increases, the current in the one stator in which the air gap increases must increase, in order to keep the voltage the same, and consequently the force is kept almost constant, and there are no difficulties.

Wm. McClellan: How large a hammer have you built and worked?

P. Trombetta: The total moving mass of the hammer is around 275 to 280 pounds.

H. L. Wallau: What is the force of the blow in foot pounds?

P. Trombetta: That can be easily calculated. When you put full power downwards it reaches a speed of about 13.8 feet per second. That squared, times 275, will give you the force of the blow.

A Relay Recorder for Remote Control by Radio

BY F. W. DUNMORE

Radio Laboratory, Bureau of Standards

Review of the Subject.—*Relays have been used for many years in wire telegraphy and other electrical work. The practical operation of relays actuated by received radio signals is a comparatively recent development, and has been made possible by the development of the electron tube amplifier.*

This paper describes the development and the operating principles of a type of relay recorder which is designed to operate from the output terminals of a radio receiving set and which may also be operated by any other source of audio-frequency signal.

By the use of special electron tube circuits the audio-frequency signal is caused to operate an ordinary telegraph relay.

In order to avoid the necessity for using a very sensitive relay, designed to operate on currents of a milliampere or less, which would have delicate adjustments and light contacts and spring tension, advantage was taken of an electron tube amplifier, which has now become a reliable radio instrument, to increase the input voltage to the relay circuit thus making possible the use of a simple ordinary high-resistance telegraph relay. The relay device has therefore been developed to operate from the output circuit of any suitable amplifier in place of the ordinary telephone receivers.

The operation of the relay may serve to work a sounder, buzzer, tape register or any mechanism for remote control by radio.

Two types are described. One type is designed to be operated from batteries. The other type is designed to operate entirely from any 60-cycle 110-volt lighting circuit and this feature makes this type simple and inexpensive to operate, durable and practical. Another unique feature is described which is that of tuning to different audio-frequencies whereby any one of three signals, each of a different audio pitch, may be caused to operate the relay to the exclusion of the others.

Curves and diagrams are shown illustrating the principles of operation.

By the use of two of these relay recorders connected in series across the output terminals of a single radio receiving set, two messages sent on practically the same wave length but of different audio-frequencies, have been accurately received simultaneously.

CONTENTS

TYPE A— FOR USE WITH BATTERIES

1. *Object of Development.* The object of this investigation was to develop a relay which should operate by received radio signals.

2. *Requirements.* To be satisfactory as a relay recorder the device should have the following characteristics: (1) it must be of simple construction with few adjustments; (2) it must be easy to adjust and capable of being put into operation quickly; (3) it must be selective and as free from static and such disturbances as possible; (4) it must be capable of operating at a speed of at least 12 times per second; (5) it must respond to weak signals; (6) it must be of strong design, durable and capable of maintaining its adjustments; (7) it must be portable.

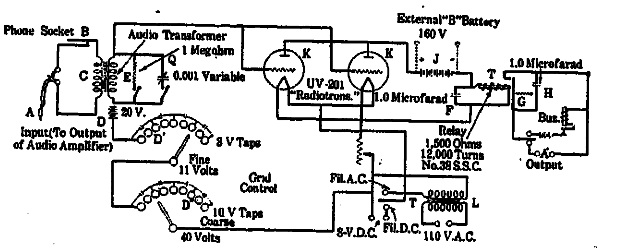

FIG. 1—CIRCUIT DIAGRAM OF RELAY RECORDER FOR USE WITH BATTERIES

3. *Circuit Used.* In order to avoid the use of a very sensitive relay designed to operate on currents of a milliampere or less, with delicate adjustments and light contacts and spring tension, advantage was taken of the radio-audio amplifier (which has now become a reliable radio instrument) to increase the input voltage to the relay circuit, thus making possible the use of a simple ordinary high-resistance telegraph relay. The relay device has therefore been developed to operate from the output circuit of any suitable amplifier in place of the ordinary telephone receivers. The only adjustment necessary is that of an ordinary telegraph relay.

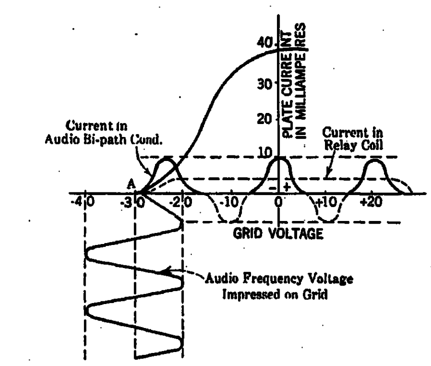

FIG. 2—TUBE CHARACTERISTIC SHOWING PRINCIPLE OF OPERATION OF RELAY RECORDER

Fig. 1 shows the wiring diagram. *A* is a telephone plug for connecting the relay device to the amplifier output. *B* is a phone socket, so that if desired the operator may listen to the received signal in the ordinary way. *C* is an audio transformer of the type used in audio amplifiers, the type used at present being a Signal Corps Type C-21. *E* is a two-megohm, grid leak.

Presented at the Spring Convention of the A. I. E. E., Chicago, Ill., April 19-21, 1922.

Q is a 0.0006-microfarad variable condenser or 0.0003-microfarad fixed condenser. D is a 60-volt variable "C" battery variable in steps of approximately three volts. J is a 160-volt dry "B" battery self-contained within the set. K is a type *UV*-201 Radiotron. F and H are each a one-microfarad paper condenser. T is an ordinary telegraph relay rewound with 12,000 turns of number 38 S. S. C. enamel wire. A' is the output to be connected to the apparatus to be controlled. L is a step-down transformer for operating the tube filaments from the 110-volt a-c. supply when such a supply is available.

4. *Principle of Operation.* The principle of operation is illustrated in Fig. 2. By means of the variable "C" battery D, the grid voltage is adjusted to approximately 30 volts at which value the plate current is zero, as shown at A. The incoming audio-frequency voltage impressed on the grid varies the grid potential,

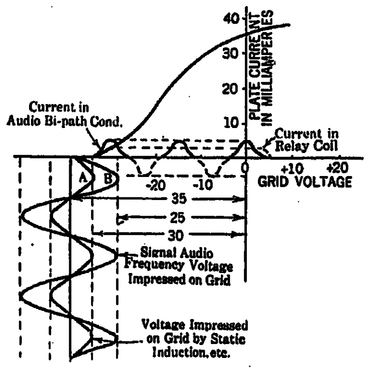

FIG. 3—METHOD OF ELIMIATING STATIC AND INDUCTION NOISES WHICH ARE NOT STRONGER THAN THE SIGNAL

for example, from − 30 to − 20 volts. The 10 volts decrease from − 30 to − 20 causes an increase, for example, from 0 to 10 milliamperes, while the increase from − 30 to − 40 volts is not effective in causing a plate current to flow due to the fact that − 30 volts is already sufficient to reduce the plate current to zero. The result will be a pulsating direct current of 10 milliamperes, maximum amplitude, in the plate circuit. This current, flowing through the plate circuit and condenser F causes an increase in the plate current at the keying frequency, which change, passing through the relay coil will pull the relay armature over, making contact at T, which contact may control any mechanism desired. With the "C" battery grid voltage adjusted for maximum sensitivity it was found that static induction, etc., operated the relay. When these disturbances are not as strong as the signal their effect on the relay may be overcome as shown in Fig. 3. For example, the "C" battery is shown increased to − 35 volts, the critical value for maximum sensitivity being − 30 volts. The disturbances due to stray currents, etc., merely reduce the "C" battery voltage to − 30 which is not sufficient to cause plate current to flow. However, the signal, being of greater intensity than the stray currents, reduces the voltage to − 25 which causes a plate current of five milliamperes. It will be seen therefore that all disturbing effects, if of less intensity than the signal, do not affect the relay.

5. *Method of Increasing Sensitivity and Selectivity.* During the development of this relay it was found that the rectified audio-frequency current in the plate circuit caused the relay armature to chatter rapidly and make a poor contact with the fixed contact point through which the circuit is closed. This was overcome completely, however, by the addition of a one-microfarad condenser across the relay coils. This served the purpose of an audio-frequency by-path for the highly inductive winding of the relay, thus greatly decreasing the resistance of the circuit. The change of plate current due to this audio-frequency caused a second change which occurred at the keying frequency. This latter change passes readily through the relay coils and exerts a strong steady pull on the relay armature without the least chattering.

It was also found that the 0.0006-microfarad variable condenser, Fig. 1, across the secondary of the input audio transformer made possible audio tuning, which increased the selectivity considerable. This tuning was very sharp and it was found that European stations could be made to operate the relay while a high-power station here in the United States would fail to operate it, although the high-power station was coming in on the same wave length and slightly stronger. This was made possible by adjusting the heterodyne note of the European station to a frequency different from that of the local station and then tuning the secondary of the audio transformer to that frequency. The 0.0006-microfarad variable condenser may be replaced by a 0.0003-microfarad fixed condenser and the audio tuning accomplished by adjusting the heterodyne note to the resonant frequency. By means of this audio tuning one of three stations transmitting simultaneously has been selected and caused to operate the relay although all were of equal intensity.

By the use of two relay recorders connected in series across the output terminals of a single radio receiving set, two messages sent on practically the same wave length, but of different audio frequencies, have been accurately received simultaneously.

6. *Speed of Operation.* Tests showed that with a signal strength sufficient to produce a plate current of 10 milliamperes the relay could be operated at a speed of 48 contacts per second, the contact being sufficient to operate a buzzer. With three milliamperes in the plate circuit a speed of 27 contacts per second was obtained. With one milliampere a speed of 19 per second. In each case the relay armature spring tension was adjusted for the best operation.

7. *Sensitivity.* As stated above, this relay was designed primarily with the intention of obtaining a device which should be durable, simple in operation, and strong in construction. Sensitivity is obtained by

means of radio-audio amplification thereby increasing the voltage input to the relay circuit and eliminating the necessity of extreme sensitivity in the relay. Tests at 600 cycles showed that the relay circuit was fairly sensitive, as approximately 1.3 volts at the input terminals of the audio transformer in the relay circuit, caused a current of five milliamperes to flow through the relay coil in the plate circuit.

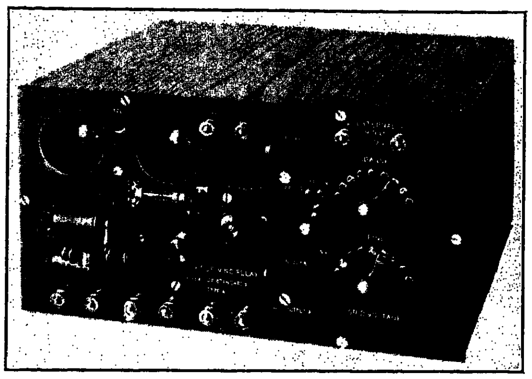

FIG. 4—TYPE A RELAY RECORDER FOR USE WITH BATTERIES

8. *Durability.* As the relay instrument used in this recorder is of the ordinary telegraph type its durability is well established. The only elements requiring occasional renewal are the two electron tubes, the 60-volt "C" battery, and the 160-volt "B" battery.

9. *Portability.* The complete recorder with the exception of the filament lighting battery is contained in a cabinet 7 in. by 13 in. by 11 in., as shown in Fig. 4.

10. *Uses.* 1. As an ordinary receiver it has advantages over reception with telephone receivers, for one may receive by buzzer or sounder with all induction and interfering noises eliminated (if not louder than the signal.)

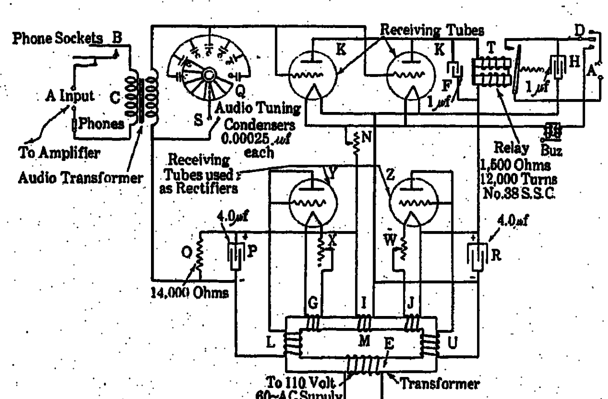

FIG. 5—CIRCUIT DIAGRAM OF RELAY RECORDER FOR USE ON THE 110-VOLT A-C. SUPPLY

2. A tape or drum-type recorder may be used and a copy made without a trained radio operator.

3. Time signals may be recorded.

4. A call system may be worked by a time switch connected to close the filament circuit for a given time at set calling intervals.

5. Any form of mechanism may be operated by an incoming signal.

6. A receiving station may be located remotely from the transmitting station and the radio signals relayed by wire to the operating room some miles distant.

In conclusion it may be stated that a relay of this type should operate satisfactorily, *without attention,* on an airplane where mechanical vibration may be excessive as the pull on the armature with three milliamperes, or over, in the relay coil makes possible the use of a spring tension on the relay armature sufficient to keep it from moving due to mechanical vibration of the relay.

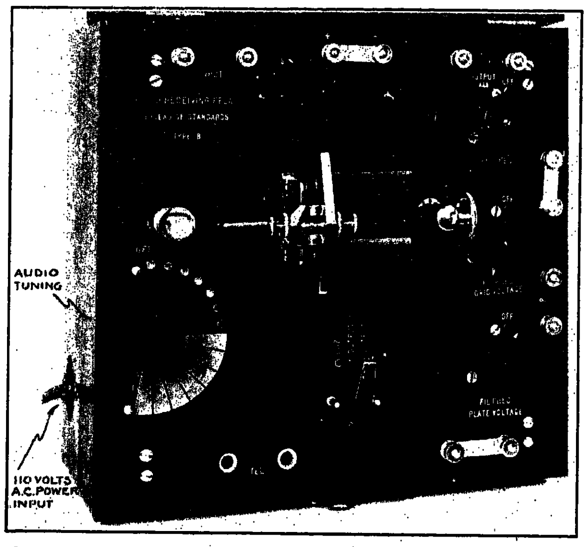

FIG. 6—TYPE B RELAY RECORDER FOR USE ON THE 110-VOLT A-C. SUPPLY

It would seem that the above-mentioned feature makes this remote control relay more serviceable than those now on the market which require delicate adjustment of spring tension, contact points, and suspended vibrating elements.

TYPE B—FOR USE ON THE 60-CYCLE, 110-VOLT, A-C. SUPPLY

This recorder is similar in construction and operation to the Type *A* recorder, except that the plate and grid voltages (B and C battery) are supplied from the 60-cycle, 110-volt a-c. supply. The current for operating the tube filaments is also obtained from this source, so that the recorder is operated entirely independent of any form of batteries. It is only necessary, therefore, to connect to the 110-volt a-c. line and the recorder is ready to operate.

The method of operating the recorder from the a-c. supply consists in the use of the two receiving tubes as rectifiers as shown in Fig. 5. The tubes *Y* and *Z* are used as half wave rectifiers, one supplying the plate voltage, and the other the grid voltage. When used

as rectifiers, receiving tubes should have the grids and plates electrically connected together. A special transformer M with six windings is used. Two of the windings G and J, supply the filaments of the two rectifier tubes. A third, I, the filaments of the recorder tubes. A fourth, U, the high voltage for the plate. The fifth, L, supplies the grid voltage, and the sixth, E, is the 110-volt primary winding. The rectified alternating current is smoothed out by means of four microfarad condensers P and R, connected across the output terminals. As the currents in the grid and plate circuits are small, smoothing out inductance was found unnecessary. It was found necessary to put 40,000 ohms as shown at O, across the output circuit of the rectifier tube supplying the voltage to the grid, as the grid is otherwise insulated from the filament of tubes K by the rectifier tube. By means of the filament rheostats, X and W, the grid and plate voltages may be varied over any ranges desirable for the most efficient operation of the recorder. By the use of binding posts with straps as shown in Fig. 6, the type B recorder may be operated from A, B and C batteries for supplying the filament, plate and grid voltages respectively in cases where the a-c. supply is not available.

In cases where very high-speed operation is desired, the ordinary relay may be replaced by one designed for high-speed operation.

Discussion

Wm. McClellan: Is it practical, may I ask, to use that device for the tripping of relays in connection with circuit breakers?

E. E. F. Creighton: I am not sure from the author's remarks whether he used two frequencies, a fundamental and then a note frequency in addition to that, in order to prevent accidental operation. Suppose this device were used to operate a distant oil circuit breaker, what would be the chances of its operating through picking up some wireless wave.

Allan C. Forbes: I think that Mr. Dunmore has a very clever device; the possibilities of which are unlimited, due especially to the fact that it is more compact than any relay that I have yet seen. I happen to have had a great deal of experience in a high power station for the Marconi Company, having done the first testing between San Francisco, Honolulu and Japan; also between Marion, Mass. and Stavanger, Norway, and I have seen a great many recorders, I have worked on them personally and this is the first really successful thing that I have seen that is efficient and yet simple,—plug it into the light socket and let it go.

Mr. Schraeber: The author has explained that you might control a ship or airplane in this way, and he has also explained that he is able to get very close tuning, it being possible to tune both to the audio frequency and to the radio frequency. Having adjusted his device, I would like to know whether he has had any particular experience toward the end of always being able to send out the proper wave, either audio or radio, so that the device in which there is no individual to do the tuning will surely respond to those impulses. Can you set it and leave it perhaps for a day or so at some distant point and then start up a signal which will be closely tuned to it.

Allan C. Forbes: I tried out a device in Bolinas, Cal. (Marion Co.), the 300-kv-a. Radio Station of the M. W. T. Co. of America, while there as dynamo tender, and later on as engineer. We had a schedule of starting up at 10:00 o'clock in the morning to work Honolulu until 2:00 p. m. and then shut down; then start up again maybe at 4:00 or 5:00 o'clock and send what few messages we had. Then we would shut down until 9:00 o'clock at night and then get rid of all the business from 9:00 o'clock until 12:00. This was in 1915-16.

Now there would come long stretches, during good reception, when we could afford to shut down, possibly for an hour. Then the operator would want power quickly. We had induction motors, and all automatic starting; it would take us about sixty seconds to start up. Well, I thought out a great many plans whereby I wouldn't have to get out of my soft box. So I rigged up a relay device, unbeknown to the Marconi Wireless Telegraph Co. of America. I had it fixed so that I kept current on the circuit through the relay, and all the operator had to do was to touch his sending key, that tripped the circuit which threw in the automatic starter and started the main motor-generator set with the main motor generator on the way to going up, all I had to do then was to tell the dynamo tender to start the air compressors and open the valves and we were all ready.

We used a grounded circuit, several amateurs in and around San Rafael had one kw. stations. They were not careful as to their antenna and they used a great deal of power. The relays we used were very sensitive, so much so that one time the whole station was put into operation, and when I got it all going I didn't hear any signaling going over it, so I called up the operator and he said, "No, I didn't ring for the juice." I shut down, and shortly thereafter I started up the same way again. So I disconnected it and sat over by the relays and I could read all the signals that the amateur was sending out from San Rafael. Our line was at right angles to San Rafael, and San Rafael was over twenty miles away. We could have provided against that if we had had Mr. Dunmore's relay with his audio tuning device.

D. D. Clarke: I am connected with an operating company and a device of this kind appeals to us as one that could be put on an auto or truck and enables us to reach the trouble man at all times, without the necessity of his keeping his head set on.

Victor E. Thelin: In connection with the possibilities of this relay controlled by radio, I have been thinking of one thing which no doubt is of interest to you engineers, as many of you no doubt are power engineers, whose work brings you in touch with the furnishing of power from rotary converter and motor-generator substations. Large metropolitan systems, of which the Chicago Surface Lines is typical, heretofore have been fed from multi-unit substations, the capacity of which range from 4000 to as high as 20,000 kw. While complete shutdowns due to trouble on the high-tension system do not happen very often now, due to the fact that practically all of the high-tension lines are equipped with reverse-power relays, which isolate a defective line, yet there are times when quite a number of substations are shut down, and it is necessary, in order to restore service, to open sufficient feeder switches to reduce the load on the feeder bus to the amount capable of being picked up by one rotary, and then as additional rotaries are connected to the station bus more of these feeder switches are closed.

If the large substations in the residential districts and in the outskirts of the city were separated into a number of automatically controlled single-unit substations or, at the most, two-unit substations, it might be possible to have same so arranged that a load despatcher could have complete control of same, through the use of a radio controlled relay which might enable him to connect all of the stations to the system simultaneously. Furthermore, in case of a shutdown on a low-tension d-c. lighting system, such as is used by the Commonwealth Edison Company in Chicago, it is necessary to have a great reserve capacity in storage

batteries in order to restore service, as it is impossible without these batteries for any one rotary converter substation to be connected to the distribution system, due to the fact that this distribution system is one solid network, and the first substation in operation would open up on overload. It might be possible to have all the rotaries in both manually and automatically operated substations running ready for service, and the actual connecting of same to the distribution system could be done simultaneously by a load dispatcher through the use of the radio relay described here today. There is one point, however, on which I am not clear, as I have not as yet become a "wireless bug" and that is as to whether or not it would be possible to arrange these relays so that they could be operated independently of all the others in regular service and yet all be closed simultaneously in case necessity so demanded.

H. L. Wallau: There is a possibility of having one or more of these devices to perform different functions in the remotely controlled wireless substation, and I should like to know whether there would be any great difficulty in establishing a code of audio signals that could be easily transmitted from some central point.

F. W. Dunmore: I have, in developing this relay, merely developed it as a mechanism to be operated by radio, having left the finer details of selectivity by means of group signals to someone else who may design a ratchet mechanism that would be operated by this relay. The air service is doing work along this line and has actually obtained results. You have probably read of their radio controlled auto which they have been steering through the streets of Dayton, Ohio, maneuvering it right and left and starting and stopping it and blowing the horn. That has all been done, first, through a relay, and secondly by means of a series of signals properly spaced, and of suitable length, operating a selectivity mechanism, mechanically selective, which, in turn, gives the different controls. These methods for obtaining selectivity, may be used for the control of oil circuit breakers in order to prevent them from being operated by any other signal.

I remember reading recently in one of the radio magazines an article which stated that there had been developed a relay, which performed a similar function to that of mine, but was so fixed mechanically, by certain ratchet mechanism, that it would respond only to three dots, three long dashes, and three more dots (the distress signal). This could be put on a ship without an operator and would ring a bell whenever a ship sent a distress signal.

I cite the above merely to show it is possible to make a relay doubly selective, not only electrically selective by radio, both to radio frequency and audio frequency, but also mechanically selective to the extent that it will not operate a control switch or a signal bell unless a certain number of signals are received in a given time and suitably spaced. A somewhat similar method was used by the air service in the control of the auto in Dayton.

There is another method of obtaining mechanical selective control with which I am familiar, but which I cannot go into now, whereby any number of controls could be made. It is very flexible, making possible 25 or more different controls.

I believe the foregoing will answer the first two questions. In the development of my relay no attempt was made to obtain mechanical selectivity.

As for keeping an enemy from operating the relay, this could be taken care of by the use of a combination of electrical and mechanical selectivity. The code could be deciphered in time but the relay may be constructed so as to operate on a number of different codes.

As for leaving the relay at a substation without an attendant, there is always the danger of a tube burning out, but as the life of a tube is several months, this danger is remote. The control signal could be sent from a given point, and on a given wave length, and be of such character that it would operate the mechanically selective mechanism, which in turn would open or close the circuit breakers.

By utilizing electrical and mechanical selective features, it should be possible to keep an interfering station from operating the relay mechanism.

Regarding the use of the relay on trucks in order to call linemen, it would be simpler to use a radio receiving set without the recorder. This would not require as much mechanism. If the truck were in motion, the relay could be used to make a visual indication or call.

The relay was developed primarily for use on airplanes, and for this reason was designed to operate on a signal of sufficient strength to give positive action. For use on an airplane a relay should be very rugged and simple, with no delicate adjustments of spring tension and relay contacts or suspending elements. In my type of relay the spring tension can be made considerable, thus pulling the armature back so that vibrations on the plane will not move it until the signal is received. The ignition noise is picked up by the radio receiving set, in some cases just as I received it here from that commutator, and in cases where it is very loud it might operate the recorder. It is possible to shield the ignition systems on airplane engines so as to reduce the noise from the ignition to a minimum. If this interference is not stronger than the received signal, it will not operate the recorder. Thus the relay may be readily used for visual indication on a plane, as the noise is so great from the roar of the engine that it is hard to read a signal by ear.

As for controlling a number of substations by means of one central radio transmitting station, this may be done by sending a signal of a given wave-length and character as I have previously mentioned. Each substation should have a radio receiving set in operation ready to receive the signal. This would mean that the filaments of the tubes would have to be lit, so that the radio receiving set would be ready to function, and thereby operate the relay.

Mr. P. D. Lowell and I have recently developed at the Bureau of Standards a radio receiving set that operates entirely from the a-c. power line. It consists of six stages of amplification. This might be used in conjunction with the recorder on the a-c. supply.

Some very interesting questions have been asked by Mr. Varley of New York, some of which might interest you. He inquired why twenty volts are necessary to reduce the plate current to zero. I am using such a high plate voltage that it requires a large grid voltage to reduce the plate current to zero. Mr. Varley stated that three volts should be sufficient. Three volts would be all right with a plate voltage of 20 volts; I have 200 volts, so I must have a correspondingly higher grid voltage. The use of a-c. does not affect the operation of the recorder. When the relay is adjusted for maximum sensitivity, with a spring tension so that the armature is just about to make contact, there is a slight 60-cycle chatter of the armature but is not objectionable because the relay is never operated in that condition.

Mr. Varley also asks why 4000 ohms were used across the condenser in smoothing out. It should be 40,000 ohms. It serves as a grid leak and keeps the grids from being insulated from the rest of the circuit. A receiving tube cannot be operated with the grids insulated from the filament.

Magnetic Flux Distribution in Transformers

BY KARL B. McEACHRON
Member, A. I. E. E.
Engineering Experiment Station, Purdue University

It is customary when discussing magnetic leakage in the transformer to consider the primary and secondary windings as having a counter e. m. f. induced by a flux surrounding the coil and having the core for a part of its path. This leakage flux is frequently represented by closed lines.

Since the main flux is also represented by closed lines in the core, apparently two fluxes are to be found in the core under a given coil, namely, the leakage flux and the main flux.

The main flux is the flux found in the core at a point not under either the primary or secondary winding, and has been commonly considered as being the flux which causes the secondary induced voltage.

If the leakage fluxes have a separate existence, i. e., if they are to be represented by closed lines, then the flux along the edges of the core would consist largely of leakage lines while that to be found in the middle portion of the core would be the main flux. Since these fluxes are out of phase with one another it should be possible to identify them if they are present as separate fluxes.

Using a simple test core-type transformer, provided with belt exploring coils under both the primary and secondary windings, data concerning the magnitudes and phase positions of the fluxes in different sections of the core were secured.

The results show that leakage fluxes do not exist as separate fluxes in the core. It is also shown that the primary and secondary induced voltages are equal to the primary and secondary terminal voltages diminished and increased respectively by the corresponding I R drops.

Some difference of opinion exists among engineers concerning the distribution of lines of magnet flux in a transformer operating under load. Many and in fact practically all of the text-books, in the writers, treatment of the transformer, divide the so-called leakage reactance into two parts, one part being due to the primary ampere turns, and the other to the secondary ampere turns. This notion of the leakage reactance assumes that a secondary leakage flux exists, and in many cases is taken as being equal to the leakage flux of the primary. Others believe that the leakage flux actually to be found in a transformer is the result of the combination of primary and secondary m. m. fs. rather than a combination of the fluxes produced by each m. m. f. acting separately.

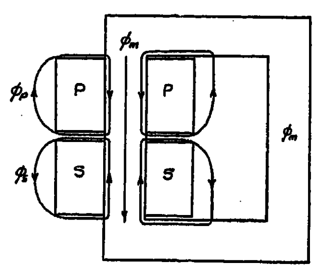

FIG. 1

ϕ_m = main flux.
ϕ_p = primary leakage flux.
ϕ_s = secondary leakage flux.

OBJECT OF THE PAPER

In order that the experimental evidence might be secured, a small transformer was built up, and the flux distribution studied. It is the purpose of this paper to describe this investigation, and point out some conclusions which may be drawn from the results obtained.

EXPERIMENTAL APPARATUS: THE TRANSFORMER, INSTRUMENTS AND GENERATOR

By reference to Figs. 1 and 2, which are drawn in accordance with the two theories outlined above, it will be seen that the difference in the flux distribution is to be found in the space underneath the secondary coil. The flux under the primary coil is the same according to either theory.

In order that the flux and its phase relations might be determined, it was decided to make use of belt coils similar to those described by Kennelly and Alger in their paper on "Magnetic Flux Distribution in Annular Steel Laminae" before the Institute in 1917. The simple type of transformer shown in Figs. 1 and 2 was chosen, and belt coils were threaded through holes bored in the core underneath the primary and secondary coils.

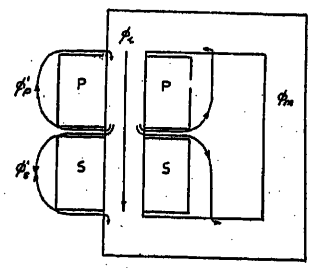

FIG. 2

ϕ_i = flux which threads both primary and secondary.
ϕ_s' = flux which threads primary, but which passes outside secondary.
ϕ_p' = flux which threads primary only.

The core was built up out of straight laminations 8 in. (20.3 cm.) long, 2 in. (5.08 cm.) in width, and having a thickness of 0.014 in. (0.455 mm.). These laminations were cut from a good grade of silicon transformer steel. The punchings were all carefully annealed after cutting, and the oxide thus formed was depended upon to furnish sufficient insulation between sheets. The core data are given herewith.

Presented at the Spring Convention of the A. I. E. E., Chicago, Ill., April 19-21, 1922.

Number of laminations......	=	128
Depth of core..............	=	1.875 in. (4.76 cm.)
Thickness of lamination.....	=	0.014 in. (0.355 mm.)
Cross-section of core........	=	3.375 sq. in. (21.7 sq. cm.)
Stacking factor.............	=	0.9
Weight of core..............	=	24.2 lb. (10.52 kg.)
Number of air gaps.........	=	4

Six holes, 0.154 in. (0.391 cm.) in diameter, were drilled through the core in the locations shown in Fig. 3. They were carefully reamed out to size, all burrs removed, and the surfaces painted with shellac. Through these holes, 40 turns of No. 34 B & S enameled

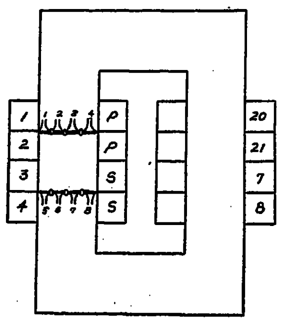

FIG. 3

Core area diminished by the area of the belt coil holes = 2.9 sq. in. (16.7 sq. cm.)

All transformer coils have 200 turns each, and are wound with No. 16 B and S wire.

Coils 7 and 8 were used as tertiary coils. Coils 20 and 21 were not used in this investigation.

Resistances of transformer coils at 25 deg. cent:

(1) = 0.772 ohm	(4) = 0.769 ohm
(2) = 0.767 "	(7) = 0.775 "
(3) = 0.771 "	(8) = 0.782 "

Belt coil area (cm.)^2 :

(1) 4.59	(5) 4.43
(2) 3.80	(6) 3.77
(3) 3.74	(7) 3.81
(4) 4.67	(8) 4.76

wire were wound, forming altogether eight belt coils, with 80 wires per hole. The belt coils were numbered from 1 to 8, numbers 1 to 4 being under the primary coil.

The positions of the various coils when placed upon the core are shown in Fig. 3. As seen in the figure, the primary and secondary each consisted of two coils, with the belt coils under the middle of each winding. Each coil before taping was one inch square in cross-section.

After canvassing the list of available instruments, it was decided to connect a low-reading milliammeter in series with the belt coil under test and a sensitive element on the oscillograph. The ammeter has a full-scale deflection of 0.030 ampere, a reactance of from 0.25 to 0.27 henry and a resistance of 304.5 ohms. To prevent the current through the belt coil in use from distorting the flux, it was necessary to provide a similar load for each of the three belt coils not under test. To do this three coils were each wound to an inductance of 0.25 henry and a resistance of 300 ohms. The winding data for these coils were obtained from the curves given by Brooks in Bulletin 53, University of Illinois, Engineering Experiment Station.

To make changes in connections easily and quickly, the three loading coils and the test circuit were connected to telephone plugs as shown in Fig. 4.

An alternator rated at 7.5 kv-a., 110 volts, 60 cycles, furnished practically a sine wave for the test.

METHOD OF TEST AND RESULTS

Tests were made with the transformer operating under the following conditions:

(a) No-load.

(b) Secondary short-circuited, with impedance volts supplied to the primary.

(c) Non-inductive load.

(d) Inductive load.

A magnetization curve was taken, and a point chosen on it below the knee of the curve so that the exciting current would not show distortion due to changes in permeability.

Oscillograms showing the phase relation of the belt coil current and the impressed voltage were taken. The voltage wave, designated by the letter e on the oscillograms, was used as a reference for determining the position of the current flowing through the particular belt coil under test. In each case while the current in one belt coil was being investigated, the other three belt coils were connected to their respective loading coils.

On account of lack of time the usual method of taking oscillograms was not followed; instead bromide paper was placed on the viewing screen and exposed for a period of about 10 seconds. The oscillograms appearing in this paper are from photographs of these prints.

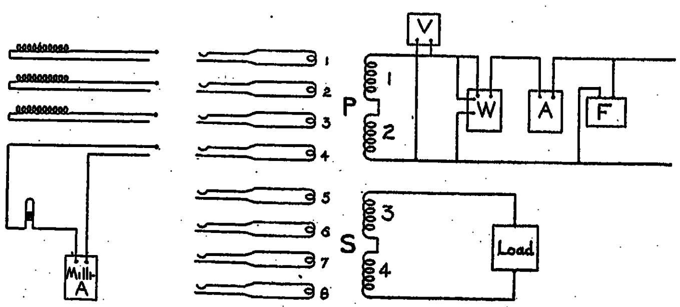

FIG. 4

Using the belt coil ammeter readings, and the constants of the ammeter circuit, the voltage induced in each belt coil was calculated. From these voltages the fluxes linking the various belt coils were obtained.

Using the calculations given in the appendix based upon the no-load and impedance test data, the phase positions and magnitudes of the various voltages were calculated. The data obtained from the belt coils are compared in each case with the results obtained by calculation.

The vector diagrams are drawn to scale using the calculated data.

(a) *No-Load Conditions.* Core loss test data: 115 volts, 0.08 ampere, 2.47 watts, 61-cycle frequency.

TABLE I.

Results of Tests Made Under No-Load Conditions.

Belt Coil No.	Belt Coil Amperes	Flux per sq. cm. (B'_{max})	Degrees Displacement	Average B'_{max}	Average Angle
I	II	III	IV	V	VI
1	0.0086	5680	40		
2	0.0084	6690	40	6230	37 lag
3	0.0086	6950	35		
4	0.0088	5600	32		
5	0.00835	5640	35		
6	0.00835	6610	33	6070	33 lag
7	0.0085	6640	33		
8	0.0086	5390	32		

Fluxes in column (III) are calculated from column (II) and show the maximum value of flux threading the belt coil turns.

Angles in column (IV) are taken from the oscillograms, and have been diminished by 180 degrees since an applied voltage rather than an induced voltage was used as a reference.

The flux density corresponding to the impressed voltage (115) is 6240 lines.

The lag angles shown in Table I show but little variation, and an angle of 33 degrees will, therefore, be subtracted from the angles measured on the oscillograms. This correction when applied to the position of the belt coil current wave, should give the approximate location of the voltage induced in the belt coil winding.

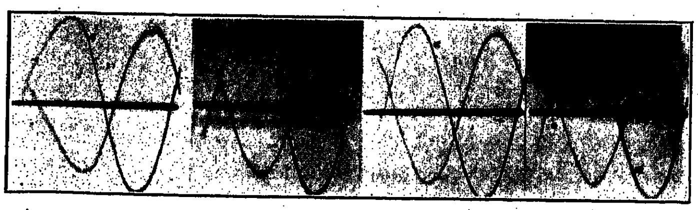
Primary Belt Coils



5 6 7 8
Secondary Belt Coils

FIG. 5—NO-LOAD CONDITIONS—SHOWING POSITIONS OF BELT COIL CURRENTS
e = reference voltage

The flux density given by the table is seen to be greater in the middle of the core than on either side. This condition is true for both the primary and secondary, the primary being slightly greater in value.

It will be noticed in all the following tests, that the flux distributes itself across the core in about the same manner no matter what the condition of loading may be.

(*b*) *Impedance Conditions.* (*Secondary Short-Circuited.*) Test data: Impedance volts (E_p) = 60 volts, primary current (I_p) = 4 amperes, input watts (W_p) = 51.3 watts, tertiary volts (E_m) = 24 volts, frequency (f) = 60 cycles.

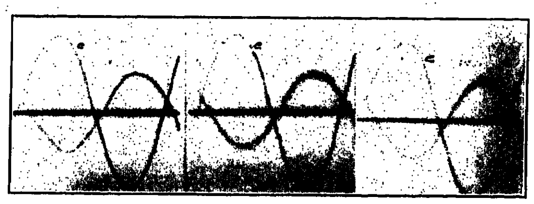
TABLE II.

Results of Belt Coil Tests Made Under Impedance Conditions.

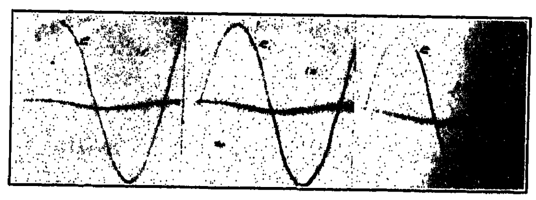
Belt Coil No.	Belt Coil Amperes	B'_{max}	Degrees Displacement	Corrected Angle	Average B'_{max}	Average Angle
I	II	III	IV	V	VI	VII
1	0.0046	3040	24 lag	9 lead		
2	0.0045	3580	22 "	11 "	3330	8 lead
3	0.0045	3640	27 "	6 "		
4	..	..	..	..		
5	..	310*	98 lag	65 lag		
6	..	370*	98 "	65 "	340	66 lag
7	..	370*	100 "	67 "		
8	..	..	..	..		

Angles in column (V) are equal to those in column (IV) diminished by 33 degrees.

*These fluxes were calculated from the amplitude of the current wave, the oscillograph element having been previously calibrated.



1 2 3
Primary Belt Coils



5 6 7
Secondary Belt Coils

FIG. 6—IMPEDANCE CONDITIONS—SHOWING POSITIONS AND MAGNITUDES OF BELT COIL CURRENTS
e = reference voltage.

Voltages and flux densities, calculated (see appendix) from the constants of the transformer, and the test data, are given in Table III.

TABLE III.

Voltages and Flux Densities Obtained by Calculation. (Impedance Conditions)

Voltage	B_{max}	B'_{max}	Degrees Displacement
I	II	III	IV
$\overline{E}_p = 60 + j\,0$			
$\overline{E}_p' = 58.7 + j\,6.0$	2530	3290	6 lead
$\overline{E}_m = 23.9 - j\,1.6$	1030	1470	4 lag
$\overline{E}'_s = -1.32 + j\,6.1$	260	340	76 lag
$\overline{E}_s = 0.0 + j\,0.0$			

$\overline{E}_p$ = primary impressed voltage. $\overline{E}_p' = \overline{E}_p$ diminished by $\overline{I_p R_p}$.
$\overline{E}_m$ = voltage induced by main flux, i. e., flux in parts of the core not under either primary or secondary coils.
$\overline{E}_s$ = secondary terminal voltage. $\overline{E}_s' = \overline{E}_s$ increased by $\overline{I_s R_s}$.
B_{max} = normal flux density in the core.
B'_{max} = normal flux density in the core based on undiminished cross-section of core.

From a comparison of the flux densities and angles shown in columns VI and VII of Table II with the corresponding values in columns III and IV of Table III, it is clear that the voltage induced in the primary is $\overline{E}_p'$ and that the secondary induced voltage is $\overline{E}_s'$. $\overline{E}_m$ has been commonly referred to as the voltage induced in the secondary winding, but the data show that the flux found under the secondary winding is only sufficient to induce a voltage equal to the secondary $I\,R$ drop.

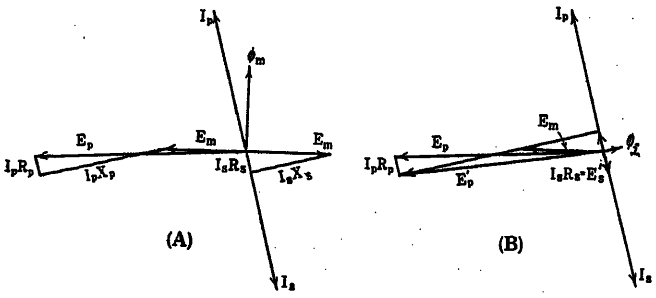


FIG. 7

No trace of the leakage flux is found in the core under the secondary as a separate flux, the distribution across the core being similar to that at no-load, and the angle of lag practically constant across the core. The only flux found under the secondary coils is that sufficient to overcome the secondary $I\,R$ drop.

The vector diagram shown in Fig. 7A, is drawn in the manner usually found which assumes that there is an actual reactance drop in both primary and secondary, and that the induced voltage is equal to E_m. Another diagram based upon the idea that the induced voltages are those found in this test is shown in Fig. 7B.

Either method will give the same numerical results, but it is to be remembered that the leakage flux and the main flux cannot exist in the core as separate and independent fluxes. Further discussion of the two methods will be found later in this paper.

(c) *Non-Inductive Load.* Test data: $E_p = 115$ volts, $I_p = 3.82$ amperes, frequency = 60 cycles.

TABLE IV.

Results of Belt Coil Tests Made with Non-Inductive Load

Belt Coil No.	Belt Coil Amperes	B'_{max}	Degrees Displacement	Corrected Angle	Average B'_{max}	Average Angle
I	II	III	IV	V	VI	VII
1	0.0082	5400	18 lag	15 lead		
2	0.0080	6380	18 "	15 "	6020	14 lead
3	0.0080	6500	20 "	13 "		
4	0.0085	5500	20 "	13 "		
5	0.0067	4600	54 lag	21 lag		
6	0.0068	5460	54 "	21 "	5050	20 lag
7	0.0069	5500	52 "	19 "		
8	0.0070	4450	51 "	18 "		

TABLE V.

Voltages and Flux Densities Obtained by Calculation (Non-Inductive Load)

Voltage	B_{max}	B'_{max}	Degrees Displacement
I	II	III	IV
$E_p = 115 + j\,0$			
$E_p' = 109.8 + j\,2.86$	4800	6240	1 lead
$E_m = 93.3 - j\,26.8$	4240	5510	16 lag
$E_s' = -82.7 + j\,46.0$	4120	5360	29 lag
$E_s = -77.4 + j\,43.2$			

A comparison of Tables IV and V shows that the voltage induced by the flux under the primary corresponds to E_p' while the flux under the secondary induces a voltage of E_s'. While the numerical values do not check as closely as might be desired, yet they are sufficiently close to lead to the conclusion given.

(d) *Inductive Load.* Test data: $E_p = 115$ volts, $I_p = 4.03$ amperes, frequency = 60 cycles.

Load characteristics: $E_s = 54$ volts, $I_s = 4.04$ amperes, $W_{load} = 50.6$ watts.

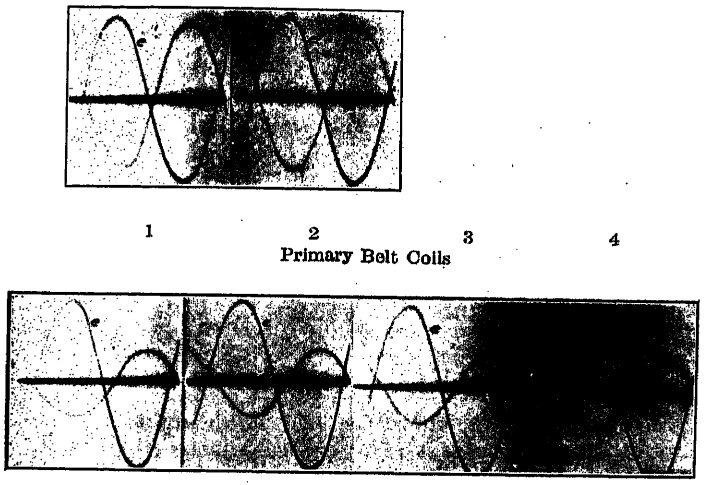
$E_s = -54.2 + j\,0.86$			

DISCUSSION

The flux threading the belt coils was found in every case to be sinusoidal. The reluctance of the four air gaps in the core effectively prevented the distortion noted by Kennelly and Alger in their paper previously referred to.



5 6 7 8
Secondary Belt Coils

FIG. 9—INDUCTIVE LOAD—SHOWING POSITIONS OF BELT COIL CURRENTS

e = reference voltage.

All the evidence of the tests made goes to prove that the voltage induced in the primary winding is the supplied voltage diminished vectorially by the primary $I\,R$ drop, and that the voltage induced in the secondary winding is equal to the secondary terminal voltage increased vectorially by the secondary $I\,R$ drop. The flux usually referred to as the main flux, and so called in this paper, does not alone produce the induced voltage in either the primary or secondary.

Practically all of the flux found in the ordinary low-voltage transformer, as for example the type generally used for distribution, is produced by the ampere turns of the primary. The ampere turns of the secondary modify the flux produced by the primary, but do not produce any flux which enters the core. The secondary winding may produce flux which does not enter the core, and this will be the case with the higher voltage coils where the distance between coils and core becomes quite large.

It would seem, in view of the fact that the leakage fluxes do not have a separate and independent existence in the core, that it is better not to represent such fluxes by closed lines in the core, because the use of the line conveys the idea that the leakage flux occupies a place close to the edge of the core, thus crowding the main flux to the middle of the core. The conception of lines of force is merely for convenience, and in cases where two or more m. m. fs. not in the same phase are acting upon a common part of the core, an altogether wrong conclusion may be arrived at, if the idea of lines is adhered to closely.

A figure (Fig. 10) suggested to the writer by Prof. Alfred Still, of Purdue University, will perhaps serve to make the presentation of what occurs in the core more accurate than the diagrams as usually drawn. The main flux is represented by three arrows showing the direction of the m. m. f. of the primary winding. Under the primary winding four arrows are found, indicating that the primary leakage flux is out of phase with the three arrows representing the main flux. This flux, and in fact all of the fluxes in the core may be

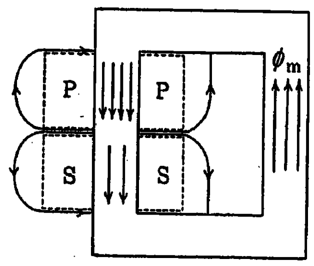


FIG. 10

considered as spreading across the core in the same manner as when no current is flowing in the secondary winding. Under the secondary winding the flux indicated by the two arrows is the vectorial difference of the four arrows under the primary, and the four arrows representing the leakage.

The calculation of the leakage paths has always nelgected the path in the iron, and since the air paths shown in the figure have not been changed, the method of calculation and the numerical results obtained therefrom are not affected by this investigation.

CONCLUSION AND SUMMARY

This investigation has shown that for the simple type of transformer investigated the leakage fluxes are not to be found as separate fluxes under the primary and secondary coils. Thus the method of representing the leakage fluxes so commonly used in text-books dealing with transformers in which the leakage fluxes are represented by lines in the same part of the core with other lines out of phase with them, does not picture a condition which actually exists.

It has also been shown that the voltage induced in the primary winding is equal to the supplied e. m. f. diminished by the $I\,R$ drop, and that the secondary

induced voltage is equal to the secondary terminal voltage increased by the secondary $I\,R$ drop.

The writer wishes to express his appreciation to the members of the Staff of the School of Electrical Engineering at Purdue University, who have taken a lively interest in the matter and who have offered many suggestions of value. Especial thanks are due to Prof. Alfred Still, who has followed the work closely, and under whose general supervision the thesis,[1] of which this is an abstract, was conducted.

Appendix

Calculation of Fluxes from Belt Coil Ammeter Readings

Measured inductance of ammeter = 0.25 henry.

Resistance of circuit including ammeter, belt coil, oscillograph and connections = 311 ohms.

Then $\sqrt{\overline{(311)}^2 + \overline{(377)\,(0.25)}^2}$ = 325 ohms impedance at 60 cycles.

The e. m. f. induced is:

$4.4\,f\,N\,\phi\,10^{-8}$ and equals $325\,I$,

The maximum flux density is then $\dfrac{325\,I\,10^8}{4.4\,A + 40}$

where A = belt coil area, f = frequency, I = belt coil current in amperes, 40 = turns per belt coil.

Calculations for the Different Conditions of Loading

The following list of symbols will be used.

E_p = Voltage impressed on the primary.
E_p' = Voltage induced in the primary winding.
E_m = Voltage induced by the main flux in the tertiary coil.
E_s = Secondary terminal voltage.
E_s' = Voltage induced in the secondary winding.
I_p = Primary current.
I_s = Secondary current.
W_p = Watts input to primary.
W_{load} = Watts output of secondary.

Test (b) Impedance Conditions: Calculation of E_m. Test data: $E_p = 60$, $I_p = 4$, $E_s = 0$, $E_m = 24$, $W_p = 51.3$.

Let $E_m = e + j\,e'$. Assuming that $E_p = 60 + j\,0$ then the primary current $I_p = 4\ (0.214 - j\,0.976) = 0.856 - j\,3.9$.

The voltage usually called the primary $I\,X$ drop may be represented by $a\,(0.976 + j\,0.214)$, where a is its real value in volts.

The primary $I\,R = 1.54\,(0.856 - j\,3.9) = 1.317 - j\,6.0$

Then $E_p' = (60 + j\,0) - (1.317 - j\,6.0)$
$= 58.68 + j\,6.0.$

Also $(e + j\,e') + a\,(0.976 + j\,0.214)$
$= 58.68 + j\,6.0$

and $(0.976\,a + e) + j\,(0.214\,a + e')$
$= 58.68 + j\,6.0$

These are identically equal, and therefore,

$0.976\,a + e = 58.68$, and $0.214\,a + e' = 6.0$ also, (1)

$\sqrt{e^2 + e'^2} = 24$, since from the data, $E_m = 24$. (2)

Eliminating a between the equations in (1), substituting in (2) and solving for e' we have

$e' = 11.36$ or -1.60.

From the vector diagram it may be seen that -1.60 is the correct value. Substituting this value in equation (2) and solving we obtain,

$e = 23.95.$

Thus $E_m = 23.95 - j\,1.60.$

Primary $I\,X$. For use in the following calculations it will be useful to find value and phase position of the primary $I\,X$:

It is $(58.68 + j\,6.0) - (23.95 - j\,1.6) = 34.73 + j\,7.6.$

The primary reactance is then

$$\frac{34.7 + j\,7.6}{0.856 - j\,3.90} = 0 + j\,8.88$$

The primary resistance is

$$= \frac{1.317 - j\,6.0}{0.856 - j\,3.90} = 1.54 + j\,0.$$

The primary impedance is therefore $1.54 + j\,8.88$. The total transformer impedance is then

$$\frac{60 + j\,0}{0.856 - j\,3.90} = 3.2 + j\,14.6 \qquad (3)$$

Since the ratio of the transformer is 1 to 1, the secondary impedance may be taken as the difference between the total and that in the primary. The secondary impedance is then $1.66 + j\,5.72$. The measured value of the secondary resistance was 1.54.

This check is quite satisfactory when it is remembered that the value of R depends upon the wattmeter reading. The fact that the core loss was neglected tends to make the resistance come out higher than it should. The secondary impedance will therefore, be taken as $1.54 + j\,5.72$.

Then $E_s' = (-23.95 + j\,1.60) - (0.855 - j\,3.9)\,(1.54 + j\,5.72) = 1.32 + j\,6.1.$

Test (c) Non-Inductive Load. Test data: $E_p = 115$, $I_p = 3.82$.

Let $E_p = 115 + j\,0$.

Using (3) we have,

$$I_p = 3.82 = \frac{115}{\sqrt{R^2 + (14.6)^2}} \text{ or } R = 26.4 \text{ ohms.}$$

then

$$I_p = \frac{115 + j\,0}{26.4 + j\,14.6} = 3.35 - j\,1.86.$$

$$E_p' = (115 + j\,0) - (1.54 + j\,0)\,(3.35 - j\,1.86) = 109.8 + j\,2.86.$$

1. Graduate Thesis, "Investigation of Leakage Fluxes in Transformers," by K. B. McEachron, Purdue University, 1920.

$$E_m = (109.8 + j\,2.86) - (O + j\,8.88)\,(3.35 - j\,1.86) = 93.3 - j\,26.84.$$

$$E_s' = (-\,93.3 + j\,26.84) - (O + j\,5.72)\,(-\,3.35 + j\,1.86) = -\,82.68 + j\,46.0.$$

$$E_s = (-\,82.68 + j\,46.0) - (1.54 + j\,O)\,(-\,3.35 + j\,1.86) = -\,77.5 + j\,43.14.$$

The voltage E_s will be found to be in phase with the secondary current.

Test (d) Inductive Load. Test data: $E_p = 115$, $I_p = 4.03$, $E_s = 54$, $I_s = 4.04$, $W_{load} = 50.6$.

The resistance and reactance of the load respectively, are:

$$R_l = \frac{50.6}{(4.03)^2} = 3.1 \text{ and } X_l = \sqrt{\left(\frac{54}{4.03}\right)^2 - 3.1^2} = 13$$

Total resistance including load $= 3.08 + 3.1 = 6.18$.
Total reactance including load $= 14.6 + 13.0 = 27.6$

$$\text{Total } I_p = \frac{115 + j0}{6.18 + j\,27.6} = 0.889 - j\,3.97.$$

$$E_p' = (115 + j\,0) - (0.889 - j\,3.97)\,(1.54 + j0) = 113.6 + j\,6.11.$$

$$E_m = (113.6 + j\,6.11) - (0.889 - j\,3.97)\,(0 + j\,8.88) = 78.4 - j\,1.88.$$

$$E_s' = (-\,78.4 + j\,1.88) - (-\,0.889 + j\,3.97)\,(0 + j\,5.72) = -\,55.6 + j\,6.98.$$

$$E_s = (-\,55.6 + j\,6.98) - (-\,0.889) + j\,3.97)\,(1.54 + j\,0) = -\,54.2 + j\,0.86.$$

Discussion

R. E. Hellmund: The points brought out in the paper simply emphasize something which is overlooked too much in teaching. In electrical engineering, we frequently cannot see the real thing and are forced to adopt conventions in order to make things clear with our limited mental facilities. Now, as long as we have to adopt conventions, we are perfectly at liberty to adopt the one or the other, but the thing that is neglected is to make it perfectly clear that we are dealing with conventions instead of facts. It is all right to teach the separate fluxes to the students, but we must keep in mind that in doing so we are adopting conventions and that the actual resultant fluxes may be different as shown in the paper.

This same point has been discussed for many years, especially in connection with induction motors, where similar problems arise. For instance, if we have induction motor slots (*A*) and (*C*) as shown in Fig. 1, we can represent the main flux by lines (*b*), the primary leakage fluxes by lines (*a*), and the secondary leakage fluxes by (*c*). Now if we assume the extreme case of standstill and zero resistance in the secondary squirrel-cage winding, we know that the resultant flux entering a secondary tooth must be zero; in other words, the secondary leakage flux (*c*) must be equal and opposite to the main flux (*b*). It follows, therefore, that as a matter of fact we do not have separate fluxes (*b* and *c*), but a flux (*d*) which flows around the primary slot, across the air gap, and across the secondary slot opening; in other words, we have here a condition in an induction motor similar to those discussed in the paper for a transformer. Here it is again convenient to adopt conventions dealing with separate main and secondary leakage fluxes, while as a matter of fact, the real fluxes are entirely different. There is no harm in adopting the convention so long as it is made clear that we are dealing with conventions, not actual facts.

Another similar case is the so-called zigzag leakage in induction motors, which is frequently illustrated by a flux line (*a*) as shown in Fig. 2. We have, of course, in addition to the leakage fluxes, the main flux lines (*b*). It is at once evident in this figure that we will not actually have in the air gap portions (P_2) certain fluxes (*a*) flowing in one direction and another flux (*b*) flowing in the opposite direction, but that we actually have a resultant flux density in the gap portions (P_2) which is the difference between the fluxes (*a*) and (*b*). In other words, the zigzag leakage fluxes merely weaken the field in the gap portions (P_2). Similarly, it is evident that the leakage fluxes (*a*) strengthen the flux in the air gap portions (P_1). It is, however, practically impossible for us to work up theories taking into account the effect of the leakage fluxes along the actual line of weakening the main flux in certain portions of the gap

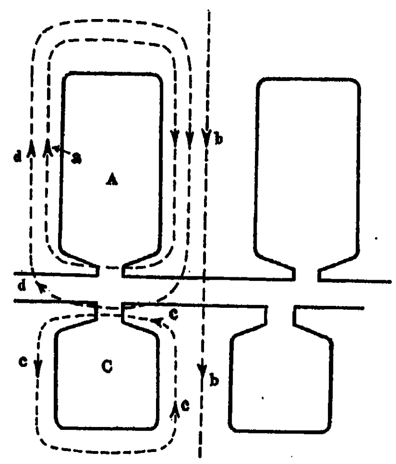

FIG. 1

and strengthening it in others; while, if we adopt the convention of separate fluxes, the desired result is obtained without much difficulty.

An exception to the more usual cases, where the leakage fluxes do not actually exist in line with the adopted conventions, is found in the end connection leakage of induction motors. Fig. 3 shows primary core (*D*) and secondary core (*F*), with coil windings in the primary and squirrel-cage windings in the secondary. The main flux is illustrated by a line (*b*). There will be primary end connection fluxes (e_1) going through the air

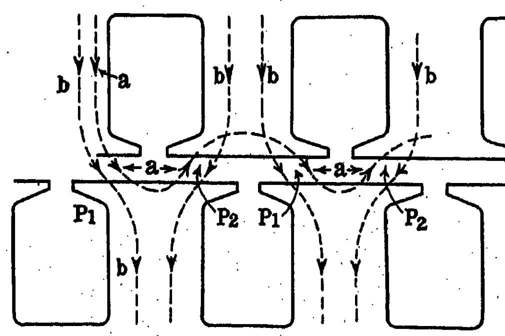

FIG. 2

around the coil ends. There will also be secondary end-connection leakages (e_2) going around the end rings of the squirrel-cage motor. These leakage fluxes actually exist separately of the main flux. In addition to these fluxes, there may be other end-connection fluxes (e_3), for instance, which go around the end rings of the secondary, but which go partly through the secondary core. As shown in this latter case, they may not exist separately, but again modify other fluxes.

It will be seen that the facts depend entirely upon the case, and that it is difficult to take into account the actual conditions

for all the varieties which are met in practise. The main point is that we must always keep clearly before the student the conventions that are adopted in working out a problem.

P. Trombetta: If the self-inductive reactance of the primary

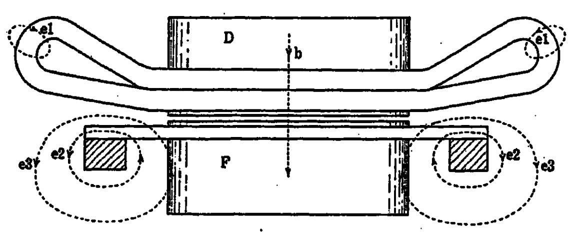

FIG. 3

of a transformer is X_0 and of the secondary is X_1 then if the voltage applied to the primary be E_0 the flux Φ_0 surrounding the primary must be such as to balance the voltage $E_0 - R_0 L_0$ where I_0 and R_0 are the current and resistance of the primary circuit.

When there is no load in the secondary the voltage induced in it is $E_0 - Z_0 I_0$ where Z_0 and I_0 are the impedance and current

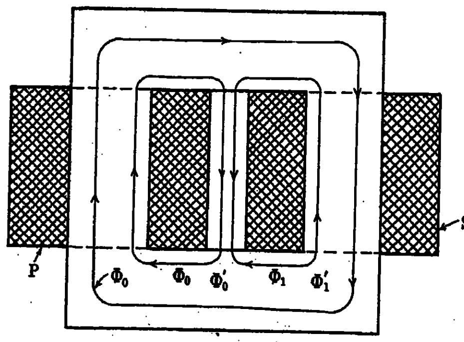

FIG 4

in the primary circuit. When there is a load in the secondary the voltage distribution in it is: $E_1 = E_e + Z_1 I_1$ where E_e is the voltage consumed in the load and $Z_1 I_1$ = voltage consumed in secondary impedance $Z_1 \; I_1 = \gamma_1 \, i_1 + j \, x_1 \, i_1 = i \, (\gamma_1 + j \, x_1)$

Now it is immaterial whether in the calculations of a transformer or an induction motor we assume that $j \, x_1 \, I_1$ is generated

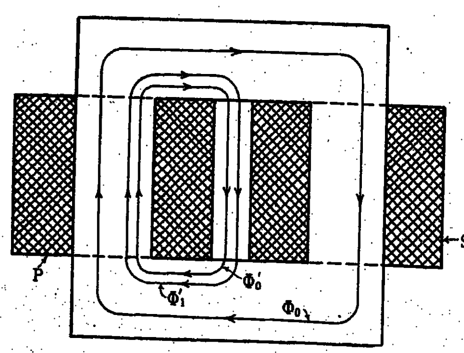

FIG 5

and consumed by the self-inductive reactance of the secondary circuit or that it is not generated at all. The most significant point to note is however, that this quantity can be found by finding the leakage reactance voltage of the secondary. The exact fact is, however, that this part of the secondary e. m. f. is not generated at all. In Fig. 4 is shown precisely what actually happens; namely, there are three different sets of lines of forces in the magnetic circuit of the transformer, Φ_0 may be called the main flux and goes through both the primary and secondary, Φ'_0 is the primary leakage flux and goes through the primary coil only, Φ_1' is the secondary leakage flux and goes through the secondary coil only. But it is seen that Φ_1' and Φ_0 are flowing in opposite directions inside of the core while Φ_0' and Φ_0 are flowing in the same direction inside of the core. In the primary, therefore, we have a real leakage flux which actually exists and represents a certain voltage consumption. In the secondary, on the other hand, we have conditions which cannot physically exist. On the outside of the secondary coil Φ_1' and Φ_0 can flow in the same direction and consequently what actually happens is that Φ_1' does not represent a real leakage flux but a part of the main flux which is taken from the inside of the secondary coil to the outside, that is, the flux inside of the secondary coil under load conditions is not Φ_0 but $\Phi_0 - \Phi_1'$ and since Φ_1' represents the leakage voltage, the actual voltage induced in the secondary is:

$$E_1 - j \, x_1 \, I_1 = E_e + \gamma_1 \, I_1$$

In other words, the total voltage induced in the secondary is the voltage consumed in the load plus the resistance drop in the secondary winding. The conditions above described are represented in Fig. 5.

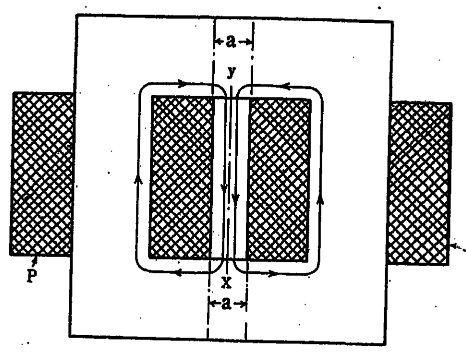

FIG 6

The basis for the above conclusions are to be found in the following physical explanation of reluctance and permeance.

It is well known that every substance (including vacuum which is not a substance but empty space) has a definite coefficient of permeability μ; in some cases this coefficient is variable, in iron for instance. For other substances it is constant. Taking into consideration the fact that we have definite knowledge of μ for those substances for which it is variable, we may state that having given the m. m. f. acting on a magnetic circuit of a certain substance we can calculate the flux flowing through that magnetic circuit. On the other hand if we apply a m.m. f. F_1 to a circuit in which there is already applied a m. m. f. $- F_1$ the resultant flux through that circuit is zero. This may be expressed mathematically in two ways first we may say that the total m. m. f. acting on the circuit is the summation of the two m. m. fs. F_1 and $- F_1$ and therefore equals to zero; second we may say that the permeability of the magnetic circuit has become zero. In either case we are correct. When F_1 is numerically larger or smaller than $- F_1$ there will be some resultant flux and if we write the equation

$$\phi = \frac{F_1}{R}$$

we find that R is very much increased if $F_1 > - F$; while if $F_1 < - F_1$, R actually becomes negative. On the other hand it is found that the permeability of the medium between the two coils has been greatly increased, in other words, in Fig. 6 the permeability of the iron included in the length "a" has become

of infinite reluctance while the air along the path $x\ y$ has been made more permeable.

That the application of a m. m. f. to a body is equivalent to increasing its permeability in one direction and decreasing it in the opposite is shown by the fact that electromagnets, whatever may be the nature of the core material, when placed in a magnetic field behave exactly in the same manner as a substance, the permeability of which is such that when exposed to the same field would increase the magnetic flux by the same amount that it would be increased by the new system with substance of different permeability and with a given m.m. f. applied to it.

In other words take (Fig. 7) a solenoid of diameter d and length l with copper core and let a current I flow through it. When this solenoid is placed in a uniform field of intensity H at an

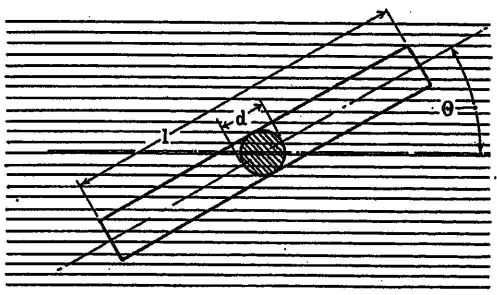

FIG. 7

angle θ to the axis of the solenoid, it will have a torque T tending to place the solenoid parallel with H. It is now possible to replace the solenoid by a cylinder of diameter d and length l which will give the same torque, provided the permeability is such that the increase in the amount of flux passing through the core for a given amount of rotation of the core is the same as in the case of the solenoid. In other words the torque or couple acting on the cylinder is

$$T = K \frac{d\,\phi}{d\,\theta}$$

Where ϕ is the flux passing inside of the cylinder and θ is the angle between the axis of the cylinder and the field intensity of the medium.

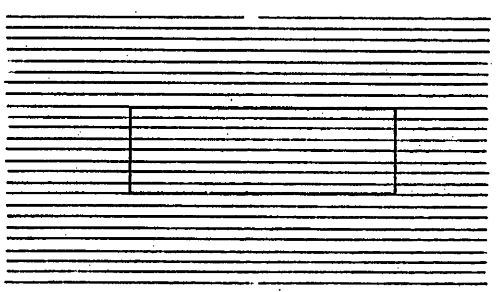

FIG. 8

A further proof of this theory is afforded by the converging or diverging lines into and away from a substance of permeability higher or smaller than that of the ambient in which it is placed, when the ambient has a magnetic field of uniform strength. Thus in Fig. 8 is shown a cylinder of a material of unity permeability placed in air parallel with a field of force of uniform density H, it is seen that the density inside of the rod is the same as that outside, in other words the rod has not converged the field at all.

In Fig. 9 is shown a cylinder of permeability $\mu > 1$ placed in a uniform field of density H. It is seen that inside of the rod the density is higher than it would have been if the rod were not there, while outside the cylinder the density is smaller than it would have been if the cylinder were not there. It is immaterial whether we consider the increase of the flux inside of the cylinder as being constituted by the flux which is now missing outside of it or if we consider all the additional flux inside the cylinder as returning outside of the cylinder in the opposite direction to that of the main field and therefore cancel or neutralize as many lines outside of the cylinder as there have been increased inside of it. In fact it is possible to study the field distribution inside and outside of a cylinder of permeability μ by replacing it by a solenoid through which is flowing a current which will give a field intensity of $H_1 - H$ where H_1 is the density in the permeable cylinder after it has been placed in the uniform field of density H. By exploring the field of this solenoid when placed in a medium of zero field density and unity permeability and superimposing this on the uniform field, we get the exact conditions as would exist when we place a cylinder of permeability μ in the uniform field H. It is evident that if μ of the permeable cylinder were $- \mu$ we could obtain all the field distribution in the same manner but the superposition would have to be so that the flux inside of the solenoid were flowing in opposite direction to the field H.

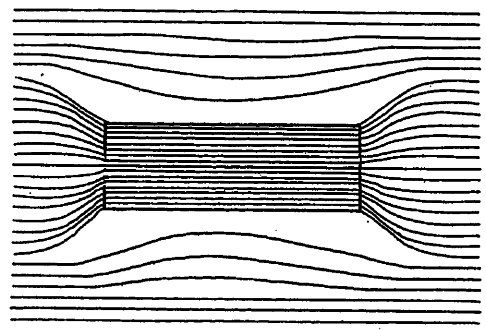

FIG. 9

What Mr. McEachron found by long, tedious and costly work might have been found analytically and much more accurately, and all of it is given in the first edition of Steinmetz's "Theory and Calculations of Electric Circuits," in the chapter on Reactance of Induction Apparatus, p. p. 217-231 (in particular at top of p. 229).

J. E. Clem: In my discussion of this paper I wish first to arrive at a mutual understanding of what the various fluxes are that are found in a transformer.

What is a leakage flux? The definition of the leakage flux should be a statement of the physical phenomenon. A leakage flux is ordinarily defined as a flux which links one winding without linking the other. Two leakage fluxes are sometimes recognized; the first being that produced by the primary current which links the primary but not the secondary and called the primary leakage flux; the second that produced by the secondary current which links the secondary but not the primary and called the secondary leakage flux. Actually, however, the idea of a secondary leakage flux is misleading and erroneous, there being only one leakage flux and that is the primary leakage flux. The leakage flux is the flux which links the primary winding but not the secondary winding.

There is no resultant flux inside a short-circuited coil except that required to supply the energy loss consumed in heat in the short-circuited coil. When the coil is on open circuit the current in the primary coil will cause a certain amount of flux to link the secondary coil, and if the coil is short-circuited a current will be set up and produce a counter flux. The counter flux set up by the current in the short-circuited secondary coil will be at all

times exactly equal and opposite to the flux coming from the primary current. Therefore the resultant flux inside the short-circuited secondary coil is zero.

The question immediately arises as to how the current can be maintained in a short-circuited coil with no flux inside it. We have seen that the condition of zero flux is in reality the balance of two fluxes. If the primary current should change there would be an excess of flux in one direction or the other which would induce a voltage and set up an additional current in the secondary coil. The current in the secondary coil will be maintained as long as no change of flux takes place inside the secondary coil.

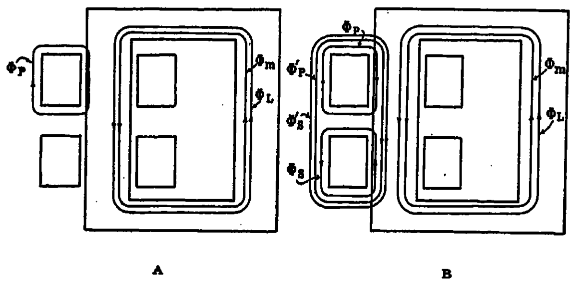

Fig. 10—Magnetic Flux Distribution in Transformers

Since there is no flux inside the secondary coil there can be no secondary leakage flux in the definition of the term as given above. Consequently all the leakage flux in a transformer must be primary leakage flux.

What is the main flux? This is primarily a matter of definition and the definition should be consistent and always lead to the same flux. There are three common definitions; (a) the flux in the core underneath the secondary windings; (b) the flux in the core at a point not underneath the primary or secondary windings; (c) the flux in the core required to maintain the secondary terminal voltage. The first definition is wrong because

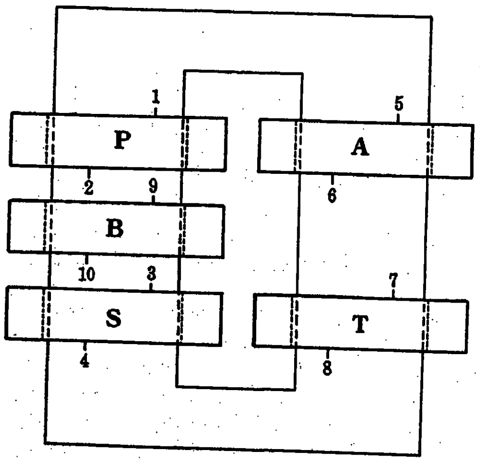

Fig. 11—Magnetic Flux Distribution in Transformers

the flux in the core under the secondary winding is different depending upon whether the primary is inside or outside the secondary. The second is wrong for a reason which will be given later in this discussion. The main flux then is the flux required to maintain the terminal voltage of the secondary winding.

The leakage and main fluxes as defined above are shown in diagram in Fig. 10A and 10B. In Fig. 10B ϕ_p and ϕ_p' are the fluxes which would exist if the coil P was by itself and ϕ_s and ϕ_s' are the fluxes corresponding for coil S. Of course in considering the coil alone the core must be assumed as taken away. In Fig. 10A is shown the resultant condition in which the leakage flux is ϕ_p linking the primary winding only. The flux ϕ_L is the flux required to supply the losses in the secondary coil and the flux ϕ_m is the flux required to maintain the terminal voltage of the secondary coil. It is clear that the leakage flux is the flux which links the primary but not the secondary and the main flux is the flux required to maintain the secondary terminal voltage.

The core flux at any part of the core will be the resultant of the various fluxes occurring there. Prof. McEachron's investigation was made to obtain experimental data in respect to the flux existing under the primary and secondary coils and elsewhere in the core. He considered that the text book method of representing the leakage fluxes as indicated in Fig. 1 of his paper required the leakage fluxes to have a separate and independent existence because they were represented by closed lines, and that they would be found along the edge of the core underneath the winding crowding the main flux to the middle of the core and further, that it should be possible to identify the separate fluxes because they were out of phase. Prof. McEachron's tests showed very conclusively that there was no resultant leakage flux within the secondary coil and that the flux within the primary coil was the resultant of the main flux and the leakage flux.

In Test b, impedance conditions, the secondary voltage corresponding to the flux inside the secondary coil is 6.14 volts. The voltage consumed in the resistance of the secondary coil is 6.16 volts. All the flux in the secondary coil is that required to supply the energy consumed in the resistance of the secondary coil and there is no other resultant flux inside the secondary coil.

Prof. McEachron's definition of the main flux as "the flux found in the core at a point not under either the primary or secondary windings" naturally led him into a wrong interpretation of the data obtained in test (b). According to his definition of the main flux the tertiary voltage should be a measure of the main flux, and he uses this voltage to determine what he calls the primary and secondary reactance. That the results of these calculations should be wrong is the result of the wrong assumption.

The tertiary voltage on the impedance test is a measure of the common reactance of the secondary and tertiary coil or it is a measure of the common induction of the primary and tertiary coils. If one wished to calculate the regulation one would use the difference between the primary applied voltage and the tertiary induced voltage, and if one wished to calculate the difference in voltage between the secondary and tertiary coils or the voltage induced in the tertiary coil one would use the tertiary induced voltage. The voltage induced in the tertiary coil depends upon the relative location of the tertiary coil in respect to the primary and secondary and therefore cannot be relied upon to measure the main flux density.

The variation of the voltage induced on the tertiary coil at different locations is clearly shown by the tests which I have made. The data are given in Table I, and were obtained from tests made on a transformer with the coils arranged as shown in Fig. 11. These tests were made by connecting the generator in turn to coils P, S, and T, with one or both of the other two coils short-circuited and measuring the voltage induced on all the other open-circuited windings. The voltage measured on the open-circuited coils varies with the relative positions of the generator, short-circuited, and open-circuited coils.

The voltage induced in any coil on the core during a straight impedance test can be predetermined if the values of the reactances between the various coils by pairs are known. The method of doing this is illustrated in Table II and the results of the calculation are tabulated in Table I. The voltage induced in a tertiary coil is equal to the secondary voltage plus the resistance drop of the secondary coil plus the common induced voltage of the primary and tertiary. The test and calculated

Calculation of Voltages

Test No. 1

$P.F. = .0898$ $W.F. = .9959$ $I = 53.4 - j\,59.9$

$M_{PT.S} = \tfrac{1}{2}(6.486 + 15.98 - 16.46) = 3.003$

$M_{PA.S} = \tfrac{1}{2}(6.486 + 16.46 - 15.98) = 3.483$

$M_{PB.S} = \tfrac{1}{2}(6.486 + 3.385 - 3.385) = 3.243$

$E_T = (5.34 - j\,59.9)(.3 + j\,3.003) = 181.4$

$E_A = (5.34 - j\,59.9)(.3 + j\,3.483) = 210.2$

$E_B = (5.34 - j\,59.9)(.3 + j\,3.243) = 195.9$

Test No. 2

$P.F. = .2948$ $W.F. = .956$ $I = 17.73 - j\,57.45$

$M_{PS.T} = \tfrac{1}{2}(16.46 + 15.98 - 6.486) = 12.98$

$M_{PA.T} = \tfrac{1}{2}(16.46 + 6.486 - 15.98) = 3.483$

$M_{PB.T} = \tfrac{1}{2}(16.46 + 16.25 - 3.385) = 14.66$

$E_S = (17.73 - j\,57.45)(.3 + j\,12.98) = 780$

$E_A = (17.73 - j\,57.45)(.3 + j\,3.483) = 209.7$

$E_B = (17.75 - j\,57.45)(.3 + j\,14.66) = 880$

Test No. 3

$P.F. = .1093$ $W.F. = .939$ $I_S\,5.54 - j\,47.58$ $I_T = .99 - j\,9.47$

$M_{SA.P} = \tfrac{1}{2}(6.486 + 15.98 - 16.46) = 3.003$

$M_{TA.P} = \tfrac{1}{2}(16.46 + 15.98 - 6.486) = 12.98$

$M_{SB.P} = \tfrac{1}{2}(6.486 + 3.385 - 3.385) = 3.243$

$M_{TB.P} = \tfrac{1}{2}(16.46 + 3.385 - 16.25) = 1.798$

$E_A = 365 - (5.54 - j\,47.58)(.3 + j\,3.003) - (.99 - j\,9.47)(4.72 + j\,12.98) = 97.4$

$E_B = 365 - (5.54 - j\,47.58)(.3 + j\,3.243) - (.99 - j\,9.47)(4.72 + j\,1.798) = 181.8$

Test No. 10

$P.F. = .344$ $W.F. = .939$ $I_S = 20.7 - j\,56.5$

$M_{PT.S} = 3.003$

$M_{PA.S} = 3.483$

$M_{PB.S} = 3.243$

$E_T = 10.05 + (20.7 - j\,56.5)(.3 + j\,3.003) = 191$

$E_A = 10.05 + (20.7 - j\,56.5)(.3 + j\,3.483) = 220$

$E_B = 10.05 + (20.7 - j\,56.5)(.3 + j\,3.243) = 206.6$

$E_P = 10.05 + (20.7 - j\,56.5)(.6 + j\,6.486) = 401.5$

Test No. 11

$P.F. = .2544$ $W.F.\ .967$ $I_S = 15.32 - j\,58.25$

$M_{PT.S} = 3.003$ $M_{PA.S} = 3.483$ $M_{PB.S} = 3.243$

$E_T = 606 + (15.32 - j\,58.25)(.3 + j\,3.003) = 785.6$

$E_A = 606 + (15.32 - j\,58.25)(.3 + j\,3.483) = 813.7$

$E_B = 606 + (15.32 - j\,58.25)(.3 + j\,3.243) = 785.5$

$E_P = 606 + (15.32 - j\,58.25)(.6 + j\,6.486) = 994$

values agree very well and bear out the statement that the tertiary coil is not a direct measure of the main flux.

Prof. McEachron could have found the quantities which he calls primary and secondary resistance and reactance much more easily by using an equation based on the analysis I have outlined. It should be remembered however that the quantities are not primary and secondary reactance. If we call the common induction of the primary and tertiary when the secondary is short-circuited M_{pt} then the tertiary voltage will be

$$E_t = I\,(R_s + j\,M_{pt})$$

But $E_t = 24$; $I = 4$; and $R_s = 1.54$, from which M_{pt} is easily found to be 5.8 ohms. Now M_{pt} plus M_{st} must equal X_{rs} and we get M_{st} as 8.85 ohms. The calculations in the paper for the voltage E_m are correctly made although they give the total voltage induced in the tertiary coil and not the voltage induced by the main flux only.

Following is a brief summary of the main points in respect to the magnetic flux distribution in transformers.

There is but one leakage flux and that is the flux which links the primary but not the secondary.

There is no resultant flux inside a short-circuited coil except that required to supply the energy loss in the short-circuited coil.

The main flux is the flux required to maintain the terminal voltage of the secondary winding.

At any point in the core the various fluxes in the core do not have a distinctly separate and independent existence, but the flux at any point is the resultant of the different fluxes at that point.

The voltage induced in the secondary coil is equal to the secondary terminal voltage increased by the resistance drop in the secondary coil.

The voltage induced in the primary coil is equal to the secondary induced voltage increased by the voltage induced by the primary leakage flux.

The voltage induced in any other coil on the core depends upon its relative position in respect to the primary and secondary coils.

The practise of illustrating the various fluxes by closed lines is in general correct because the leakage and main fluxes can exist independently of each other. Whenever two or more fluxes occur at the same point the effective flux is their resultant.

Philip L. Alger: This question of the distinctions between "main flux" and "leakage" is an ever recurring one in the study of electrical machinery. Especially in the consideration of the zigzag leakage or "doubly linked" flux of induction motors are the distinctions difficult to keep in mind. In all cases one has the alternatives of either considering but one flux from which driblets keep leaking away as its path is traced further and further away fron the primary source of m. m. f.; or of considering a "main" flux constant throughout the circuit, and various leakage fluxes which flow sometimes with and sometimes against the "main" flux. As an enemy is always defeated more easily in detail than en masse, the latter point of view has advantages for quantitative work, and I prefer it.

While the two points of view, if carried out correctly, will always lead to the same result, the single flux theory is the more fundamental, and should always be resorted to in doubtful cases. Mr. McEachron has presented an interesting experimental proof of this fundamental nature of the single flux viewpoint.

I believe, however, that by modifying his arrangements, Mr. McEachron could have experimentally proved the separate existence of the primary leakage flux (though not that of the secondary). For, if the primary leakage flux actually did try to hug the outer edges of the core as shown by Fig. 1 of the author's paper, the difference in phase between it and the main flux would cause a corresponding difference in the reluctance drops in the iron, and this difference between the m. m. f's. in two adjacent parts of the core would divert the leakage flux in a transverse direction until the m. m. f's were equalized. In other words it is the low reluctance of the core in a direction at right angles to the flow of the main flux (in the section of Fig. 1) that forces the primary leakage and main fluxes to mingle indistinguishably. The question is analogous to that of the distribution of high-frequency current in a slot embedded conductor.

If, therefore, the holes for the research coils had been pierced at right angles to their chosen positions, in the same plane, so that the wires passed *between* instead of *through* the laminations, and if the outer search coils had been so placed as to include only a few of the outermost laminations, a different result would have been found from the experiments. For, in this case the relatively high transverse reluctance of the core, due to the spaces between laminations would have permitted the primary leakage flux to retain its identity more distinctly.

The 15 to 20 per cent excess of density at the middle of the core disclosed by the tests is very interesting. Such differences account for part of the inevitable excess of test core losses over those calculated from the laboratory data. I believe that this variation in density over the core section is due to the fact that the flux always takes a path which combines minimum length with minimum curvature in so far as these qualities are compatible. If the proportions of the test transformers had been different, so that the corners had played a greater (or less) part in determining the flux distribution, I believe the variation of core density would have been correspondingly altered.

P. Trombetta: I still cannot see why it is necessary to make so many assumptions. It seems to me that if the relations are studied properly it is possible to determine all leakage fluxes and when they are known it soon becomes apparent what can and what cannot be neglected. It is perfectly possible to calculate or measure leakage fluxes of primary and secondary at different values of currents and when the two are coexisting in the same magnetic circuit it is only a question of combining all of them and the resultant gives the actual facts.

Benj. F. Bailey: I think the fundamental trouble here perhaps is this. Most of the text books use in a great deal of their work the principle of superposition, yet they never take the trouble to explain that they are using that principle, or what it means. There are a great many effects that can be superimposed upon one another and treated individually. In other words they don't interfere with one another. I look, for example, at the blackboard and I see perfectly what is written there, yet there are innumerable light waves coming across the light waves which reach my eye, but there is not a particle of interference. That is superposition. It is hard to define what we mean by it, but that is simply an illustration of it. There are plenty of places where we can use superposition to advantage. But there are other places where we cannot. One of these is when we come to superimpose magnetic fields. They do not superimpose perfectly because of the change in permeability. Most of the electrical books explain magnetic phenomena on the principle of superposition, but do not make it clear to the student that that is the principle upon which they are working, and also do not make it clear that it may lead to slightly erroneous results. For example in the case of the transformer, they are not taking into account the fact that magnetic effects are not perfectly superimposable. There are changes in permeability, and consequently the result you get is not quite right.

I quite agree with what has been said about the sloppiness of some of our text books. I am a teacher myself, and I have to contend with it every day. It is certainly disconcerting to have to explain to students why the textbook is not right,—and it is not right in a very great many cases.

I think sometimes we might get rid of a good many of the troubles of teaching if we came to the idea of teaching the student that there is no difference at all between a-c. and d-c. current. In other words, Ohm's Law always holds, or the current is the electromotive force divided by the resistance. For example, consider a simple reactive coil. There is an applied voltage on the coil and another voltage induced in the coil. If we take into account both of them and call the sum the electromotive force, then Ohm's law is followed exactly. Now I don't say that I want to teach that way. I am sometimes discouraged, because when I do try to get down to fundamentals and make the thing clear from the ground up, I find it is very difficult to do.

K. B. McEachron: As stated by Mr. Trombetta, a theoretical treatment of the subject of leakage in a transformer may be found in "The Theory and Calculation of Electric Circuits" by Dr. Steinmetz. The present paper attempts only to show in an experimental way the fluxes which are actually found, and to point out how the assumptions frequently made concerning the

leakage fluxes may lead the student into an altogether wrong conception of the true conditions.

Mr. Clem in his discussion stated that the method used in determining the main flux does not give a correct measure of this flux. Strictly speaking, that is true, but for this test, it was desirable to obtain a separation of the so-called primary and secondary leakage fluxes. Tests have been made since this paper was written in which I have found, as Mr. Clem stated, several values depending on the location of the tertiary coil. The choice of location of the tertiary coil would not change the final result as outlined in the paper unless placed very close to either the primary or secondary windings.

The possibility of finding the leakage flux in the outer laminations as suggested by Mr. Alger introduces some interesting possibilities. Using the same test core, four belt coils of 40 turns each were wound around equal sections of the core under the middle of coils 7 and 8 shown in Fig. 3 of the paper. To provide sufficient space between laminations for the 80 wires of two adjacent coils it was necessary to separate the laminations 0.03 in. (0.79 mm.). This separation was made only at the point where the coils passed through the core. This arrangement, of course, introduced considerable reluctance in a transverse direction which a core tightly clamped would not have, but does, to some degree, represent the condition in a core where ventilating ducts are used.

The belt coils were numbered 9, 10, 11 and 12, 9 and 12 being on the outside. The procedure followed in making the tests was the same as that described in the paper. Coils 20 and 21 were used as the primary, all tests being made with transformer coils 7 and 8 as the secondary. The first test at no load showed a flux density of 4640 lines in the outer section under belt coil 9, and 4810 in the inner section under coil 10. The oscillograms which were taken all show the same displacement of the belt coil currents with respect to the impressed voltage. This result means that the flux at no load is evenly distributed across the core under the secondary.

With coils 7 and 8 short-circuited and 4 amperes flowing through the windings, a very different result is found. The results are given in the table, the nomenclature being the same as that used in the paper.

Impedance Conditions

Calculated			Belt Coil Tests		
Voltage	B_{max}	Degrees displacement	Belt coil no.	B_{max}	Corrected* angle
E'_p	2790	3.7 lead	9	900	151 lag
E_m	1190	7.5 lag	10	480	6 lag
$I_s X_s$	1100	169.3 lag	11	560	8 lag
E'_s	280	79.2 lag	12	790	152 lag

*The corrected angles are measured on the oscillograms and diminished by the angle found under no load conditions.

Combining the belt coil fluxes, with their respective angles taken into account, gives an average density over the entire core of 260 lines per sq. cm. with a lag angle of 115 deg. In magnitude this corresponds closely to the value of flux required to induce sufficient voltage to overcome the $I R$ drop in the secondary. The phase position does not check very closely.

Considering the position of the belt coil fluxes, it is plain that considerable leakage flux is to be found in the outer laminations, but after all in this particular case such flux is less than 1/3 of the total secondary so-called leakage flux. In the two middle belt coils a flux is found which corresponds to the so-called mutual or main flux in phase position but of less than 1/2 the calculated density. Since the main flux density is calculated on the entire area of the core, something less than 1/4 of the main flux is found.

That some flux due to the secondary and primary turns should be found in the outer laminations is only to be expected when the reluctance of the path perpendicular to the plane of the laminations is taken into account together with the high m.m.f. acting when the transformer is operating under load. In the case of a core with ventilating ducts high flux densities may be found under loaded coils which will tend to change the losses from those calculated assuming a uniform density across the entire core.

Alfred Still: In order to avoid the confusion of ideas which is likely to arise when the various components of the total flux are represented as occupying the same portion of the iron core, the vector diagram for a loaded transformer may be drawn as in Fig. 1.

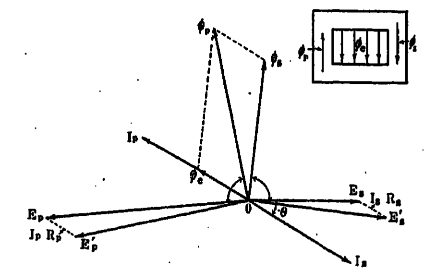

FIG. 1

Owing to magnetic leakage, the flux will not be the same at all sections of the iron core, and it is not possible to represent correctly the flux conditions in the transformer without abandoning the idea of each unit line or tube of induction being closed upon itself. In the sketch of the simple transformer shown in Fig. 1, the lines marked Φ_l represent the leakage flux while Φ_p and Φ_s stand for the fluxes which link with the primary and secondary windings respectively. The arrow-points indicate what will be considered the positive direction of these fluxes. It is then always true that the flux Φ_p is equal to the (vectorial) addition of the fluxes Φ_s and Φ_l, or,

$$\Phi_p = \Phi_s + \Phi_l$$

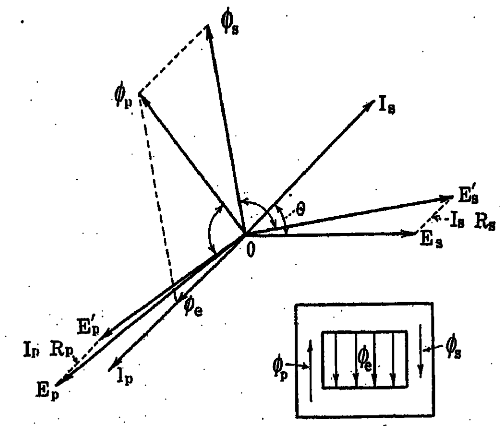

FIG. 2

On the assumption that the magnetizing component of the current is negligible and that the winding ratio is 1 to 1, the vector diagram may be constructed as follows:

Draw $O E_s$ and $O I_s$ to represent the (known) secondary terminal voltage and current with the angle θ between them corresponding to a load power factor of cos θ. The other vectors are drawn in the following order:

$E_s E_s'$, parallel to $O I_s$ and of the proper length to represent the ohmic drop of $I_s R_s$ volts in the secondary windings.

$O E_s'$, the e. m. f. which must be induced in the secondary windings.

$O \Phi_s$, drawn 90 deg. in advance of E_s', is the flux which links with the secondary windings.

$O\,I_p$, equal and opposite to I_s, is the primary current.

$O\,\Phi_l$, in phase with I_p is the leakage flux.

$O\,\Phi_p$, the resultant obtained by the vectorial addition of Φ_s and Φ_l is the flux which links with the primary windings.

$O\,E_p'$, drawn 90 deg. in advance of Φ_p, is the component of the impressed primary e. m. f. necessary to balance the e. m. f. induced in the primary windings by the flux Φ_p.

$E_p'\,E_p$, parallel to I_p and of the proper length to represent to ohmic drop of $I_p\,R_p$ volts in the primary windings.

$O\,E_p$, the voltage which must be impressed at primary terminals to produce the secondary load conditions which have been assumed.

In Fig. 2, exactly the same procedure has been followed in drawing the vector diagram for a transformer with a capacity **load.**

Waldo V. Lyon (by letter): The distribution of magnetic flux and its division into the so-called mutual and leakage components is so important a subject to the student of electrical engineering that it is well for the teacher to examine his ideas occasionally and see if there may not be some new point of view from which the explanation of the phenomena will be clearer and more in accord with physical realities. This paper and its discussion have been interesting, but some dogmatic statements have been made which were occasioned, I believe, by a too narrow regard of the problem. Furthermore, some interesting points have not been mentioned. I am sure that all who have discussed the paper will agree that they did not attempt to state new facts, but merely used an unusual method of explaining well known phenomena.

It is well to keep in mind that vector diagrams postulate currents and potentials which vary sinusoidally, a condition that is never exactly reached in a commercial power and lighting transformers. For example, there may be third harmonic component in the full-load primary current of 3 per cent., or in another arrangement, the terminal potential of the primary may contain a third harmonic which is 40 per cent of the fundamental. These harmonics in current and potential are due wholly to the operating characteristics of the transformer. Many calculations are sufficiently accurate, however, if the presence of harmonics is entirely neglected and it is customary to neglect them.

In analyzing electric machinery there is no more powerful method of attack than to resolve the quantities considered into components, and to calculate each component and its effect separately. It is, in fact, often much easier to picture the components than the actual physical condition they represent. The components, however, often have no other existence than in the imagination and I believe it is essential to keep this fact before the student constantly. From a physical standpoint, perhaps the most fundamental method of analyzing the operation of a transformer is that which equates the fall in potential across each winding to the sum of the resistance drop, the drop due to self inductance and that due to mutual inductance. Since inductances vary with the condition of the magnetic circuit, it is necessary to measure or to calculate them for the same condition that exists in the transformer while it is operating. Strictly speaking they are variable, being functions of the actual condition of the magnetic circuit. Although this method is fundamentally correct it is not as convenient to apply as that commonly employed which uses leakage inductances.

In electric machinery, when we can safely neglect all capacitance effects, there are but two sorts of electric potential that we need ordinarily consider, viz: one that is proportional to the current, the $I\,R$ drop, and the other that is proportional to the rate of change of flux linkages, $\frac{d}{d_2}\,(N\phi)$. The latter is sometimes carelessly written as $N\,\frac{d\,\phi}{d\,t}$, which is, strictly speaking, always incorrect except in those cases in which every tube of a component of flux links every turn. When these flux linkages are due to the current in a transmission line, or in a reactance coil, or when they are due to the so-called leakage flux in a transformer the electromotive force produced by their rate of change is most frequently called a reactance drop. Is it not probable that this term is an extension of the idea of resistance drop in direct-current circuits? In commercial electric circuits the alternating currents are most frequently lagging ones and the effect of these flux linkages is to produce an actual fall in electric pressure just as resistance does in direct-current circuits. The one difference is that in the alternating-current case the subtraction is vectorial. If, however, the alternating current is a leading one the effect of these flux linkages may actually produce a rise in potential, and so it seems that in this case the term drop loses some of its significance. The real physical fact is that a change in flux linkages produces an electromotive force in the circuit, the nature of which does not depend in the slightest upon what is the cause of the flux linkages, whether it be the current in the circuit itself or that in some neighboring circuit. It hardly seems consistent always to refer to the electromotive force that is due to the rate of change of certain flux linkages as a drop in potential and to that which is due to another portion of the flux linkages as a generated electromotive force, meaning a rise in potential. Especially is this so since it is often difficult to distinguish between the two portions of the flux linkages.

The important point that has been brought out in this paper is that the actual generated electromotive force in a transformer is the vector difference between the pressure at the terminals and the resistance drop. The difference is always taken so that the generated electromotive force is greater than the terminal pressure when the winding is delivering electric energy. This of course follows from the assumption that the only sources of potential are due to the rate of change of flux linkages and to the electric resistance of the circuit. For the sake of simplicity consider a transformer that has the same number of primary and secondary turns. When operating under load the magnitudes and relative phases of the primary and secondary terminal pressures and currents can be measured. The net generated electromotive forces in each winding may then be calculated by properly deducting the resistance drops. The vector difference between these generated electromotive forces is due to the difference between the primary and secondary flux linkages and is thus the measure of the leakage in the transformer. The leakage fluxes may actually link either the primary or the secondary or the primary and the secondary, depending upon the arrangement of the windings, the power factor of the load, and the moment in the cycle that is chosen. No statement short of this is general.

Leakage fluxes are those which exist at least partly outside of the magnetic core. The flux that is confined wholly to the core links every turn of both windings. The leakage fluxes on the other hand may link a portion of either or of both windings. The effect of the leakage flux in producing electromotive force depends upon the number of turns with which it links so that the term leakage flux is less useful than leakage flux linkages. If the windings have the same number of turns the total leakage flux linkages are the difference between the primary and secondary flux linkages. Since we are dealing with assumed sinusoidal quantities this difference is taken in a vector sense. The calculation of the primary and secondary leakage flux linkages based on sound physical theory is a difficult problem, and as far as I am aware has never been done.

The actual paths of the flux outside of the magnetic core change from moment to moment during the cycle since they depend upon the relative instantaneous strengths of the primary and secondary currents. It seems to have been assumed by Mr. McEachron and some who discussed the paper that the

magnetic flux in the core is always in the same direction in which the primary would produce it, and therefore opposite to the flux which the secondary would of itself produce. This is always true during some portion of the cycle. It is only true during the entire cycle when the power factor of the load on the secondary is approximately equal to the power factor of the transformer at no load. It is true during the major portion of the cycle with highly inductive loads, but with a highly condensive load the magnetization of the core is in the same direction that the secondary would alone produce it during a major

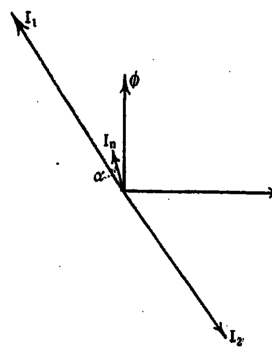

FIG. 1

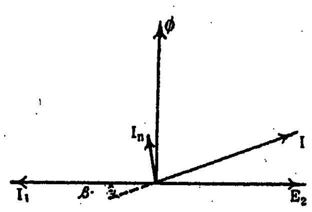

FIG. 2

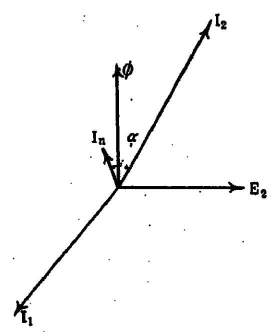

FIG. 3

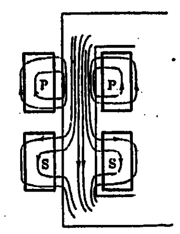

FIG. 4

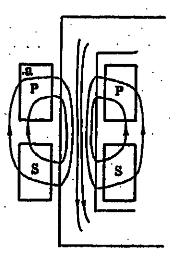

FIG. 5

portion of the cycle. This is illustrated in the vector diagrams 1, 2 and 3. It must be remembered that it is only by courtesy that the flux in the core and the net exciting current, I_n, can both be represented by vectors. Fig. 1 shows the condition with a highly inductive load on the secondary. Except during a brief portion of the cycle, determined by α, the magnetizing effects of the primary current, I_1, and the net magnetizing current, I_n, are in the same direction and opposed to the secondary current Thus during a major portion of the cycle the distribution of flux may be represented as in Fig. 4. If the load is condensive the primary and secondary currents may be equal as shown in Fig. 2. During a brief interval, determined by β, the currents will magnetize the core in the same direction. During the remainder of the cycle the magnetization of the core will be in the direction in which the primary alone would produce it but one-half of the time. For an equal portion of the cycle the magnetization of the core will be in the direction in which the secondary would produce it. Figs. 5 and 6 show the condition at the moment that the primary and secondary currents are equal and in the same direction. If the windings are symmetrically situated with respect to each other and with respect to the core as indicated in Fig. 5, the flux linkages for the primary and secondary will be the same at the moment when the currents are equal and in the same direction. That is, at this moment there will be no leakage flux linkages. On the other hand, if the windings are arranged as indicated in Fig. 6, the winding nearer the core will probably have the greater flux linkages, whether it be primary or secondary. Fig. 7 shows the condition that will exist at the moment that the mutual flux linkages are passing

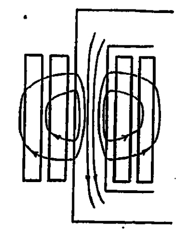

FIG. 6

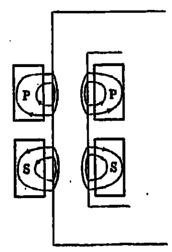

FIG. 7

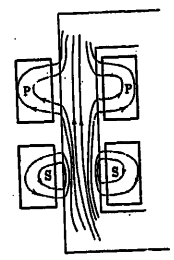

FIG. 8

through the zero. The primary and secondary currents are then essentially equal and opposite in their magnetizing effect. Both the primary and the secondary have actual leakage flux linkage as indicated. Fig. 3 shows the vector diagram for the transformer when supplying a highly condensive load. Except for the portion of the cycle determined by α the magnetization of the core is in the direction in which the secondary alone would produce it. Thus during a major portion of the cycle the flux is distributed as indicated in Fig. 8. There is actual secondary leakage but no pirmary leakage.

There is one other point of passing interest. It is that while the flux in the magnetic core is essentially a pulsating one, the flux within the body of the primary and secondary windings is a rotating one. For example, the magnetic fields at the point a in Fig. 5 due to the primary and secondary currents are not in the same direction since the point is not symmetrically located with respect to the windings. The currents are also displaced slightly in time phase. This condition of space and time phase displacement is all that is necessary to produce a rotating field. This field will of course be very decidedly elliptical.

Air-Break Magnetic Blow-Outs

For Contactors and Circuit Breakers Both A-C. and D-C.

BY J. F. TRITLE
Associate, A. I. E. E.
General Electric Company, Schenectady, N. Y.

Review of the Subject.—Magnetic blow-outs have been used in contactors, circuit breakers and controllers for many years for rupturing both a-c. and d-c. power circuits, but their commercial use, particularly on alternating current has been largely confined to relatively low voltages. Oil circuit breakers and switches have been generally used for rupturing high-voltage a-c. power circuits, and their development has reached a high state of perfection. The air break has the advantage of avoiding the possibilities which attend the use of any inflammable material—like oil, with its possible gasification and explosion on heavy short circuits.

While there are many different types of magnetic blow-outs this paper deals largely with the "individual" type, in which a blow-out coil is connected in series with each pair of current-rupturing contacts, since it is with this type that most of the progress and studies have been made in recent years.

Contactors and circuit breakers with the "individual" type of blow-out are now used almost exclusively in the main d-c. power circuits of the 1500 and 3000-volt d-c. railway systems. Oil circuit breakers have been tried for this service, but they are rather unsatisfactory because there is no periodic zero point in the current wave at which the oil can form an insulating seal between contacts. The oil under d-c. arc conditions carbonizes rapidly and involves the possible danger from explosive gases.

Recently the use of magnetic blow-out contactors on a-c. circuits has been extended to moderately high voltage and capacity. Short-circuit tests on a 6600-volt, 26,700-kv-a. alternator are described towards the end of the paper. During these three-phase tests the air-break magnetic blow-out contactors successfully ruptured 17,500 amperes, the full short-circuit current, at 5500 volts. This is 170,000 kv-a., three-phase. The maximum asymmetrical peak current through the contacts during this test was 67,500 amperes, but during a 2500-volt short-circuit test this peak current reached 80,000 amperes. Oscillograph records of the voltage and current in each phase are shown and also illustrations of the arcs.

The contactors used were rated at 5000 volts, 3000 amperes, but they successfully ruptured a circuit of 9000 volts, 3500 amperes. The oscillographic records and illustrations of this test are shown in Figs. 25 and 26. Current-rupturing tests at 2300 amperes and 3500 amperes normal voltage arc also shown for comparison in Figs. 22 to 24. In all of the tests the circuit was ruptured within the first half cycle after the tips started to part, indicating the effectiveness of this type of blow-out.

The arrangement of the current-carrying and magnetic blow-out parts are shown in Fig. 15. The main current is carried through solid copper contacts mounted at the back. The auxiliary contacts in the arc chute and the blow-out coils carry current only during the time the circuit is being ruptured. These coils with their attending arcing horns are cut into the circuit in succession, so as to obtain the strongest possible final magnetic field without undue arcing at the contact tips and across the terminals of the coils when they are introduced into the circuit. Several arc suppressor plates are provided in each half of the arc chute which increases the cooling surface, and on heavy short circuits split the arc into a number of multiple paths. See Fig. 10.

A brief description is given in the first part of the paper of a typical form of the "individual" type magnetic blow-out as used in contactors and circuit breakers, and photographs of a number of contactors for various a-c. and d-c. voltages are reproduced. Attention is directed to the tests with accompanying illustrations of successive positions of the arc in the chute taken with a high-speed camera, from which some interesting data were obtained on arc characteristics. The arc was photographed in its movement every three-thousands of a second. The time between pictures in the familiar motion picture camera is sixty-two-thousandths of a second. These tests bring out the effectiveness, in rupturing the circuit of the arc suppressor plates and narrow arc chutes.

CONTENTS

Theory of the Magnetic Blow-out

It is a well-known fact that when a conductor of length l carries a current of i amperes in a magnetic field of density of B maxwells per square centimeter, the force F in kg. per centimeter length tending to move the conductor across the field is

$$F = 10.2\, B\, i\, l\, 10^{-8} \text{ kg.}$$

In the same way, when an arc forms between switch contacts which open in a magnetic field, the resulting arc stream will be subjected to the above force and will move across the field and lengthen until the voltage between the contacts is no longer able to maintain a current flow and the circuit is ruptured. It is the function of the magnetic blow-out, which is essentially an electromagnet, to set up the magnetic field over the area within which it is desired to rupture the circuit. To be most effective the direction of the lines of force in the field should be perpendicular to the axis of the arc stream.

The direction of movement of the arc stream is the same as for a conductor moving in a magnetic field, and may be readily determined by Fleming's rules or by the right-hand screw rule. In common with flexible conductors, the arc stream always moves, and in addi-

Presented at the Spring Convention of the A. I. E. E. Chicago, Ill., April 19-21, 1922.

tion lengthens, so as to include the maximum number of ines of force. The blow-out coil must, therefore, be

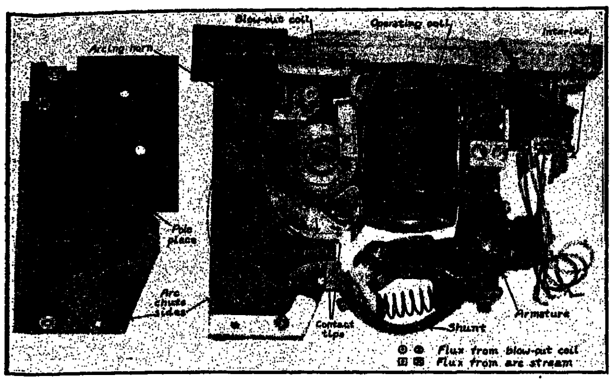

FIG. 1—600 VOLT ARMATURE TYPE RAILWAY CONTACTOR

Part of arc chute is removed and placed to one side more clearly to illustrate the magnetic blow-out. When current flows in blow-out coil as indicated by arrow the flux through the core in the blow-out coil is away from reader as indicated by a cross in a circle. This flux returns through arc chute area towards reader as indicated by a dot in a circle. When the contact tips open the arc stream (1) forms and the flux encircling this arc stream strengthens the blow-out flux at the back as indicated by a dot in a circle and a dot in a rectangle and weakens it in front as indicated by a dot in a circle and a cross in a rectangle. As the arc stream always moves from the strong towards the weak field, it will move from position 1 through positions 2 and 3, etc., until the circuit is ruptured.

wound in such a direction that its flux strengthens the flux encircling the arc stream in the rear of the moving arc stream and consequently weakens it in the front.

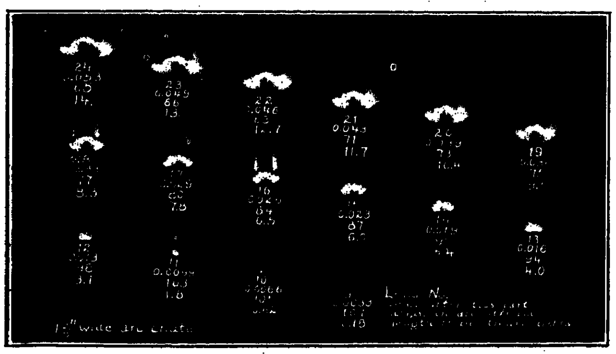

FIG. 2

Sixteen successive photographs of arc streams taken with a high-speed camera having twenty-four lenses arranged on four slanting rows of six each. In this figure the arc was ruptured 0.06 sec. after the last exposure. The lenses were uncovered in succession by a single focal plane shutter which moved across the plate at such a speed as to expose each point of the arc chute approximately 0.0016 sec. The time between pictures is approximately 0.00328 sec. The successive pictures bring out in particular the changes in the arc stream during a time interval of 0.00328 sec. The delineations on the original films were sufficiently distinct so that the length of arc in each picture could be measured. This length, together with the arc stream current and the time after the contactor tips parted, are indicated for each picture. The inside dimensions of the blow-out coil which can be seen in Figs. 4 and 5 were approximately 10 in. by 21 in. Only the inside area of this blow-out coil was effective in lengthening the arc as the flux is in the wrong direction on the outside of the coil. The maximum length of the arc within the blow-out coil was approximately 35 in.

The circuit was high in inductance. There were five d-c. motor fields in series. Width of chute 1 3/8 in., current about 100 amperes, voltage 650 d-c. This figure is to be compared to Fig. 3 in which the arc chute was 3/8 in. wide.

Fig. 1 shows a typical 600-volt railway contactor having the "individual" type of blow-out, which illustrates the above points. One side of the arc chute is removed to show more clearly the general arrangement of parts. Arrows indicate an assumed direction of current flow through the current-carrying parts and the direction of the resultant lines of force are indicatd by the conventional signs. It will be noted that the direction of the flux in the iron core of the blow-out coil is away from the

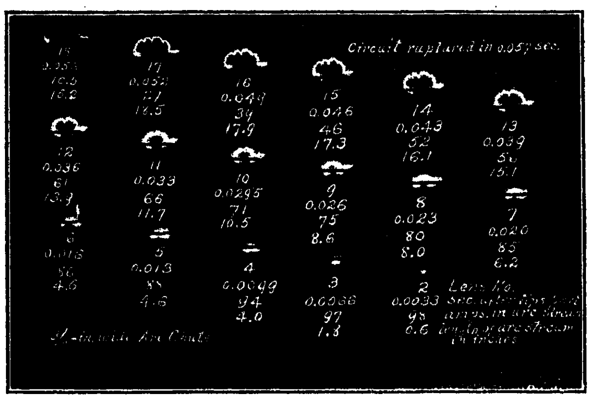

FIG. 3

Sixteen successive photographs of the arc stream taken with a high-speed camera (see details of camera in caption of Fig. 2). Conditions: Same as in Fig. 2 except that the width of arc chute is now 3/8 in. whereas in Fig. 2 it was 1 3/8 in.

reader. This flux, after being distributed by the iron pole pieces returns through the arc chute area, strengthening the flux encircling the arc stream at the back and weakening it in front causing the arc to be moved successively through positions 1, 2, 3 until the circuit is ruptured. If the direction of current is reversed through the contactor, the direction of all lines of force will also be reversed, so that the blow-out flux

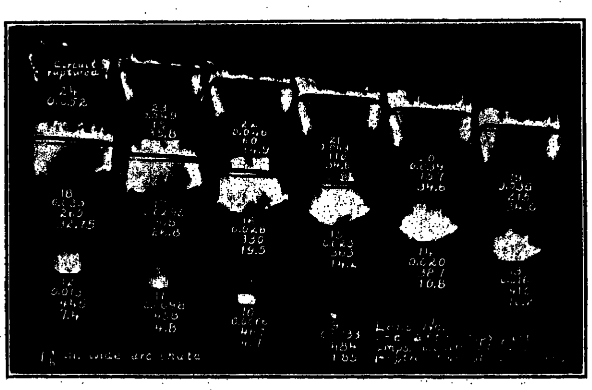

FIG. 4

Sixteen successive photographs of the arc stream, taken with a high-speed camera (see details of the camera in the caption of Fig. 2). Conditions: The current now is 500 amperes where it was only 100 amperes in Fig. 2. The arc chute width is 1 3/8 in. This figure is to be compared with Fig. 2 for the effect of variation in current, and with Fig. 5, of the same value of current of 500 amperes, for the effect of the decrease in arc chute width.

will still strengthen the field back of the arc stream, causing the arc to be moved through positions 1, 2, 3 as before. The arc chute sides which are made of arc-resisting insulation, help to cool the arc and maintain the axis of the arc stream perpendicular to the blow-out flux.

ARC CHARACTERISTICS

Some very interesting studies of arc stream characteristics were made some time ago by Mr. F. O. McMillan under the writer's general direction. Figs. 2, 3, 4 and 5 show representative illustrations taken by a high-speed camera invented by Mr. Chester Lichtenberg. This camera has 24 lenses arranged in four slanting rows of six each. The lenses are all served by a single focal plane shutter which first uncovers the lens in the lower right hand corner then the next lens to the left across the bottom row, and so on through the other rows, each row starting at the right. The speed of the shutter was adjusted so that the time interval between each picture was 0.00328 second, and each point of the arc stream was exposed approximately 0.0016 second. In order to photograph the arc, one of the arc chute sides was made of glass, and special blow-out coils were wound giving an approximately uniform flux within the area in which it was desired to rupture the circuit. Oscillographic records were taken of the current and voltage of the circuit, simultaneously with the high-speed photographs. Fig. 6, gives curves plotted from these records, which show the complete arc characteristics when rupturing a 500-ampere, 650-volt inductive circuit in an arc chute ⅜ in wide under the influence of a magnetic blow-out giving a flux density of approximately 2.5 lines per square inch per ampere.

The illustrations in Figs. 2, 3, 4 and 5 bring out in particular the changes in the arc stream during a time interval of 0.00328 second, when rupturing an inductive circuit at currents ranging from 100 to 500 amperes at 650 volts. A summary of the corresponding time characteristics of the arc are plotted in Fig. 7.

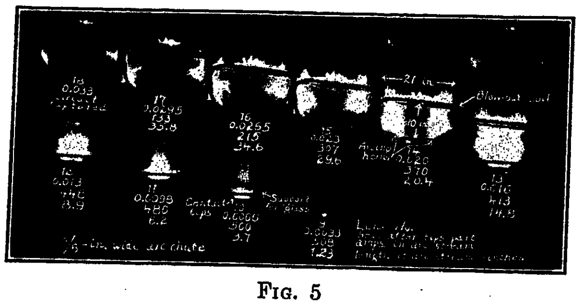

FIG. 5

Ten successive photographs of the arc stream taken with a high-speed camera (see details of the camera in the caption of Fig. 2). Conditions: Same as Fig. 4 except that the arc chute width is now only 3/8 in. where it was 1 3/8 in. in the case of Fig. 4. The current is again 500 amperes. To compare the effects of currents at 500 amperes and 100 amperes refer to Fig. 3, which has the same width of arc chute as Fig. 5.

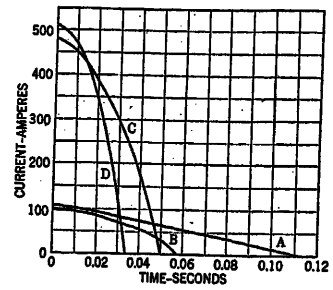

FIG. 7—FOUR CURVES OF TIME VS. CURRENT OF ARCS IN FIGS. 2, 3, 4 AND 5, RESPECTIVELY

Curve *A* corresponds to arc stream in Fig. 2, *B* to Fig. 3 *C* to Fig. 4 and *D* to Fig. 5. The width of arc chute for curves *A* and *C* was 1 3/8 in. and for *B* and *D* 3/8 in. These curves are intended to illustrate the effectiveness of both narrow slots and suppressor plates in the arc chutes. See Fig. 10.

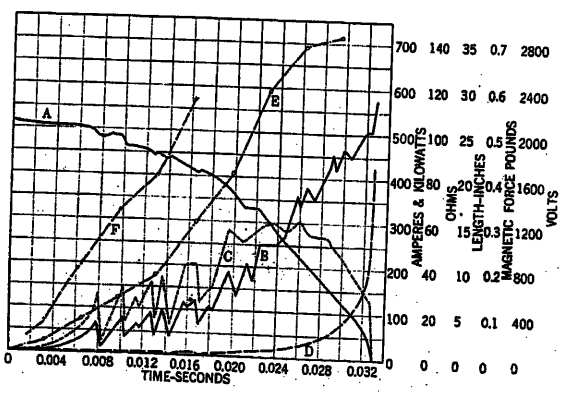

FIG. 6—ARC CHARACTERISTICS

The data for these six curves were obtained from oscillographic records taken in connection with the current-rupturing test recorded in Fig. 5. The width of arc chute was 3/8 in. and the flux density approximately 2.5 lines per square inch per ampere.

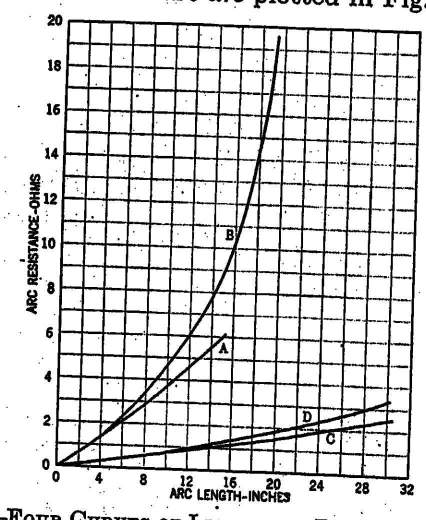

FIG. 8—FOUR CURVES OF LENGTH VS. RESISTANCE OF ARCS IN FIGS. 2, 3, 4 AND 5, RESPECTIVELY

Curve *A* corresponds to arc stream in Fig. 2, *B* to Fig. 3, *C* to Fig. 4 and *D* to Fig. 5. The width of arc chute for curves *A* and *C* was 1 3/8 in. and for *B* and *D* 3/8 in.

THE NARROW ARC CHUTE

Attention is directed to a comparison of Curves *A* and *B* and of *C* and *D* of Fig. 7. The conditions under which the two sets were taken were the same, except the width of the arc chute for curves *A* and *C* was 1⅜ in. and for *B* and *D*, ⅜ in. The narrow arc chute is a recent development and has contributed very mate-

rially towards the successful rupturing of high-capacity a-c. and d-c. power circuits.

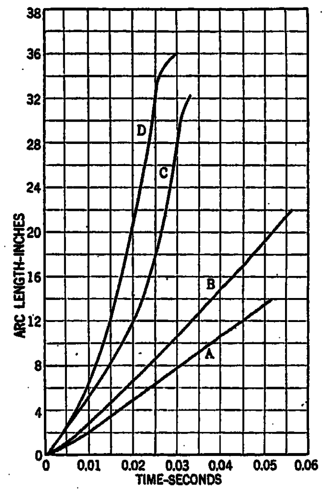

FIG. 9—FOUR CURVES OF TIME VS. LENGTH OF ARCS IN FIGS. 2, 3, 4 AND 5, RESPECTIVELY

Curve *A* corresponds to arc stream in Fig. 2, *B* to Fig. 3, *C* to Fig. 4 and *D* to Fig. 5. The width of arc chute for curves *A* and *C* wa 1 3/8 in. and for *B* and *D* 3/8 in.

The effect of the narrow arc chute is usually obtained by adding one or more arc suppressor plates to the standard arc chute. This gives a number of multiple

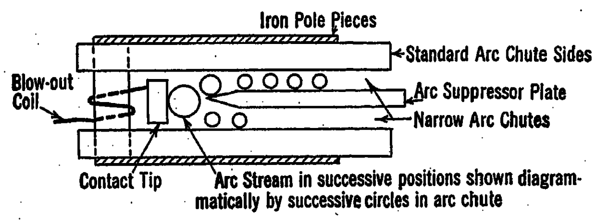

FIG. 10—SKETCH OF THE NARROW ARC CHUTE

paths or slots for the arc. See Fig. 10. Each slot is in the plane of movement of the switch contacts and the exit is materially narrower than the width

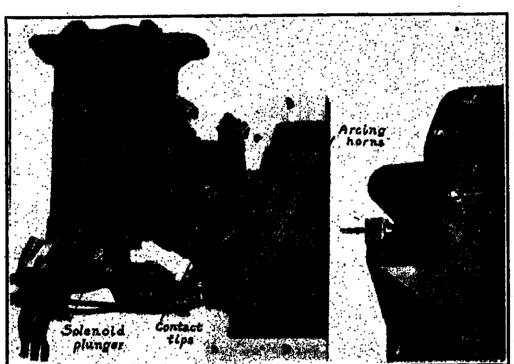

FIG. 11—600-VOLT, 425-AMPERE D-C. PLUNGER TYPE RAILWAY CONTACTOR

Part of arc chute removed and placed to one side more clearly to show contact tips and arcing horns.

of the switch contacts and the space within which the arc is formed. These slots reduce the cross section of the arc stream and serve to increase the resistance for a given length. The arc suppressor plates provide additional cooling surface to the arc, and maintain the axis of the arc stream perpendicular to the blow-out flux. In wide arc chutes, the arc stream has a tendency to wander from one side of the chute to the

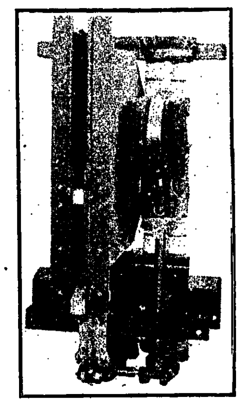

FIG. 12—3000-VOLT, 215 AMPERE D-C. CONTACTOR

Two units are used in series for 3000 volts. One arc chute removed to show parts.

other so that at times its axis is nearly parallel to the blow-out flux.

It will be noted in both tests where the narrow arc chute was used, the circuit was ruptured in approximately one-half the time of the tests where the wider arc chute was used. This approximate ratio has been found to hold for much higher currents and voltages. The reduction in cross section and quicker opening

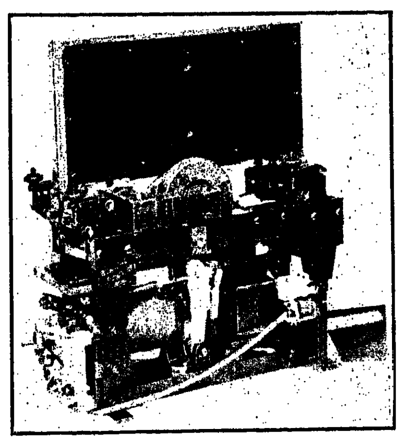

FIG. 13—HIGH-SPEED CIRCUIT BREAKER

is plainly evident from a comparison of the time and current printed under each arc stream in Figs. 2 and 3. The narrow chute is particularly effective in connection with high-speed direct-current circuit breakers where it is desirable to rupture the circuit in a few thousandths of a second.

Fig. 8 shows the relation between arc resistance and arc length for both the wide and narrow arc chutes, and Fig. 9 shows the rapidity with which the arc

lengthened under the influence of the magnetic blow-out in both widths of the chutes.

In making the above tests on arc chracteristics, it

Contactor may be closed either manually, by means of the cam shaft, or electromagnetically by means of the solenoid.

was not possible to rupture very large amounts of power on account of the danger of breaking the glass arc-chute side used for taking the photographs. Current rupturing tests have been made, however, with mag-

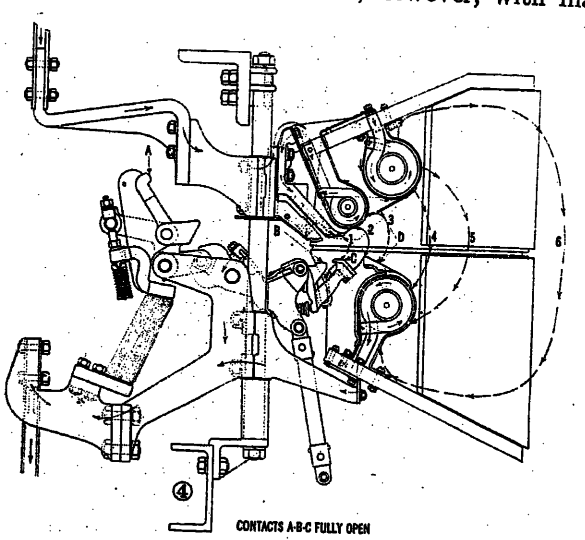

FIG. 15—5000-VOLT, 3000-AMPERE A-C. CONTACTOR (OPEN)

This contactor was developed primarily for controlling the main motor circuits of the new 180,000-horse power Battle Cruisers for the U. S. Government. Very exhaustive tests were made before and after the final designs were completed. The results amply met expectations as to the suitability of this type of contactor, not only for ship propulsion, but also for power station service.

netic blow-out air-break contactors up to 6000 volts d-c. and 9000 volts a-c. and the indications are that still higher voltages can easily be ruptured successfully.

TYPICAL A-C. AND D-C. CONTACTORS

Figs. 11, 12, 13, 14 and 15 show some typical forms of a-c. and d-c. contactors and circuit breakers for various voltages on which tests and data are presented in this paper.

FLUX DENSITY IN ARC CHUTES

Fig. 16 shows the average flux density curves in the arc chute of typical 600-volt and 3000-volt contactors

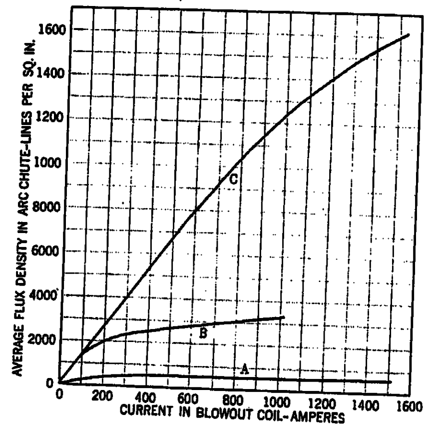

FIG. 16—ARC CHUTE FLUX DENSITY VS. CURRENT IN BLOW-OUT COIL

Curve *A*—For 600-volt, 425-ampere contactor.

Curve *C*—For 3000-volt high-speed circuit breaker.

and also of a 3000-volt high-speed circuit breaker. It will be noted that a much higher flux density is used for the 3000-volt contactors and circuit breaker than for the 600-volt contactor. Many tests and experiments have been made to determine the correct flux density for each type; but the inductance, particularly of railway circuits is so variable that it is difficult to

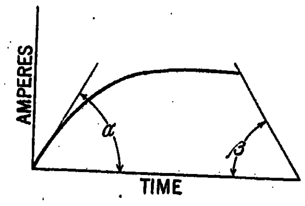

FIG. 17—THEORETICAL CURRENT-RUPTURING TEST

Curve showing current decrement to give best average results when opening a circuit. Angle β should be approximately equal to angle α so that the inductive voltage when opening the circuit will not exceed the line voltage.

select a flux density to best suit all conditions. In general, a flux density in the arc chute which will cause the current to be reduced at a *rate approximately equal to the initial rate of rise when normal voltage is applied to the circuit,* appears to give about the best average result. See Fig. 17. If the flux density in a particular design is too high, the voltage across the arc increases beyond the breakdown point of the insulation of the arc chute sides and the arc reestablishes a number of times as clearly shown by Fig. 18. Curve *A* of this figure shows the rupture of a 600-volt, 1500-ampere inductive circuit by a magnetic blow-out in which the average flux density in the arc chute at

1500 amperes was approximately 600 lines per sq. in., and Curve *C* approximately the same current and voltage under the influence of a blow-out of approximately 1500 lines per sq. in. Due to the reestablishments it

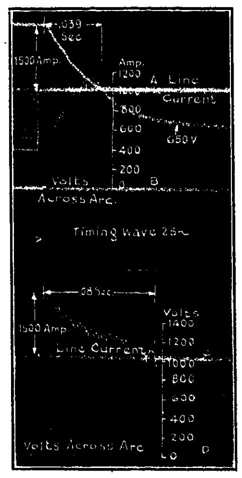

FIG. 18—OSCILLOGRAPHIC RECORDS OF CURRENT-RUPTURING TESTS

Illustrating the effect of high and low flux densities in the arc chute. Two motor fields were used in series for reactance.

The flux density in the arc chute of the contactor used when rupturing the current shown by Curve *C* was too high for this particular design, being approximately three times that of the contactor when rupturing the current shown by Curve *A*. The current and voltage fluctuations of the arc are very marked on Curves *C* and *D* while there are practically no sudden fluctuations of current and voltage where the low flux density was used as shown by the two upper curves *A* and *B*.

required more than twice the time to rupture the circuit with the blow-out giving the stronger magnetic field. The shape of the arcing horns and the size of the arc chute have a material bearing, however, and by properly proportioning these parts, relatively high

3000-volt, high-speed circuit breaker of the type shown in Fig. 13. The average flux density in the arc chute in the neighborhood of the contact tips of a typical high-speed circuit breaker is shown by Curve *C* of Fig. 16.

CURRENT RUPTURING TESTS AT 6000 VOLTS D-C.

Curves *A* and *B* of Fig. 21 are plotted from oscillograph records of current-rupturing tests on a 6000-volt

250-ampere, d-c. contactor. In the test represented by Curve *B* practically no external inductance was used in the circuit while in the tests represented by Curve *A* the fields of 11 railway motors were used in series in the circuit.

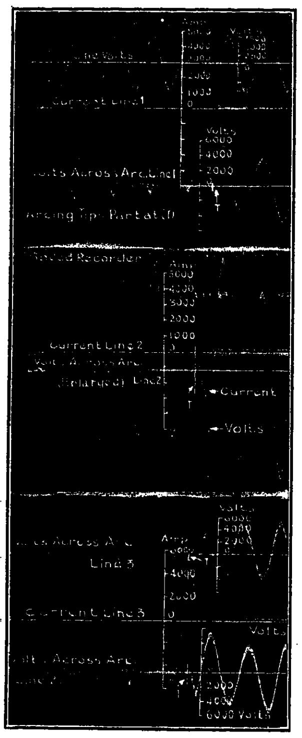

Fig. 22—Oscillographic Records of a 5000-Volt 3500-Ampere, Three-Phase, 25-Cycle Current-Rupturing Test

One contactor as shown in Fig. 15 was connected in each phase. Line voltage initial 5700 volts, under load 5000 volts. First cycle after opening 5280 volts. Line current 3630 amperes effective. External resistance 0.683 ohm per phase. External reactance 0.197 ohm per phase.

Three separate oscillograms operating in synchronism were used for this test, each oscillogram having records of three vibrators. The vibrators in the upper oscillogram are numbered 1, 2 and 3, in the middle oscillogram 4, 5 and 6, and in the lower oscillogram 7, 8 and 9. Vibrator No. 2 shows the current in line 1 and vibrator No. 3 shows the voltage across the terminals of the contactor in this line. Vibrator No. 5 shows the current in line 2 and vibrators No. 6 and No. 9 show the voltage across the terminals of the contactor. Vibrator No. 6 records the same voltage as vibrator No. 9, except on an enlarged scale. Vibrator No. 8 records the current in line 3 and vibrator No. 7 the voltage across the terminals of the contactor in this line.

The voltage between lines 1 and 3 is recorded by vibrator No. 1. Vibrator No. 4 gives a record of the mechanical movement of the contact tips, from which the exact instant the arcing tips parted was determined. This point is recorded on the zero line in each oscillogram by the letter *T*. The circuit was closed by a separate three-phase switch. The current continued for about 4¼ cycles before the arcing tips of the contactor started to part. As soon as the tips parted the voltage across the arc begins to rise. Within one-half cycle after the tips part the line current is reduced to zero and does not reestablish, and the voltage across the contact tips starts to adjust towards normal *Y* voltage. For schematic diagram of connections see Fig. 22*A*.

Current Rupturing Tests At 5000 Volts A-C.

Recently the possibility of using magnetic blow-out contactors for rupturing high power a-c. circuits has been recognized and the design and construction has already been completed on contactors rated up to 5000 volts. Fig. 14 shows a typical 3500-volt, 3500-ampere contactor and Fig. 15 a 5000-volt, 3000-ampere contactor, both of which are equipped with a magnetic blow-out of rather novel construction. One side of the arc chute was removed in both contactors to more clearly show the construction. The 3500-volt contactor is shown in the closed position and the 5000-volt one in the open position. It should be noted that the main current is carried through heavy copper contacts,

marked *A* in Fig. 15, which are located at the back of the contactor. There are no loops in the path of the main current-carrying parts which might tend to cause overheating on alternating current or to blow the contacts apart on heavy short circuits. The contacts *B* and *C*, located in the arc chute, carry practically no current during normal operation and consequently may be made light and inexpensive.

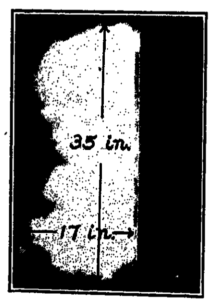

Fig. 23—Showing the Luminous Vapors of the Arc when Rupturing 5000-Volts, 3500-Amperes, A-C.

The vapors of the three phases blend in one impression on the photographic plate.

When the contactor, Fig. 15 is closed, all three sets of contacts marked *A*, *B* and *C* are in contact. As the contactor opens the tips *A* first part, transferring the main current to contacts *B* located in the arc chute. Further movement towards the open position starts contacts *B* open, transferring the current to contacts *C* and cutting the small blow-out coil at the back of the arc chute into the circuit, as indicated by the arrows. The front tips *C* part next and the arc stream marked

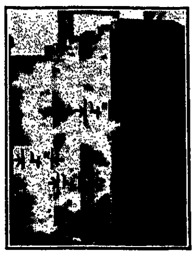

FIG. 24—SHOWING THE LUMINOUS VAPORS OF THE THREE SEPARATE ARCS WHEN RUPTURING 5000-VOLTS, 2300-AMPERES, A-C.

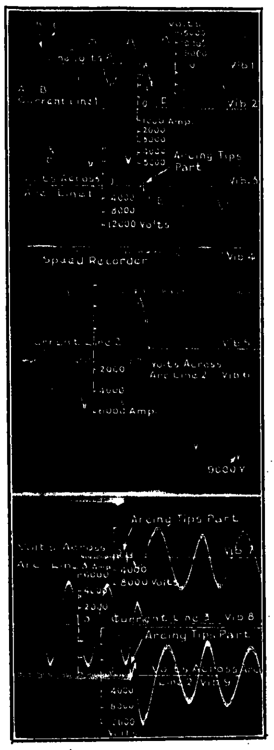

FIG. 25—OSCILLOGRAMS OF A THREE-PHASE TEST AT 25 CYCLES OF OVER-VOLTAGE BUT NORMAL CURRENT RATING

One contactor as shown in Fig. 15 was connected in each phase. Line voltage, initial 9700 volts, under load 7400 volts. First cycle after opening 8700 volts. Line current 3350 amperes effective. External resistance 1.08 ohms per phase. External reactance 0.197 ohm per phase.

The story of the oscillographic records is as follows: There are three separate oscillograms. Each oscillogram has records of three vibrators. Each of the oscillograms has a record of the normal load current and the voltage across the arc of the corresponding phase. In the upper oscillogram the load current is given for line 1 by vibrator 2 and the voltage across the arc by vibrator 3. On open circuit this is Y voltage. In the middle oscillogram the relations are the same for the load current and voltage across the arc of line 2. In the lower oscillogram the current of line 3 is given by vibrator 8 and the corresponding voltage across the arc is given by vibrator 7. In this oscillogram, vibrator 9 repeats the voltage across the arc of line 2 which is given in the oscillogram just above by vibrator 6 with a magnified scale.

Vibrator 1 of the upper oscillogram gives the voltage from line 1 to line 3 and vibrator 4 in the middle oscillogram gives a record of contacts which record the movement of several mechanical parts.

Starting with the record of normal line-to-line voltage at the point marked A in the upper oscillogram, the load current in lines 1 and 2 starts at the point marked B (shown by a sudden drop in the voltage) and the current in line 3 starts at the point marked C which causes a sudden drop again in the voltage and a corresponding change in the load current of line 1 at D. Since the neutral of the generator was not grounded, it required the closure of two contacts to start the load current and therefore there are only two disturbances in the main voltage wave. The current in line 1, vibrator 2, continues 2¼ cycles before the arcing tips part. Vibrator 3 shows the beginning of the voltage across the arc at this point. Since the current is extinguished in one-half cycle of arc, as shown by the cessation of wave in vibrator 2 at E, the voltage immediately thereafter starts in its adjustment to the normal condition of Y voltage from line to ground. This same explanation applies to the other two oscillograms of the other phases.

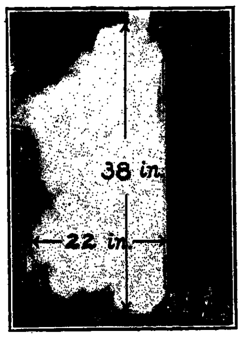

FIG. 26—EXTENT OF THE VAPORS FROM THE ARC BEYOND THE ARC CHUTE WHEN RUPTURING 9000-VOLTS, 3500-AMPERES, A-C.

The photographic plate was exposed during the whole time the gases were being expelled and the vapors from all three phases are superposed.

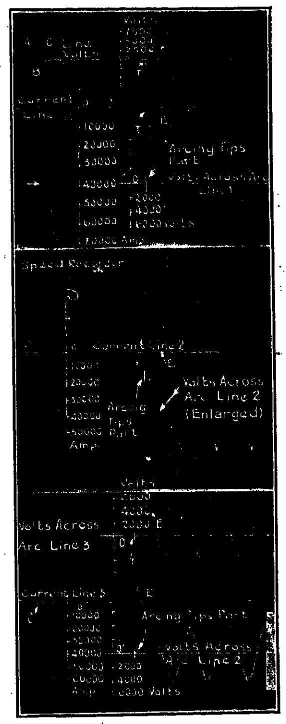

FIG. 27—5000-VOLT SHORT-CIRCUIT TEST ON 26,700 KV-A. ALTERNATOR

One contactor as shown in Fig. 15 connected in each phase. Initial open circuit voltage 5700 volts. First cycle after opening, 3980 volts. Average line current, at the instant the contactors opened 16,600 amperes effective.

The same arrangement of oscillographs and vibrators was used in this test as described in the caption under Figs. 22 and 22A. This test differs from the normal load test recorded in Fig. 22 in that the external resistance and reactance were removed from the circuit resulting in a dead short circuit on the alternator.

Referring to the record of line voltage in the upper oscillogram, there is a sudden momentary reduction in voltage at the point marked B which is due to two of the contacts of the three-phase circuit closing switch making contact ahead of the third, applying a single-phase short circuit through lines 1 and 2 for about 0.008 sec. At the point marked C on the line voltage and current waves line 3 was closed establishing the full three-phase short circuit. The short-circuit current was on the contactors for slightly more than three cycles before the arcing tips parted. The instant at which the arcing tips parted is indicated by the letter T on all three oscillograms. The circuit was completely ruptured within one-half cycle after the tips parted as evidenced by the cessation of current at the point marked E. All the voltage waves are slightly ragged during the time the circuit is being ruptured, that is between points T and E.

The current in line 1 reached the maximum possible asymmetrical value as the first cycle was displaced entirely on one side of the zero line. The maximum peak value of current in this line was 67,700 amperes. The maximum peak current in line 2 was 48,000 amperes and in line 3, 56,000 amperes. The average effective current in the three lines at the instant the tips parted was about 16,600 amperes.

1 in Fig. 15 forms between the tips. This arc stream is now under the influence of the rear blow-out coil and begins to move rapidly towards the front of the chute. When in position 2, the arc stream touches the lower arcing horn *D* introducing the lower blow-out coil in the circuit. Further movement into position 3 introduces the upper arcing horn *D* and the upper blow-out coil into the circuit. All three blow-out coils are now in series and the arc moves rapidly around the arcing horns *D* through positions 4, 5, and 6 until the arc is stretched out to a sufficient length to rupture the circuit. It will be observed that the arc chute is divided into two parts with the slot between the two halves giving an air gap to more effectively isolate the upper and lower contact tips when the contactor is open. With this arrangement, it is possible to design for a much higher voltage than would otherwise be possible, as most insulations which will stand the high temperature arc streams are usually relatively poor insulators.

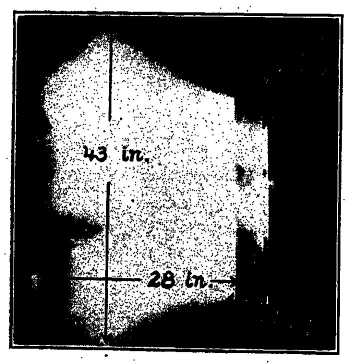

FIG. 28—SHOWING THE EXTENT OF THE LUMINOUS VAPORS BEYOND THE ARC CHUTE WHEN RUPTURING SHORT-CIRCUIT CURRENTS OF FIG. 27

As in Figs. 23 and 25, the arcs from the three phases blend in one impression on the photographic plate.

Fig. 22 shows the current and voltage phenomena in all three phases, while rupturing 3500 amperes at 5000 volts, 25 cycles, with the 5000-volt, 3000-ampere, a-c. contactors, shown in Fig. 15. Fig. 23 shows the distance the arc is visible beyond the arc chute. Fig. 24 shows the distance the arc is visible beyond the edge of chutes when rupturing 5000 volts, 2300 amperes under the same conditions. The arcs from all three contactors can be distinguished in the 2300-ampere test, but in the 3500-ampere tests the luminous vapors from the three phases blend in one impression on the photographic plate. The plates were exposed during the whole time the circuits were being ruptured so that the photographs are of value only as showing the maximum distance the luminous vapors were forced beyond the arc chutes by the magnetic blow-out. If the photographs had been taken with a very high-speed multifilm camera the results would have been more like those of Fig. 3.

Fig. 25 shows records of the same contactors, which are rated at 5000 volts, 3000 amperes, rupturing approximately 9000 volts, 3500 amperes, and Fig. 26 shows the extent of the arc. The circuit was ruptured very satisfactorily in this test and there was no evidence that the ultimate rupturing capacity of the contactors had yet been reached.

A dead short circuit on a 26,700-kv-a., 25-cycle alternator, which was very successfully ruptured by the above contactors is shown in Fig. 27. The distance the luminous vapors were forced beyond the arc chute is shown by Fig. 28. Attention is directed to the fact that the maximum asymmetrical peak current carried by the main contacts during this test was approximately 67,500 amperes and that the r. m. s. current (a-c. and d-c. components) at the instant the contactor tips started to part was 17,400 amperes for phase 1, 14,650 amperes for phase 2, and 17,800 amperes for phase 3. The current in each phase was completely ruptured within a ½ cycle after the arcing tips started to part. The fact that the current did not reestablish in the second half cycle after the tips parted indicates the effectiveness of this type of magnetic blow-out.

CONCLUSIONS

While the tests and data presented in this paper are on a-c. and d-c. current-rupturing apparatus of only moderately high-voltage rating, the fundamental principles described for the magnetic blow-outs are applicable to much higher voltages. The tests and experience indicate that we have not yet approached the limit of the alternating voltage or current which may be successfully ruptured repeatedly in the air. In fact we anticipate that within a reasonable period of time the principal of the air-break magnetic blow-out will be extended to cover applications in a-c. power circuits of the higher voltages. There is no question of the ability of the magnetic blow-out to meet the future requirements of high voltage d-c. power circuits.

Discussion

For discussion of this paper see page 282.

The Effect of High Currents on Disconnecting Switches

With Special Reference to the Mechanical Stresses Resulting

BY H. C. LOUIS and C. T. SINCLAIR

Associate, A. I. E. E.

Baltimore, Md.

Review of the Subject.—*In the early days of the electrical industry, disconnecting switches adequately performed their functions without the use of locking devices, except perhaps in a few isolated cases, where the blades opened downward, and some mechanism was provided to hold the blade in against the action of gravity (when subjected to jars, vibration, etc.). The generating capacity of central stations at this time was relatively small. Hence, the short-circuit currents obtaining were relatively low, and the forces resulting were insufficient to overcome the friction and other resistance offered by the blade and to cause opening. With the increase in generating capacity came a formidable increase in the short-circuit currents, to such an extent that it was not uncommon for a disconnecting switch to open, causing considerable damage, with consequent demoralization of operation. The result was that there were attempts made to attach locks to switches already installed, and to design new switches of which the lock was an integral part. Many of these locks were found to be inadequate, as opening occurred in many instances. In an attempt to prevent the possible recurrence of such unfortunate incidents the tests described in the following paper were planned; it was hoped thereby to improve the class of service rendered the public and safe-guard the lives of our employees.*

Specifically, it was desired in addition to a general study of the subject, to attempt to improve the locks already in use on our system and to provide locks for the switches located at dangerous points, i. e., points where short-circuit currents are likely to obtain which might open a given switch. One or more of the various types of switches in use on our system were tested, and in addition, a number of types which were considered for replacement of the obsolescent types now in use.

As a result of these tests it was possible by a very simple expedient to raise the opening point of one of our switches from about 40,000 peak amperes to 180,000 peak amperes. A very simple lock was added to another switch largely used on the system which opened at about 51,000 peak amperes so that it would withstand the mechanical forces exerted by 143,000 peak amperes.

The tests clearly demonstrated that some effective form of lock should be provided. This seems to have been generally recognized, and most manufacturers have attempted to take care of this in some way or other. Switches have been constructed (without locks) in which the current through the switch parts does not tend to open the blade. Such switches are satisfactory when used under almost ideal conditions, but certain unfavorable arrangements of the bus and leads usually found in practise, exert magnetic forces which might open the blade under short-circuit conditions, thus completely nullifying the principle of design. Although locking devices are provided they are not always effective, the various reasons being mechanical weakness of lock, current flow through lock, etc. It was noted from a study of the oscillograms that a switch seldom required more than one cycle to open, one-half cycle usually being required.

It was generally recognized that there were outward forces on the blade of a switch due to the passage of high currents; but it was not generally recognized that there were also outward forces on the jaws and insulators tending to spread them apart. These forces must be recognized and dealt with by substantial design as a number of lock failures may be attributed to this. Insulators may fail due to these outward forces, and this can be remedied only by strengthening or properly supporting the insulators.

CONTENTS

THE forces exerted by the abnormally high currents which obtain under short-circuit conditions on large power systems are often sufficient to cause disconnecting switches to open, rupture current transformers, severely injure oil switches, etc.; and the resulting damage to station apparatus is often very great, and human life is ofttimes endangered; furthermore, short circuits which should cause only voltage disturbance, or at worst, partial loss of load, may result in the total loss of load for an extended period. The following report will cover a number of tests made on disconnecting switches with the object of studying the effects of high currents on this class of apparatus. The principal points observed were:

1. The lowest value of current at which a switch blows open.

2. Time required for the switch to open; that is, duration of the short circuit.

3. Cause of the failure of lock, if such is provided on switch, and remedy for the same.

As a result of the mutual interest in such tests, the Pennsylvania Water and Power Company, and the Consolidated Gas Electric Light and Power Company, both of Baltimore, agreed to perform this work together, thus considerably diminishing the cost of an individual test by either company. Each company furnished at least one of each of its various disconnecting switches, and several manufacturers submitted their switches for test, together with several special switches. Many of the better-known makes of switches were tested, and in addition a number of more or less obsolete types.

METHOD OF TESTS

Difficulty would ordinarily be encountered in obtaining currents up to 100,000 or 150,000 peak amperes necessary for the testing of these disconnecting switches. Fortunately, the Baltimore Electro Alloys Company was able to spare one of its electric furnace transformers, which normally operates at about 40,000 effective secondary amperes. Three of these transformers

Presented at the Spring Convention of the A. I. E. E. Chicago, Ill., April 19-21, 1922.

operate in a bank on one furnace, and all three were actually available if necessary; however, one transformer was found to be ample for our tests.

These transformers are wound for 13,200 volts on the primary, the voltages on the secondary varying from about 138 to 169 (the secondary voltage is varied by changing taps on the primary). The 158- and

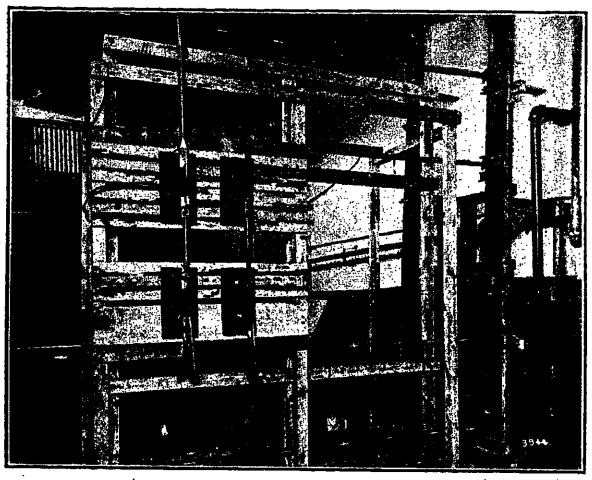

Fig. 1—Bus Structure

169-volt taps were used on these tests generally. To carry the heavy currents, and to minimize the secondary resistance, standard 8-in. by ⅜-in. cold-rolled copper bus was used. Taps were taken from the secondary of the transformer and run horizontally, as shown in Fig. 1, and then vertically downward. Taps were then taken off of the two vertical busses to the reproduced test bus described below.

In order to simulate existing conditions, a bus structure similar in dimensions to those in actual use in our stations was erected as shown in Fig. 1. The top and bottom phases only of the main and auxiliary bus were erected, as these represent the two extreme conditions. The switches were placed as shown, and tested in this position.

In some of the higher-current tests a loop was used (described later) which required the two bus leads from the transformer being run side by side separated by a ⅜-in. asbestos spacer. These two busses with their spacer were held together by heavy clamps spaced from 12 inches to 17 inches apart along the length of the parallel busses. On one of the tests in which the switch opened in one-half cycle at 141,000 peak amperes, the ⅜-in. by 8-in. copper bus actually buckled out away from the asbestos spacer about ¾ in. in the 17-in. braced section. The calculated maximum force between the axes of the busses in the 17-in. section was about 21,200 lb., applied in .01 second (¼ cycle).

The power for the short circuits was supplied by a generator at our Westport steam station of either 7500 kw. or 20,000 kw. capacity as desired, and was connected to the electric furnace transformer by means of a No. 0000, 13,000-volt, three-phase cable, involving a run of about 30,000 ft.

On some of the tests the power source was the Holtwood generating station about 40 miles away. While one machine was used at Westport, it was necessary to use two 10,000-kw. machines at Holtwood to furnish the higher short-circuit currents; the transformers at each end connected by one transmission line completed the arrangement. The fields of the two machines were arranged to be opened simultaneously.

A third arrangement was used for very low currents on several occasions. A frequency changer running inverted was tied in from one of the city substations, by means of some of the city cables, and this machine was used to supply current.

Telephonic communication was provided between the test floor, the Highlandtown substation and Holtwood (or Westport), and this communication was maintained throughout the test.

In the first few tests the short circuits were made by closing in all switches and then closing the field breaker of the generator, and ammeters were used for measuring the current. It was first thought that this scheme might be used in making the tests, thus obviating the use of the oscillograph, and considerably simplifying the tests. However, it was found that the switches heated very rapidly, and would weld together before the current had risen to a value that would have opened them. The large majority of the tests were suddenly applied by closing the high-tension oil switch (Fig. 2), and the oscillograph was used to record the current through the disconnecting switch under test. A second element of the oscillograph was used to record the potential across the switch, and thereby indicate the exact instant of opening.

Oscillograph Application

As stated above the oscillograph was used to obtain a record of the current and voltage across the switch

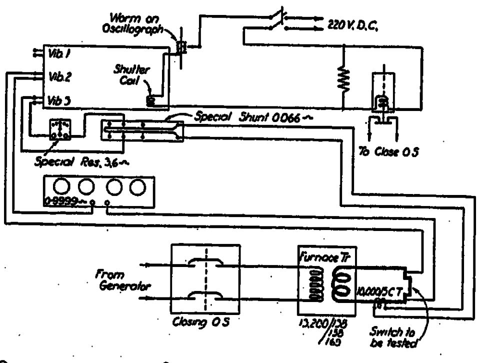

Fig. 2—Oscillograph Set up for Disconnecting Switch Tests

under test. The oscillograph used was the General Electric instrument.

In order to measure currents of the magnitude of 100,000 to 150,000 peak amperes a 10,000/5 Westinghouse through type current transformer was used. On some of the later tests a shunt was used which is

believed to be more accurate than the current transformer in recording transients. Recent tests have shown that current transformers are subject to error in recording transients, the actual current being greater than that indicated by them.

Fig. 2 shows the scheme of connections for the oscillograph. It was desired to have the apparatus so arranged that the operation of the trigger on the oscillograph performed all the necessary functions after the circuit had been set up for test. The sequence of events should be as follows:

1. Shutter of oscillograph opens exactly at beginning of film.
2. Oil switch closes, applying the short circuit several cycles later.
3. After about one revolution of film, short circuit is cleared.

The third item was not automatic on all of these tests, for it was felt that the repeated clearing of a number of heavy short circuits by an oil switch was undesirable, and so it was decided to clear the short circuit by opening the field of the generator. This was done at the generating station by the operator as soon as he observed that the short circuit was on.

The method of obtaining the required sequence is shown in Fig. 2. Instead of operating the oscillograph shutter from a six-volt battery, 220 volts d-c. was used and an auxiliary relay placed in series with it (the shutter). This relay had its contacts connected to the "close" leads of No. 3 feeder oil switch.[1] When the trigger of the oscillograph was pulled, the moving contact dropped down into the thread of the hard rubber worm and, at the instant the film overlap was opposite the slot, made contact with the metallic thread. This opened the shutter and closed the auxiliary relay which closed the oil switch, throwing on the short circuit. This arrangement caused the initial rush of current to take place near the beginning of the film. The operator at the generating station would then open the field of the machine causing the current to die out.

1. In primary of electric furnace transformers used on these tests.

The oscillograph was at first calibrated before and after each series of tests, but this was found to be unnecessary as there was practically no difference in the two calibrations. Alternating current was used almost exclusively in making the calibrations, principally on account of its convenience.

Procedure in Test

After a switch was in place for test the contacts were given a final examination, as was the alignment of the blade and jaws. The pull in pounds necessary to open the switch was then measured at the eye of the switch by means of a spring balance, and this pull adjusted to what was thought to be a normal value, by bending the jaws if necessary. This necessitated further inspection of the jaws for good contact. After the test was made the pull required to open the switch (in case it did not open) was again measured.

When it was desired to make a test on a switch one of the above mentioned circuits was set up with No. 3 feeder oil switch open. When everything was in readiness the operators were notified that the switch would be closed in one-half minute. The oscillograph was given the final adjustments, and at the expiration of the 30 seconds it was operated. The oil switch was opened manually after the film had made one revolution

SUMMARY OF TESTS

as by this time the operator had opened the field breaker and the current had died down to a low value. At least one other oil switch was then opened together with the disconnecting switches at the primary of the furnace transformer before anyone was permitted to examine the switch tested. The film was developed and the magnitude of the current ascertained.

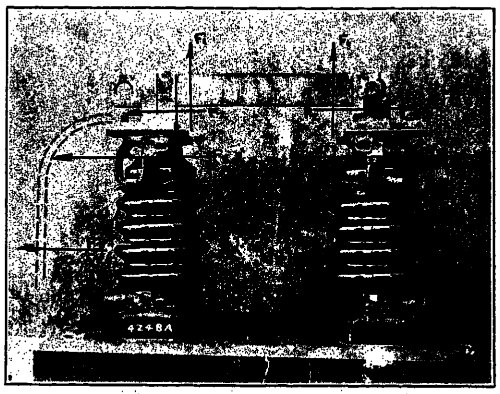

FIG. 3

In case the switch did not open another test was usually made at a higher current, but not before carefully dressing and polishing the burned parts.

RESULTS OF TESTS

The accompanying tabulated summary of tests shows both the *test* current and the *equivalent* current. This item "equivalent current" is intended to take care of the added force produced by the rear bus when a switch was tested in the loop (to which reference was previously made). It is the current which would produce the same force met with in test if there should be no rear bus present. If the switch was not tested in the loop, the test current and the equivalent current were the same. The basis of this calculation is

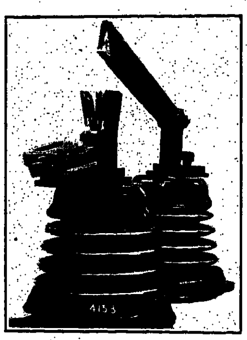

FIG. 4

the formula proposed by Mr. H. B. Dwight in the June 1920 JOURNAL of the A. I. E. E. As calculated, the effect of the side busses is ignored, and the rear bus only is considered.

This tabulation may be used to compare the various switches tested; and in addition a brief discussion of some of the more interesting points of the tests will be given.

It has been previously recognized that there are outward forces on the blade of a disconnecting switch, when subjected to high currents, that tend to open the blade. These forces are shown as $F_1 F_1$, Fig. 3. However, in addition to these forces there are other forces tending to separate the jaws and insulators, as shown at $F_2 F_2$. When the connections are run to the switch as shown by the dotted lines, there is repulsion between these conductors as shown in $F_3 F_3$. In a description of some of the tests in the appendix, it will be shown that many designers of locks have completely ignored the forces $F_2 F_2$ and $F_3 F_3$. These horizontal forces tend to open some types of locks, and to break off the insulators. For this reason locks should be either on the outside of the loop, or some means should be taken to prevent the insulators from spreading.

It was observed on many tests in which the blade opened, that the break jaws spread apart (see Fig. 4). As the two sections of this jaw carry current in the same direction, one would expect them to be drawn together, which occurred only in one or two cases. The only explanation that has been advanced is that the explosive action of the metal vapor or of a small quantity of oil that might be present, forces these sections apart.

In the 43 cases in which the blades of the switches were blown open, 21 cases were within the first half-cycle, 9 cases required one cycle, and 14 cases required more than one cycle for opening. The conclusion might be drawn that a switch will ordinarily open within the first cycle, and possibly within the first half cycle. It is evident from this that it is not the average force exerted by the current which opens the switch, but the maximum force resulting from the peak value of current, and it is this peak-value which should be used in all short-circuit calculations pertaining to the forces acting on disconnecting switches. Furthermore, it is the *initial* peak which will more than likely cause opening. And it should be remembered that this initial peak may have a displacement of twice the symmetrical value usually used in short-circuit calculations.

It was found that the major portion of the locks tested were incorrectly designed. In fact, one manufacturer asserted that electrical expulsion forces only tend to hold this lock more firmly in its place. And as a matter of fact examination of the switch and lock would lead one to believe that such was the case. Yet this particular lock proved to be rather inferior, and blew open at relatively low currents. (Make *F*).

One of the causes of the failure of a number of effective looking locks is due to the fact that designers have failed to take into consideration the fact that in addition to the outward forces on the *blade*, there are outward forces on *each insulator*, which are ofttimes just as effective in causing the lock to open as the outward forces are in causing the blade to open. (Makes *F, D, B* type *P*).

Another cause of at least two types of locks failing is the fact that the lock itself carries current, and repulsion by other current carrying portions cause the lock to open. (Make *B* Type *C*, *D* Selector type).

Still another cause is due to inherent mechanical ineffectiveness of the lock. By this is meant that the lock simply does not hold even when a simple mechanical pull is exerted on it. In this class would come the two types of Make *D*, and Make *B* type *P* locks.

And there is the switch that has a lock that is not mechanically strong enough to resist the forces. This includes the Make *B* lock on the type *O* selector switch, the Make *A* lock, and the Make *E* lock.

The fact that a lock may carry some of the current may cause it to fail thermally. The failure of the Make *A* lock might be attributed to this cause, as might be the failure of the Make *B* type *O* selector switch lock. As a matter of fact it may have been a combination of mechanical and thermal effect which caused these locks to fail.

Fig. 5

It is desired to call attention to the fact that there is a tendency toward building a switch with the current-carrying portion too light, which is typified in a number of the switches which failed to stand up under test.

Generally speaking, it is believed that the double blade disconnecting switch (such as Make *C*) is superior to the single blade switch, particularly where the design is such that it permits the blades to clamp the jaws due to the parallel high currents flowing in the same direction. Furthermore there is more radiating surface per unit cross section of the blade on this type of switch. It also permits the switch to be so constructed that the contact pressure is readily adjustable.

It may be stated here that while bringing the return circuit behind the switch materially adds to the force action on the blade and hence renders it more liable to open, this is preferable to running it *alongside* of the blade which is still more likely to open the switch. With the return conductor alongside of the blade, a side blow is delivered for which the switch was not designed. This is shown in Fig. 5 where the return conductor was run alongside the blade, and the switch was badly injured.

It is merely repetition to state in this report that switches should not be placed in loops if it is possible to avoid them; but this is usually determined by the original design of the station, and concerns generally station designers rather than operating engineers.

These tests show that the Make *C* switches are generally speaking superior to the other switches tested. This applies to mechanical construction and performance on the tests. Several years ago some difficulty was experienced in these insulators failing on high potential test, but data at hand shows that this defect has been largely remedied.

It might be mentioned here that the split hinge jaw is thought to be undesirable, as it may open instead of the lock. This is described fully in the appendix.

Appendix

This appendix is intended to give briefly detailed information concerning all of the important switches tested. Many switches are included here which may be more or less obsolescent; these switches are included for one of two reasons; first, some point is brought out that is thought to be of general interest; second, these switches are in more or less general use, and the information may be of value to the users.

It is desired to call attention to the fact that these tests were not made primarily to compare the most recent designs of disconnecting switches of the various makes, but to obtain data on switches in actual use on our system.

Over two hundred tests were made, covering in all about thirty types of switches. The manufacturer will in each case be designated by a letter as *A, B, C, D, E, F* and *G*. It will be noted that peak values of current only are used.

(*a*) *Make A 300-Ampere Switch Without Lock, Fig. 3.* A single blade is provided with a hinge jaw split in three parts, and the break jaw in two parts. The insulators are mounted on the base by means of a clamp and *U*-bolts, and the two jaws are mounted by a similar arrangement. It is believed that this scheme is rather inferior as it permits considerable motion of the insulator.

About 28 tests were made on this switch. The first scheme was to start at a low generator voltage, say 4000, and gradually work upward in steps of 500 or 1000 volts, making three tests at each voltage. But this method was soon found to be unreliable as after a few tests the blade and break jaw would become burned and pitted so that welding would take place, and the switch would not open at all. The method then adopted was to examine the switch to be tested, and

estimate the current that it would withstand and test at that current value; then, after an examination of the switch after test, a next higher (or lower) current would be decided upon, and so on until the switch

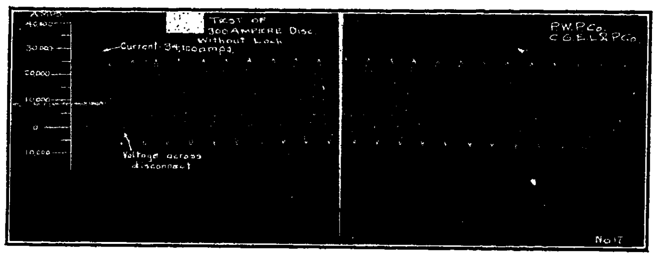

Fig. 6

opened. The pull at the eye of the switch was adjusted before each test to be about 15 to 17 pounds, corresponding to 16.5 to 18.5 pounds at the break jaw.

This switch opened on the first three tests at 43,100, 36,000 and 34,100 peak amperes in ½, 1 and ½ cycles respectively. The latter figure, 34,100, is the lowest value at which the switch opened.

Fig. 6 (Oscillogram 17) shows the switch opening in one-half cycle at 34,100 peak amperes. The mechanical force at the break jaw required to open the switch on tests No. 17 was 18.5 pounds. The current required to exert this force is 38,400 amperes, calculated from the Dwight formula. The switch actually opened at a current 11.2 per cent lower than this (34,100 amperes).

It would be expected that the actual current required would be greater than 38,400 amperes, as the attraction of the two sections of the switch jaws (at the break jaw in particular) should exert a pressure on the blade, thus increasing the pull at the break jaw above 18.5 pounds. The two sections of each of the jaws carry current in the same direction, and hence attract each other.

It was noted that in most cases when the switch blew open the break jaws spread apart. That is best shown in Fig. 4, another type of switch being shown.

Fig. 7

This may be due to the explosive action of the metal vapor as the switch opens, or to the presence of a small quantity of oil in the jaw, or to both.

On several subsequent tests the switch failed to open at somewhat higher currents, but this was found to be due to welding. This is shown rather conclusively in tests No. 39 and No. 40, where the burned break jaw of previous tests was replaced by a new one. The switch opened in these two tests at 39,200 peak amperes and 35,900 peak amperes, while on a number of previous tests currents up to 46,500 peak amperes failed to open the switch with the burned jaw in place.

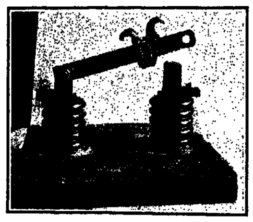

Fig. 8

(b) *Make A 300-Ampere Switch with Make E Lock Attached.*

This switch is identical with the previous switch except that a lock has been added as shown in Fig. 7. The lock is of more or less familiar design, and will not be described further than to say that the latch fits into a notch filed into the jaw of the switch.

Both the hinge and break jaws of the switch are slotted as shown in Fig. 7; and while this probably gives better contact, the switch is materially weakened, especially at the hinge jaw. For when a hole is drilled through the middle section to receive the hinge bolt there is little metal left to resist the outward forces. As a matter of fact, on one of our tests on this switch (described later) the switch blew open at the *hinge* jaw rather than the break jaw due to this weakened condition.

Five tests were made on this switch, which opened at 40,500 peak amperes. From an examination of the lock it would appear that such an arrangement would hold against the action of almost any reasonable current, or at least up to the point where the dogs of the latch would shear off. But it should be remembered that in addition to the outward component of force tending to open the *blade* there is an outward

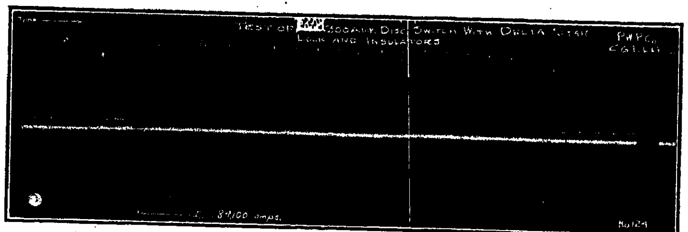

Fig. 9

component tending to spread the *break* and *hinge* jaws and pull the latch out of engagement with the notch. This was confirmed by a number of tests in which markings were made on the blade of the switch before test and noting the position after test. Movements of 3/16 in. were frequently noted. Welding of the blade and jaw often took place, and a blow would bring the blade and jaw back into normal contact.

(c) *Make A 300-Ampere Switch with Make D Lock and Insulators.*

The weakness in the above switch with lock was found to be in the insulators, and it was believed that if more rigid insulators were used the lock would be more effective. Hence the arrangement shown in Fig. 8 was made up similar to the above mentioned switch except that more rigid insulators were used. This arrangement opened at 84,100 peak amperes, or more than double the value with the original insulators (40,500). Fig. 9 (Oscillogram 124) shows the switch opening in one-half cycle. Fig. 10 shows the burning at the break jaw and blade. The jaws in this particular case actually drew together and welded, which is exactly opposite to the action that usually exists, as shown by Fig. 4.

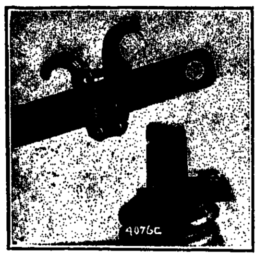

Fig. 10

(d) *Make A 600-Ampere Switch.*

This switch is similar in construction to the 300-ampere switch, with the exception of the current-carrying parts which are correspondingly heavier.

Tests were made with and without lock, as in the 300-ampere switch. Without lock, the opening occurred at 75,000 peak amperes, with a pull at the break jaw of 28 pounds. In testing with lock, the break jaw pull was reduced to 11.5 pounds to make the lock itself withstand the force action, as far as possible. Under these conditions the switch opened at 56,700 peak amperes.

Fig. 11

(e) *Make A 300-Ampere Switch with Special Locks.*

In an effort to find a simple and effective lock for this switch, a number of designs were constructed, such as pin lock (the pin passing through both blade and jaw), door latch arrangement (on the outside of break jaws), notched blade lock, pinned blade lock, etc.

Fig. 11 shows a satisfactory arrangement in which the blade of the switch notched so as to fit down over the clamp around the jaws. The object in this arrangement is obviously to prevent the insulators and jaws from spreading with the consequent disengagement of the latch. This scheme was very effective, the current required for opening being 125,000 peak amperes. Opening occurred after 13 cycles, the current having died down to 102,000 peak amperes. The dogs of the latch sheared off as shown in Fig. 11, thus permitting opening. This is one of the few cases in which more than one cycle was required to open a switch. Figure 12 shows the phenomena.

A somewhat similar scheme, designated as the pinned blade lock, held up equally well on subsequent tests. Instead of the blade being notched with a clamp around the break jaws, a pin was driven through the blade which butts against the break jaw thus preventing any outward motion.

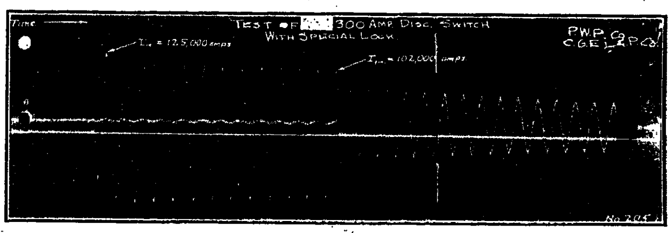

Fig. 12

(f) *Make A 300-Ampere Switch with Make A Lock.*

It is understood that at the time of test this switch was the latest design by this manufacturer. The current-carrying portions are very similar to those of the older type; but the insulators show considerable improvement. Fig. 13 shows this switch with the new type of lock in place. Fig. 14 shows a more detailed view of this lock from which its operation is evident. It is believed that the lock occupies considerable space for its effectiveness. Furthermore, the quality of workmanship is not as high as in the other portions of the switch. The insulators are strong and well constructed, and showed no signs of weakness in the tests. The method of mounting the insulators could be improved, as it is necessary to remove the entire switch to make replacements. It is worthy of note

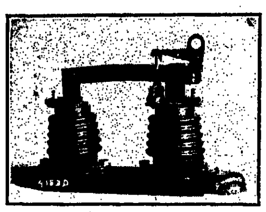

Fig. 13

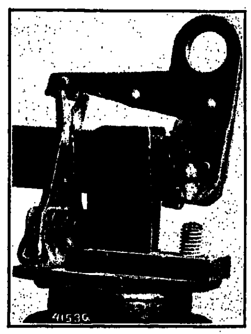

Fig. 14

that the effectiveness of this lock is not dependent upon the rigidity of the insulators.

The switch was given five tests up to 90,300 peak amperes, which current was effectively withstood. However, burning was evident on all tests, and on the fifth test the blade turned red. A sixth test was made at 105,300 peak amperes, and the switch opened after one-half cycle, burning the blade, jaws, and lock badly as shown in Figs. 13 and 14, these pictures being taken after the last test. It is thought that the tips of the dogs sheared off, permitting the blade to open. The arc then burned the lock, blade and jaws as shown.

The dogs butt directly against one another, and the amount of metal that resists the shear of the blade is small. The lock could be so designed that the two dogs would be staggered and each one would then extend all the way over the blade, thus offering considerably more metal to resist shear.

Test was made with the switch in the loop previously referred to. The calculated force due to this rear

FIG. 15

bus was 112 pounds at the break jaws, and the force due to the current passing through the switch was 227 pounds, giving a total force of 339 pounds at the break jaw. This force is equivalent to a current of 127,000 peak amperes through the switch, if there were no rear bus present, ignoring the effect of the sides of the loop. The pull at the break jaw was 21.5 pounds for this test.

(g) *Make B 300-Ampere Type O Switch with Lock.*

Fig. 15 shows the construction of this rigid insulator switch. The blade is double but is so constructed that it does not properly take advantage of the clamping action of the blades. This clamping action due to the passage of current in the same direction in the two sections, might be utilized in clamping the break jaw, both increasing the friction and insuring better contact. This force action is felt only during the flow of high currents through the blade. The lock is a simple hook arrangement located on the outside of the loop formed by the conducting portion of the switch.

The lowest current at which this switch opened was 66,800 peak amperes in one-half cycle, breaking off the hinge jaw insulator. Burning at the lock indicated that it carried current, and it was thought that forces might have resulted which caused the lock to open. To confirm this suspicion, currents averaging about 60,000 peak amperes, sustained value, were passed through the switch with the blade bolted shut and a contact mechanism in front of the lock (about 3/16 in.

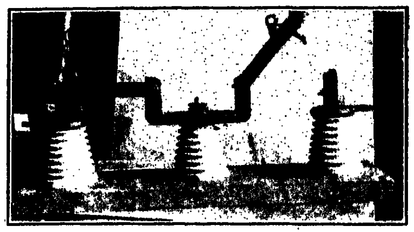

FIG. 16

distant). This contact mechanism completed a battery circuit through the oscillograph vibrator, and at the above current repeated contact was made as shown on the oscillograph film, indicating that this was the cause of the lock opening.

(h) *Make B 300-Ampere Selector Type O Switch with Lock.*

Fig. 16 shows this switch with its locking mechanism.

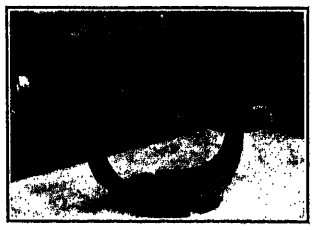

FIG. 17

It is rated at 300 amperes, but the current-carrying parts are fragile as compared to other switches of the same rating. Opening occurred at 53,900 peak amperes. The lock was bent and badly burned. A part of the break jaws welded to the blade, and was pulled off with it when opening occurred (see open blade in Fig. 16).

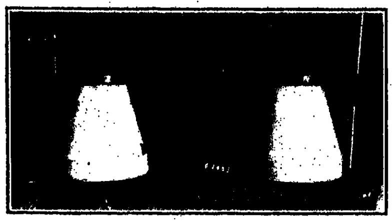

FIG. 18

(i) *Make B 300-Ampere Type M Switch without Lock.*

The type *M* switch (Fig. 17) is one of the older designs, and was tested for the reason that a number of them are in use at this time. With a break jaw pull of 20 pounds, opening occurred at 39,000 peak amperes.

(*j*) *Make B 300-Ampere Plain Insulator Switch.*

The name "plain insulator" switch was applied to this type for want of a better name. In fact, there is no marking on the switch to indicate the maker, but the assumption that it was a Make *B* switch was confirmed by one of the maker's representatives. Fig. 18 shows the switch, provided with a lock, described below. While the design of this switch is not beyond criticism, it must be said that the workmanship is as good as on any switch tested, referring principally to the current carrying parts. The current required for opening was 51,200 peak amperes (without lock), with a break jaw pull of 20 pounds.

Fig. 19

As many of these switches were in use on the system located at points where short-circuit currents of sufficient magnitude might obtain to cause opening, it was desired to apply some sort of locking mechanism to this switch that would render it safe up to approximately 100,000 peak amperes. The scheme finally decided upon is shown in the illustration. It has the disadvantage that two motions are required to close and

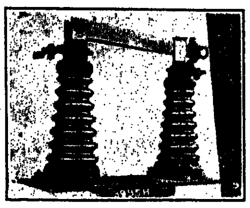

Fig. 20

lock the switch, one to close the blade, and one to lock the switch. The first test was made with the lock pedestal insulated, and the blade held satisfactorily at 116,000 peak amperes. The insulation was then removed permitting the lock to carry a portion of the current. It was then tested at 96,600 peak amperes, which was successfully withstood.

Testing was with a rear bus present and 116,000 peak amperes is equivalent mechanically to 143,000 peak amperes passing through the switch with no rear bus.

(*k*) *Make B 600-Ampere Selector Type P Switch with Lock.*

This switch, Fig. 19, was never completely tested, as it was received in such condition as to require considerable dressing before it could be put in service. The type of lock used will be discussed later. It might be mentioned that several tests were made on this switch as received and it did not open (up to 84,500 peak amperes) due to the burning and welding at the contacts.

(*l*) *Make B 300-Ampere (35,000-Volt) Type P Switch with Lock.*

Fig. 20 shows this switch. The lock is similar to the switch previously mentioned. It is not particu-

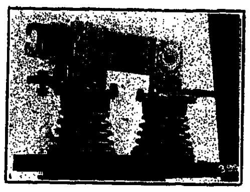

Fig. 21

larly effective, for it may be opened with a little effort by pulling on the blade. Opening occurred at 34,000 peak amperes, after 6.5 cycles.

(*m*) *Make B Switches of other Types.*

Fig. 21 shows a 1200-ampere type *S* switch, one of the later switches of this make. The locking mechanism is fairly simple and substantial. With a pull at the break jaw of 39.5 pounds, 142,000 peak amperes

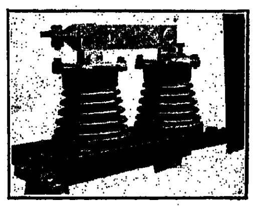

Fig. 22

failed to open it. This is equivalent mechanically to 208,000 peak amperes as the test was with a rear bus.

Fig. 22 shows a 600-ampere switch designed by Mr. F. E. Ricketts, of Baltimore. The principle, that of avoiding loops is obvious. The jaws are so designed that the current passes straight through the switch, thus eliminating any tendency to open. The first

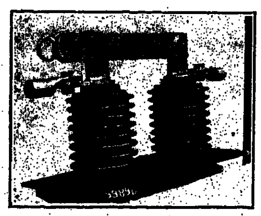

Fig. 23

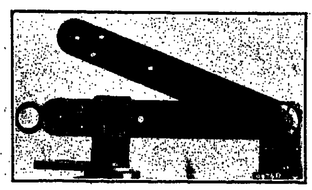

Fig. 24

group of tests was made with the connections extending in a straight line on either side of the switch for about five feet, thus avoiding loops that would tend to open the blade. With these connections the switch remained closed up to 90,700 peak amperes. The connections were next brought in from the rear at right angles to the blade, in the plane of the blade opening, thus form-

ing a short loop (about 17.5 in. between the two leads). Opening occurred after 18.5 cycles at 58,300 peak amperes. As the connections to a switch in service are usually as in this last test, it is felt that this scheme is

FIG. 25

FIG. 26

hardly applicable to most installations. The design may prove valuable in bus section switches, or other places where loops are avoided.

A 1200-ampere switch of this design was tested up to 93,000 peak amperes, but it showed no signs of distress. No attempt was made to test it further.

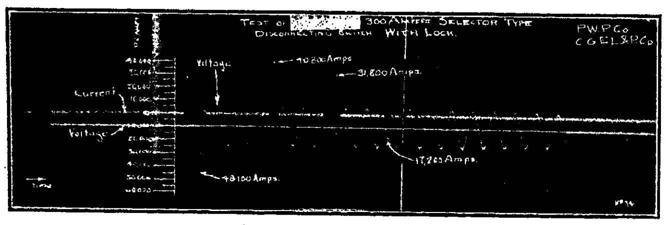

FIG. 27

(*n*) *Make C 600-Ampere Switch with Lock.*

Relative to the design and construction of this switch it might be said that it is the equal of any switch tested. Fig. 23 shows the switch to be a double blade switch with jaws and lugs cast integral. The blade is so designed as to take full advantage of the clamping

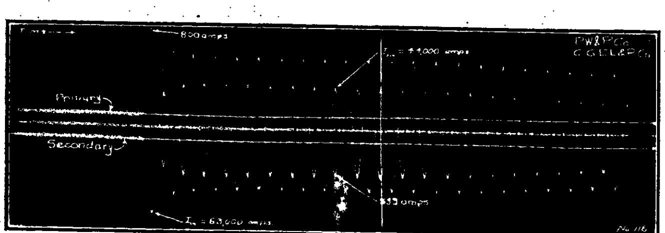

FIG. 28

action due to the passage of high currents. The lock is simple and strong. The contact between the blade and jaw is ground giving accurate contact, and these jaws may readily be removed without changing the insulator. Fig. 24 shows the lock mechanism, which is located on the outside of the break jaws. Outward movements of the insulator will not tend to disengage it.

It was impossible to open this switch at currents up to 144,000 peak amperes, which test was with rear bus, and equivalent mechanically to 181,000 amperes. The burning was relatively slight up to 111,000 peak

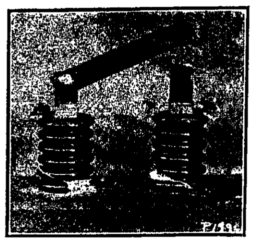

FIG. 29

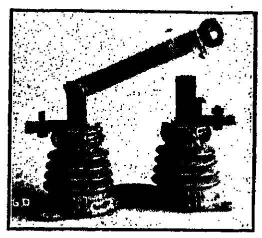

FIG. 30

amperes. Fig. 24 was taken after the tests were completed and shows the relatively slight burning even at these high currents. This switch with its locking mechanism remained operative after the tests were completed.

Without locking mechanism this switch opens at 52,200 peak amperes.

(*o*) *Make C 300-Ampere Switch with Lock.*

The 300-ampere switch is similar in design to the 600-ampere switch described previously. Currents up to 129,000 peak amperes failed to open the blade, the mechanical equivalent due to the rear bus being 152,000 peak amperes. On previous tests the blades were drawn together somewhat and the hinge jaw lug was bent due to the burning loose of one of the leads. This lug was straightened out, and on this last test burned loose at the end of the eighth cycle. This is obviously the fault of the bend in the lug, and not an inherent fault in the switch. Fig. 25 shows this burn, and in addition, the drawing together of the blades due to the passage of high currents.

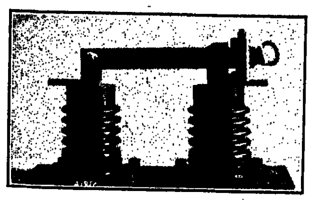

FIG. 31

(*p*) *Make D 300-Ampere Selector Type Switch with Lock.*

This familiar type of switch is shown in Fig. 26, in which the mounting of the insulators with the studs running through to form the back connections, may readily be seen. Attention is called to the large loop formed by these studs which means that a relatively great outward force is exerted on the blade, for a given current through the switch. However, the outward forces on the break and hinge jaws cause no movement due to the method of supporting the insulators. The lock used on this switch consists in a hinged leaf engaging in a notch in front of the break jaw.

The switch was first tested with the lock removed. With a break jaw pull of 16 pounds the opening occurred at 28,200 peak amperes in one-half cycle. The lock was then replaced and the break jaw pull reduced to about 8 pounds. Opening occurred after 15 cycles at 41,600 peak amperes.

The switch was then tested with both of the break jaws alive at one polarity, and the hinge jaw alive at the opposite polarity. The blade opened at 48,100 peak amperes after one cycle and blew into the opposite jaw, thus establishing the current again, blowing back and forth, making four contacts in all. Fig. 27 (oscillogram 74) shows this phenomena with the duration of contact and the interval between.

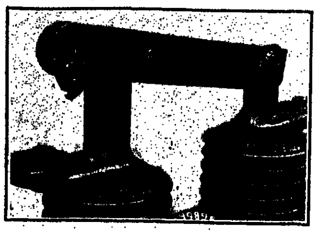

Fig. 32

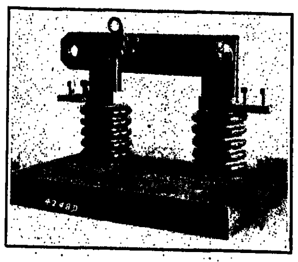

Fig. 33

It could not readily be seen just why this lock should open, and the only explanation advanced was that some of the current flowed through the leaf in such a direction as to cause repulsion between the blade and itself. This seemed very unlikely however, and several lock opening tests were made similar to those described above, by bolting the blade to the jaw. The oscillograms showed that the lock opened at the peak of each half cycle. An examination of Fig. 28 (oscillogram 166) shows this opening, the notches in the middle line under the peak of each half wave indicating that the lock opened and made contact.

(q) Make D 300-Ampere Switch with E N Lock.

In Fig. 29 is shown one of the latest locks of this make. It will be noted that the hinge jaw is not split which is a very desirable feature. At a current of 90,300 peak amperes the insulators broke off, which evidently permitted the lock to open, but with stronger insulators it is believed that the lock might stand up better. The "equivalent" current in this case was 113,000 peak amperes.

(r) Make E 300-Ampere Switch with Lock.

This switch is, generally speaking, more generous in its proportions than many other switches tested. The hinge jaw is not split, making a strong hinge joint. The break jaw is split, but due to the design of the lock, this is not a disadvantage. The locking mechanism is contained in a head riveted on the end of the blade, as shown in Fig. 30.

This switch showed up well up to 75,800 peak amperes but at 141,000 peak amperes (break jaw pull 16 pounds) the blade opened. Examination showed that the head had pulled off of the blade, probably due to the shearing of the three rivets which holds the lock head on the blade. Fig. 4 shows this switch after tests. As this last test was in the loop the 141,000 peak amperes is mechanically equivalent to 169,000 peak amperes.

(s) Make F 300-Ampere Switch with Lock.

There are many features in the design of this switch, Fig. 31, which are worthy of note, such as the solid hinge jaw, the adjustable and interchangeable insulators the locking mechanism, etc. To all outward appearances the lock is well made and effective. For this reason no attempt was made to test at the very low currents. Several tests were made in which the blade opened at currents from 65,000 to 75,000 peak amperes.

A thorough examination of the switch was then made to determine just why the lock should open. It was found that when the insulators were spread apart the lock opened, due to the cams on the pull ring pushing against the dogs which open the lock. The remedy that suggested itself was to separate the cams and dogs ⅛ in. by moving the insulators together by this distance. This being done, the switch was tested at 121,700 peak amperes, at which current both insulators broke off and the lock opened, releasing the blade. The current equivalent mechanically to 121,700 peak amperes (due to the rear bus) is 154,000 peak amperes.

(t) Miscellaneous Makes Tested.

Fig. 32 shows a cam lock fitted on a standard make switch, designed by Mr. F. T. Leilich of Baltimore. This lock consists of a cam which presses against the break jaw when an outward force is exerted on the blade or jaw. The switch was tested up to 68,000 peak amperes without opening, but injury to the switch prevented it being tested further.

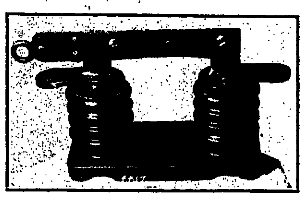

Fig. 34

Fig. 33 shows an arrangement of parts made by various manufacturers and used at various points on the system. With the lock properly adjusted 81,500 peak amperes opened the blade.

(u) Make G 300-Ampere Switch with Lock.

In Fig. 34 is shown a switch very similar in design to the Make *C* switch. The photograph was taken after the switch had been opened at 124,100 peak amperes, equivalent mechanically to 152,000 peak amperes. Attention is again called to the drawing together of the blades.

(v) Make G 600-Ampere Switch with Lock.

The 600-ampere switch is similar in design to the 300-ampere switch described in the preceding paragraph. Currents up to 145,000 peak amperes, equivalent mechanically to 193,000 peak amperes, failed to open the blade.

Discussion

AIR-BREAK MAGNETIC BLOW-OUTS FOR CONTACTORS AND CIRCUIT BREAKERS, BOTH A-C. AND D-C. (TRITLE) AND THE EFFECT OF HIGH CURRENTS ON DISCONNECTING SWITCHES WITH SPECIAL REFERENCE TO THE MECHANICAL STRESSES RESULTING (LOUIS AND SINCLAIR).

H. D. James: The investigation of basic arc rupturing phenomena is necessary for the proper design of control apparatus. Mr. Tritle in his paper has made a valuable contribution toward our knowledge of this subject. Similar investigations have been made by Messrs. O. H. Escholz and J. W. Legg. The practical results of these investigations are fundamentally the same but different methods have been followed so that the photographs and curves obtained will supplement Mr. Tritle's paper.

Mr. Legg developed a rotary type of high-speed camera which is fully described in the *Electric Journal* of December 1919. This high-speed camera has been found to be exceedingly useful in the study of arc phenomena, particularly in the development of magnetic blow-out switches. Some of the phenomena disclosed by its use are discussed by Mr. Escholz in the *Electric World*, September 3, 1921, and were reprinted in leading technical papers including the *E. T. Z.* of February, 1922.

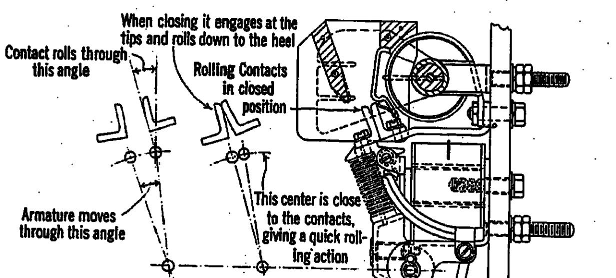

FIG. 1—DRAWING SHOWING ACTION OF ROLLING CONTACTS

At the annual meeting of the Association of Iron & Steel Electrical Engineers in September 1919 I presented a paper illustrating a line of magnetic contactors embodying improved arc rupturing means resulting from these investigations. This paper was printed in the *Electric Journal* in November 1919 and also in the *Transaction* of the Iron & Steel Electrical Engineers for that year. I will not repeat the details of these papers as they are a matter of record and can be examined by those interested in this branch of the art.

Briefly described, the electric arc is an elastic conductor consisting of a core of ionized gases surrounded by a luminous gaseous envelope. The arc is ruptured by simultaneously lengthening and cooling it. Every arc has a critical length on constant potential systems and will be ruptured if extended beyond this length. This critical length can be decreased by artificial cooling.

Mr. Tritle has brought out the advantages obtained by cooling the arc and a design of contactor utilizing this cooling effect.

Another form of arc box not only cools the arc but confines the critical length within a smaller area of magnetic field. (See Fig. 1).

This is accomplished by an insulated barrier placed transverse to the arc stream causing the arc to form a double loop so that its length is increased more rapidly than if this barrier or splitter were absent.

In addition to stretching or lengthening the arc, this splitter interposes a cooling surface to the arc stream very shortly after the arc has formed. This is the most effective time to begin cooling because of the high energy density per unit length of the arc stream. The arc splitter may have a piece of copper attached to the tip nearest the arc which very materially assists in increasing the cooling. This copper will not form a part of the arc circuit until the two extreme points of the copper shield have become heated to the point where they will emit electrons and ions. By the time this condition has been reached the arc has been stretched to a very considerable length so that its energy density or heating effect is small and in many cases the copper shield is never heated sufficiently to form a terminal point for the arc.

If the arc box is enlarged, additional barriers or arc splitters may be introduced. These splitters may have copper shields on the tips if conditions warrant. The small contactors operate

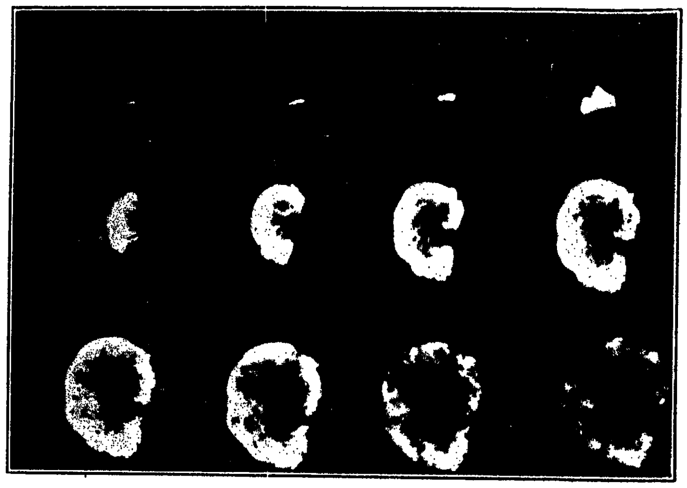

FIG. 2—VARIATION IN ARC CONTOUR ON RUPTURING. 40 AMPERES, 250 VOLTS, RESISTANCE LOAD. MAX. LENGTH = 20 IN., 1600 EXPOSURES PER SEC.

satisfactorily without the copper tips and even in large contactors or those used on high voltages only a very few arc splitters require copper shields.

When these arc splitters are properly designed and located they are not subjected to any more burning than other parts of the arc box. Referring to Mr. Tritle's illustration, Fig. 10 it is conceivable that transient parallel arcs may be formed in each compartment, but test data have shown that arcs in parallel without individual stabilizing means are exceedingly unstable, and it is to be expected that one of these arcs will be very quickly transferred to the other chamber, thereby reducing the volume efficiency of the arc box.

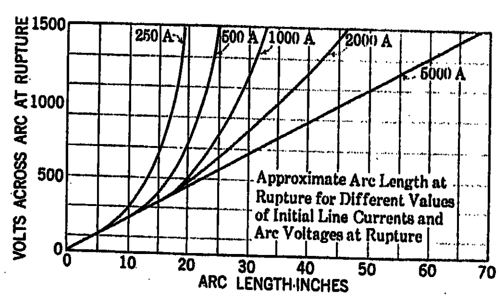

FIG. 3

The dimensions of an arc box are determined by two major factors, the most important being the critical arc length at which rupture occurs and the second the approximate arc width. The critical length of the arc is illustrated by Fig. 3, taken with the high-speed camera. This shows the arc from the time it is first formed until it has reached the critical length where it remains for a short instant and is then ruptured. The critical length of the arcs obtained from test under normal conditions without artificial cooling are shown in Fig. 4 which gives the relation between the volts across the arc at the instant of rupture

and the length of arc at that time for various initial line currents. Introducing various cooling agencies will shorten this critical length. Fig. 5 shows the same conditions of ruptures as illustrated in Fig. 3 except with the addition of a barrier transversed to the arc stream. This barrier functions both to cool the arc

FIG. 4—ARC CONTOUR RUPTURING 400 AMPERES, 250 VOLTS. MAX. LENGTH = 19.5 IN., 1600 EXPOSURES PER SEC. NOTE ARC "SPLITTER"

stream and to cause the formation of a double loop which decreases the area of the arc shield necessary to rupture an arc of a given critical length. An extreme development of the arc splitter is shown in Fig. 6, where three barriers are employed. The illustration at the left shows the arc stream making initial

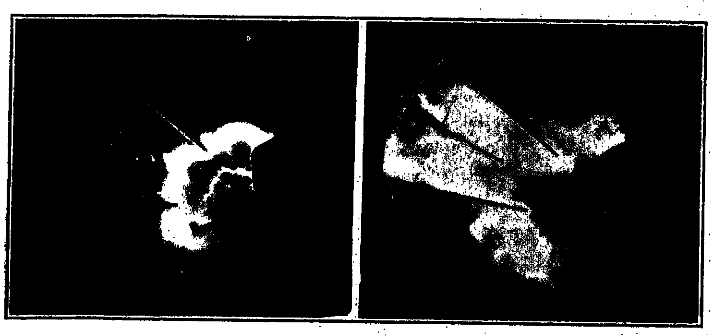

FIG. 5

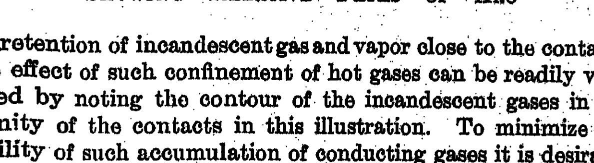
contact with the splitters, and that at the right shows the appearance of the loops immediately prior to rupture. The photograph indicates that the three barriers have not been properly disposed to make the best use of the space. In locating barriers or arc splitters in an arc box, care must be exercised to prevent



Without Arc Splitter With Splitter

FIG. 6—DRAWING OF CONTACTS AND BLOW-OUT UNIT SHOWING RELATIVE PATHS OF ARC

the retention of incandescent gas and vapor close to the contacts. The effect of such confinement of hot gases can be readily visualized by noting the contour of the incandescent gases in the vicinity of the contacts in this illustration. To minimize the liability of such accumulation of conducting gases it is desirable to provide as free an exit for such gases as possible.

Any restricting means placed in the path of the arc stream will tend to create a back pressure and result in the accumulation of incandescent or conducting gases in the neighborhood of the contacts, therefore, an arc box structure should be proportioned to give ample exit areas. The current density of the arc stream under atmospheric conditions is approximately 500 amperes per sq. in. It is, therefore, evident that if the width of the arc box is less than the normal diameter of the arc stream that this stream will be forced to assume approximately an elliptical shape. This will retard the exit of the arc and its hot gases and augment the accumulation of conducting gases in the vicinity of the contacts.

To summarize, the arc is ruptured by stretching to the critical length.

The rupturing capacity of a given arc box is increased by the use of splitters Figs. 6 and 7, due to:

(a) The cooling effect which decreases the critical arc length.

(b) The confinement of a longer arc stream within the available magnetic field.

The box width and position of barriers should be designed to permit the free exit of conducting gases to avoid arc reignition.

B. G. Jamieson: The problem of interrupting a circuit, under load conditions particularly, is of course a difficult one, and the extent to which this air rupturing may be carried is a

A B

FIG. 7—A. EXAMPLE OF CONTACTOR WITHOUT ARC SPLITTER OPENING CIRCUIT UNDER HEAVY OVERLOAD. B. SAME CONTACTOR EXCEPT EQUIPPED WITH ARC SPLITTER.

thing which will interest all of us. Of course, when we think of the application of this principle to indoor work, the first idea that strikes us is, "How much space can we afford the arc after it leaves these chutes, and how much danger is there of reestablishment of the circuit even after the chute has been cleared?" The pictures given by the author mention the arc in one case as 43 x 28 in. If that is symmetrically disposed across three phases it at once brings to our mind the necessity for doing something with these gases after they have left the chute.

In some of the experiences to which the Commonwealth Edison Company have been subjected, the real serious part of the whole affair has been the taking care of the arc after it has left the contacts. A point in that connection which also suggests itself is that there has been a demand created by certain exigencies for circuit breakers, more particularly d-c. perhaps, which will operate within very limited areas or space contents. I was talking with a manufacturer who had been considering the problem of building breakers of the capacity of 1500 amperes, low voltage, and it was necessary to house these breakers, per-

haps build them so they could be mounted on 4-in. centers. I asked him if his difficulty lay in the disposal of the arc gases. He told me that much to his surprise the indications were that the disposition of the arc within that enclosed small space was a simple matter, there seemed to be some favorable tendencies of extinguishing the arc, or at least of preventing the re-establishment. So that the point I would like to make is that however efficient this device may be towards the excluding or expulsion of the gases from the point of their origin, to carry this to a successful final usage means perhaps a consideration of the disposal of the gases somewhat beyond the points indicated by the author.

Also there is suggested in this type of circuit rupturing device the question of effect of a passage of those gases past any working parts. I would expect, personally, that there would be considerable damage to parts. Perhaps the design of the breaker takes care of that, but if the breaker is used in a service where it is not convenient to make frequent renewals, it seems to me that more attention perhaps, or more emphasis might have been placed on the adequacy of the breaker with respect to that point.

The paper by Sinclair affords us a somewhat definite measure of the forces and effects operating and produced by certain measured conditions; all operating men have probably experienced some of the untoward results, but they are always at a loss because they don't know, or it is not convenient or easy to determine just what the forces were that produced the results, and that accurate measurement of cause and effect is a very useful step in the determination of the design of apparatus of this sort.

In our own Chicago experience we have had disconnecting switches blow open, not due to the displacement of the blade from the plane of the main conductor alone, but by reason, apparently, of the proximity of other conductors, and there is just a little question whether there isn't a resulting effect which, in the case of three-phase alternating, at least has to be taken into account. Locks have been destroyed when it wasn't possible to account for their destruction by the ordinary explanations given in the paper.

I might add, some years ago, in sort of an experimental attempt, we built some disconnecting switches which were designed to operate directly in the plane of the conductor or rather in the line of the conductor. This switch, if you will imagine a section of a conductor between two insulators removed and a couple of lugs put on the end of those conductors at a distance of 18 inches, and a blade right in the center line of that conductor, you will have an idea of the comparison of the experimental device that we built. We went a little further. We split that blade and we caused it to operate with a scissors-like motion so that the two halves of the blade operating oppositely presented no resultant unbalanced force, so far as the actuation of the device was concerned. Those switches have been in service for some years, and there have been no results, that is to say, no results which would give us any basis for the accuracy of that design. But it would seem as though if we want to get to an easier type of construction, that our difficulty is lessened as we approach the center line of the conductor.

J. B. MacNeill: The theory of the magnetic blow-out is a proper one to apply to switching equipment of any type where it is desirable to cause maximum extension of arc in a minimum time with consequent reduction in amount of arcing and distress on the switching unit. For high currents considerable blow-out effect can be secured by simple relationships of the current carrying parts and without the addition of blow-out coils.

Such a simple and effective relationship is obtained in the ordinary oil circuit breaker where the contacts into and out of the tank form a loop which gives the positive blow-out effect on heavy currents. On light currents, where the blow-out effect is inadequate for rupturing purposes the addition of blow-out coils and magnetic coils gives the desired result. It may be interesting to note that the Westinghouse Co. has been working for some time on the development of oil immersed switching equipment with magnetic blow-outs to secure high speed rupturing of the arc on comparatively low current. This development will probably be published in the near future.

Air switching using magnetic blow-outs will probably find a serious limitation in difficulties of insulation for high voltages. It would appear that even at voltages of 12,000 to 15,000, the insulation difficulties would become very considerable. This difficulty would, of course be greater for outdoor applications than for indoor. Indoor applications of this principle will find some objection from the noise developed when rupturing an arc unless special provisions are made for reducing the same.

The Louis-Sinclair paper brings out very forcibly some features of past disconnecting switch practise which should be avoided in the future and, therefore, paves the way for improvement in this field which is of considerable importance to operating companies as the concentrations of power become heavier.

Given a lock which performs satisfactorily on short-circuit currents, there is still the hazard that an operator may not completely close a switch in which case the lock does not become effective. In this case poor lock and good lock fare alike as the first short circuit that occurs blows the switch open if of sufficient magnitude. The switch shown in Fig. 22 (page 275) of the April JOURNAL was developed to overcome this difficulty. The relationship of the leads to the switch and the blade is such that if the switch is not completely closed the force generated by the short circuit closes it more completely. A disadvantage of this switch is that the leads to and from it must not be looped in such a way as to neutralize the desired magnetic action.

Switch locks have been developed to overcome the difficulty of an operator not latching the switch. The usual method is to have a lock in which the operator cannot remove the hook stick until the switch has been completely latched. Such devices, however, while they have been on the market for several years have not become widely popular, as they can be fooled by the use of a wrong hook stick.

Supposing lock difficulties have been disposed of, there always remains the possibility with an ordinary hook stick type of switch of an operator pulling the wrong switch with serious consequences. In some of the later high powered stations, therefore, remote control, gang operated switches, operated from the breaker aisle and properly inter-locked with the circuit breaker mechanism have been used. Such switches generally are self-locking by a toggle which goes over center in the closed position. Such switches seem to involve minimum risk to operators and maximum ease and speed in operation. The possibility of trouble with such an arrangement is limited to breakage of remote control linkage which is very remote.

F. C. Hanker: The development of the high speed oil circuit breaker is one which will take care of conditions where we want very high speed of interruption, as is the case in reducing the inductive effect of the short-circuit current. The difficulty we will probably have to overcome will be the minimum current we can interrupt; that is, whether the arc will hang on with small current on account of the difficulty of confining the arc to any specific structure such as a chute. On the high voltage type, to get a material that will stand the high arc temperatures and still confine them is one of the difficult problems.

H. L. Wallau: In connection with the use of locks vs. switches the relative hazard might be illustrated by a practise of our own company in which locks are placed on disconnecting switches which are inserted in the main circuits. The disconnecting switches which are used to cut out potential transformers are not so provided. We have never had any trouble with any of these disconnecting switches on potential transformer circuits, and probably one of the reasons for this is that it is our practise to use a No. 14 varnished cambric conductor to make the connections between the bus and the switch and the switch and the transformer. In every case where there has been any

transformer trouble this No. 14 conductor has acted as a fuse, the conductor has usually been completely vaporized simply leaving the enclosing envelope of insulation. No damage whatever has been done either to the switch or the cell structure or anything outside of the particular piece of apparatus in which the fault developed.

H. P. Liversidge: The results which have been presented covering the investigation of the performance of disconnecting switches under high-current stresses bring out some very interesting facts, particularly in reference to the resulting mechanical stresses which are imposed upon the entire switch combination. Certainly the tests made under actual current conditions aid very materially in visualizing actual performance, and it is interesting to note that many of the results obtained check very closely with values obtained by calculation. It is unfortunate, however, that in the combination of the various elements making up the completed switch, further consideration was not given to certain factors which, based on the performance recorded in the paper, must be regarded as variables, and because of this, the results—so far as they apply to separate parts of the combination, can hardly be regarded as conclusive.

It is evident from the report that the high-current tests on switches were instituted with the idea of determining the characteristic performance of switch combinations, as used in one particular system. However, as these tests proceeded, it would appear from the report that the performance of switch combinations taken more or less at random, was used as a basis for establishing the characteristics of various specific designs of switches.

In analyzing any switch test of this nature, consideration must be given to a combination of (a) the switch, including the blade and contacts; (b) the switch lock; (c) insulators with their fittings; and (d) the insulator base.

Since the combination of the different parts making up the switch bears a very definite relation to switch performance under conditions of the character imposed by these tests, it is clear that any conclusions which are drawn as the result of such performance must be based upon a correct knowledge of the design and characteristics of the switch in relation to the duty for which it was intended. It is evident that a light-duty combination which was reinforced by a notched blade so arranged as to act as a tie across the tops of the insulator-supports would show better results than another light-duty combination which was not provided with this reinforcement. On the other hand, a combination of switch, insulator and base designed for high mechanical strains, and of comparatively rigid construction, would, if correctly designed, require no bracing to prevent spreading, and the performance would be largely a question of lock design. Under such conditions, therefore, stresses imposed on various combinations of switch and lock would be largely a matter of resisting the outward thrust of the blade alone.

In looking over the report, it is quite evident that the various switches which were tested showed a random selection of locks, insulators and bases, and in combinations, which, under certain tests, gave rather misleading results. As an example, if switches reported as Makes *D* and *F* and shown in Figs. 29 and 31, had been mounted on insulators designed for the duty which was imposed upon them, the results so far as the effectiveness of the lock is concerned would, undoubtedly, have been far different. The conclusions which have been drawn by the authors, therefore, and which refer particularly to the operation of switch locks, cannot be regarded as conclusive insofar as the performance of different types of locks is concerned. In commenting upon locks of Make *F*, the authors state that this particular lock proved to be rather inferior and blew open at relatively low currents. An examination of this switch combination would indicate that this type of lock is designed primarily for use on a rigid type of insulating support and base. Where the amount of energy is very limited, a light-duty type of equipment is furnished; and where the forces are heavier, the insulator design and base are proportionately increased, always with a factor of safety sufficient to prevent any movement of the insulators, and, in this manner, positively prevent any relative movement which would affect the operation of the lock. In the particular test cited, a light-duty combination which was not designed for such expulsion forces, was used. While the lock did not open because of any electrical strains, it was forced open by reason of the spreading of the insulators, and the bending of the flat steel plate insulator base. What was actually tested, therefore, was not the lock but the insulators, and this seems to have been the case in quite a few of the tests recorded. On this particular test, the use of the notched blade furnished under certain requirements, in combination with the light-duty insulator, would quite likely have given the true performance of the lock alone.

The writer trusts, therefore, that the authors will continue the work which they have started and inaugurate a second series of tests with the idea of eliminating the variables included in this first series, so that the performance of locks,—which was evidently one of the principal reasons for instituting the tests—may be investigated under the exact conditions for which the combinations have been designed. Unless such tests are carried to a conclusion, it is felt that quite erroneous impressions covering the relative performance of various makes of locks and switch combinations may be secured.

H. B. Dwight: The method of testing disconnecting switches used by Messrs. Louis and Sinclair is very practical and should be of the greatest value in improving the design of such switches. As in the tests made by Mr. Torchio and described in the JOURNAL of the A. I. E. E. of February, 1921, the disconnecting switches were not subjected to a laboratory test, nor to an imitation of operating conditions, but they were made to carry actual full-size short-circuit currents from large generators. Since the most exacting duty required of disconnecting switches is to carry short-circuit currents, weaknesses or improvements in design disclosed by such tests may be trusted in forming a judgment of the relative value of different designs.

While the final criterion of the value of a design of a disconnecting switch is its performance under actual short-circuit conditions, calculated values of forces are useful in correlating test results, and in pre-determining the operation of the switch when it is not practicable to make full size tests. This is also true of the effect of the neighboring parts of the circuit, one or two cases of which were tested by Messrs. Louis and Sinclair. Many different forms of circuit may arise in practise, and comparisons between them can usually be made by calculation, using the methods, and in many cases the partial formulas, of the complete paper by the writer in the 1920 TRANSACTIONS.

These methods of calculation and partial formulas can be used also for calculating the force at each point of the switch supports, tending to move the insulators apart in a direction parallel to the switch blade, as described by Messrs. Louis and Sinclair.

The comparison between the measured force and the calculated force given in connection with Fig. 6, by which they differ by 11 per cent shows very satisfactory agreement between test and calculation, considering the nature of the test measurement and of the problem calculated. While the currents in the parallel parts of the jaw would tend to squeeze the jaws together and increase the friction, the explosive action of metal vapor or oil vapor in the jaw would tend to decrease the friction, even if it did not force the jaws apart as in Fig. 4. The authors state that "in most cases when the switch blew open the break jaws spread apart." It would be expected that this action would be more pronounced when a lock is used, since heavier currents would flow at the time of opening than would flow if no lock were used.

H. R. Woodrow: The paper by Messrs. Louis and Sinclair bring out two points which I would like to emphasize. One is the effect of the circuit external to the disconnecting switch

on the electromagnetic forces on the disconnecting switch. It is therefore, of paramount importance that the operating engineer or the consulting engineer take into account the conductors leading away from or in proximity to the disconnecting switch, in determining the forces on the switches.

The second feature is pulling stresses produced at the clips of the disconnecting switch, which tend to pull the switch in two. This makes it desirable to have the locking device constructed in such a way as to counteract the forces produced in line with the switch, as well as the opening force.

Fig. 8—Record of Change in Arc Diameter, Arc Voltage Arc Current, on Rupturing 260 Amperes 250 Volts. Vertical Carbon Electrodes.

J. C. Bank: I would like to ask Mr. Tritle what the chances are of developing his switches for out-door use? I am afraid that many of the operators will be somewhat hesitant about putting switches which produce large arcs indoors at the stations, but if they could be put outside, where more space would be available, it would be a very valuable feature.

O. H. Eschholz: Mr. James has referred to two important characteristics of the arc during the period of rupture, *i. e.* the critical or unstable arc length and the area of cross section of arc stream, that merit further comment.

The critical arc length on rupturing a direct current supplying energy to a resistance load is a function of the line current as well as of the voltage at rupture. For large initial current values it may be computed by assuming one inch length per 22 volts of the line or surge voltage. With the critical length of arc approximated, the contour of the magnetic field may be chosen to assure the application of a positive directional force on the arc stream until rupture occurs.

The selection of arc chute width, location of splitters or barriers and method of breaker ventilation, are determined chiefly by the area of the arc stream section. A narrow arc chute and improper barrier positioning may result in rapid switch depreciation, noisy break and excessive arc duration due to arc reignitions resulting from the trapping of large incandescent gaseous masses near the breaker contacts.

Although the exact determination of the arc stream section is not necessary, some conception of its order of magnitude is essential. Through the use of an ingenious optical system devised by J. W. Legg, simultaneous records of arc voltage, arc current, and approximate arc width, as shown in Fig. 8, were secured. Although the sensitized film is affected by both the wave length and intensity of the radiated energy, it was possible, by the inspection of numerous films, and the known performance of various structures, to arrive at a working value of arc stream diameter. This was found to be roughly in inches, $D = 2t + 0.046\sqrt{I}$, where t is the thickness of arc envelope in inches and I the initial line current.

The effect of employing too narrow an arc box, or of confining the incandescent gases near the contacts, on arc rupture characteristics is shown in Figs. 9 and 10. For most purposes it was found convenient to determine the arc core section by assuming a current density of 600 amperes per square inch and an envelope thickness varying from ¼ in. to ½ in. depending upon the magnitude of the initial current and the applied voltage.

With the development of similar fundamental data and knowledge of operating principles, it has been found possible to extend the field as well as to place the design of magnetic blowout breakers on a similar plane with that of other electrical apparatus. I am therefore in hearty accord with Mr. Tritle' conclusions that the limiting values of current and voltage that may be successfully ruptured in air have not been reached by service requirements.

J. F. Tritle: I wish to thank Mr. James for his very excellent contributions to the subject, having in mind particularly Mr. Jamieson's remarks on the desirability of rupturing these arcs in the smallest possible space. It seems to me that any device or combination of devices which helps in doing this materially advances the art.

The arc barrier placed transverse to the arc stream, described by Mr. James, certainly cuts down the amount of vapor, and increases the rupturing capacity of a given design. We also made tests on arc barriers of this kind and our results more or less checked Mr. James' results. However, when rupturing high power circuits at 600, 1500, 3000 and 6000 volts we obtained materially better results from the arc suppressor plates, which split the arc into a plurality of multiple connected paths.

Of course, the number of arc suppressor plates and the width of the slots must be properly proportioned for each particular design so as to provide for the exit of the maximum arc with the attending hot gases. We consider it an advantage to have the

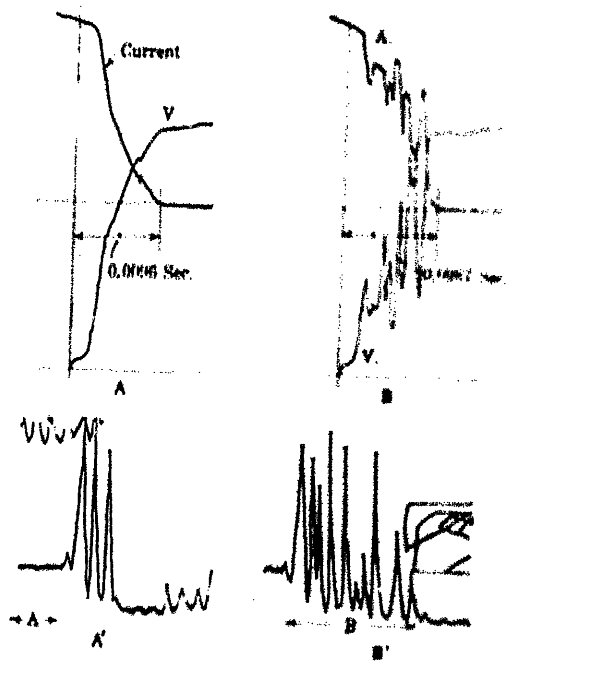


Fig. 9—Variation in Arc Current, Arc Voltage and Arc Noise on Rupturing 500 Amperes, 600 Volts, Resistance Load, in a Magnetic Blowout Field.

A and *A'*—Arc passing through center of arc box.

B and *B'*—Arc impinging against wall of arc box.

The switch noise intensity was approximately recorded by securing the oscillographic record of resistance variation in a granular-carbon type of telephone transmitter, upon the impact of sound waves. It will be noted that the current and voltage changes in *A* are quite regular, while in *B* both oscillate at moderately high frequencies. These oscillations produced a ripping or tearing noise in *B* having a higher intensity and pitch than the more muffled sound in *A*.

width of the arc box or the slots less than the normal diameter of the arc stream, as this arrangement forces the arc stream to take an elliptical shape, thus giving the maximum area in contact with the arc chute sides for cooling effect.

Our tests indicate, that as the normal cross section of the arc stream is reduced the arc resistance is increased and therefore the critical arc length is reduced. When the arc suppressor plates and narrow slots are used, we can assume in excess of 40 volts per inch length of arc rather than the figure of 22 volts mentioned by Mr. Escholz.

Regarding the instability of the transient parallel arcs it

lustrated in Fig. 10 of the paper, it is true that these arcs are very unstable, but photographs taken looking into all the slots distinctly show the hot vapors coming out of all of them, particularly when rupturing heavy currents. We have not been able to measure the exact distribution of current, and it is probable that the final rupture of the circuit takes place in one slot. The other slots and suppressor plates, however, are effective in absorbing energy from the circuit when the arc stream current is the highest.

Mr. Jamieson commented on the space required for rupturing the circuit with this air break device. I agree that the amount of space, 43 by 28 inches, appears rather large. However, this particular contactor was really designed for a lower voltage. That is, when we started out we had in mind rupturing only about 2500 volts, and something like 1500 to 2000 amperes. As the tests developed, we found we were able to rupture a great deal more power than that. If the arc chute had been designed especially for the higher voltage and current, the amount of vapor outside of the arc chute could have been very materially decreased. Fig. 24 is more nearly illustrative of normal conditions. In this test 5000 volts and 2300 amperes were ruptured, and the luminous vapors came out only four inches. In addition, it is possible to put covers over the front of the arc chute so as to direct the vapors. For instance, on a three-phase circuit you can direct the vapors from one phase up, the second phase out and the third phase down so as to practically eliminate the danger of short circuits between phases. Regarding the effect of the passage of the gases through the arc chute, It is quite possible to design both the arcing horns and the arc chutes side to have a very long life. The arc is moved through the arc chute so quickly that it doesn't have time to rapidly erode or burn away any one particular spot. One of the outstanding advantages of the air break contactor is the large number of short circuits or heavy currents which may be successively ruptured without attention to the arc chutes and current carrying parts.

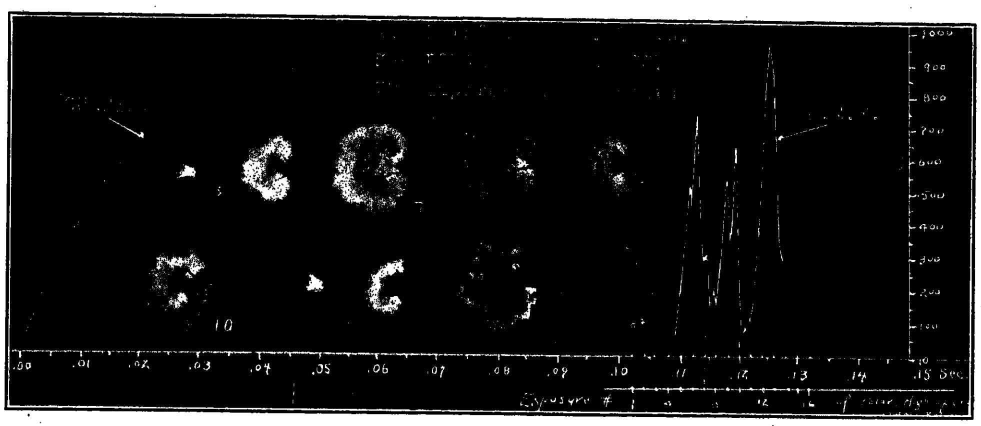

Fig. 10—Arc Re-Ignitions

Arc rupture characteristics of an experimental switch under conditions causing pocketing of incandescent, conducting gases in region of contacts. Note arc stream development and the two subsequent arc re-ignitions at the contacts shown both in the oscillographic and photographic records.

Mr. Trombetta asked about the progress of development work to decrease the amount of gases. The arc suppressor plates, arc barriers and the arrangement described by Mr. Creighton are the most effective means that I know of.

Regarding the effect of inductance and speed of rupture on the length of the arc, inductance increases the arc voltage, so that necessarily in rupturing an inductive circuit a much longer arc results than from a non inductive circuit. I don't know that there is any particular relation between speed of rupture and arc length.

Mr. Bank inquired about the chances for outdoor installations. The type of contactor described has all the parts exposed, and for outdoor service it would be necessary to provide a switch house or enclosure to protect it against the weather.

The design shown in Fig. 14, is arranged for both cam operation and for remote control by means of a solenoid so that it would be suitable for this kind of an installation or for mounting on galleries in the main station at a distance from the operator.

C. T. Sinclair: We realize the short-comings and incompleteness of our tests, particularly with regard to the effect of return conductors on adjacent switches carrying short-circuit currents. For example, our tests in only one or two instances were concerned with the effect of an adjacent conductor, as explained in the description relative to Fig. 5. But where we have three disconnecting switches located in compartments relatively close together, it is evident that a short circuit between phases will produce forces, as Mr. Woodrow and Mr. Jamieson brought out, on the other switches which will mutually react on one another. The nature of the short circuit will determine the ph se displacement of the several currents involved and consequently any calculation would have to take this displacement into consideration.

I was very much interested in the switch described by Mr. Jamieson which is apparently very similar in principle to Mr. Rickett's switch; that is, a switch in which the current passes straight through the conducting elements. In Fig. 32 in the paper is shown a cam lock switch which was designed by F. T. Leilich of Baltimore. This switch was constructed partially to take care of the difficulty as outlined by Mr. MacNeill, that the operator might not close the switch far enough to cause it to lock; in case this switch is even partially closed the cam lock will hold effectively. The tests on this switch are unfortunately, not complete.

Regarding the criticism of Mr. Liversidge, I would like to say this: that the authors attempted to bring out these very points in this paper, that the *combination* of lock, switch and insulators is of paramount importance. This is simply another illustration of the fact that a chain is no stronger than its weakest link, and apparently in the switch referred to by Mr. Liversidge, the weakest link is in the insulator and mounting. I assume the reference is to Fig. 31, which is a switch that was submitted to us for test by a manufacturer. We requested that the manufacturer send us a switch with *heavy duty insulators*. Not being familiar with this particular manufacturer's design, we could only assume that we had received the switch with insulators as requested by us and as specified by them.

H. C. Louis: I would like to accentuate the fact that it is not our intention in this paper to criticise for the sake of condemnation any particular designs or makes of disconnecting switches but to impress on manufacturers and operating companies the importance of understanding and taking care of the various factors involved. Mr. Liversidge in his discussion has stated that the performance under our tests of a certain lock was not due to the design of the lock itself but to other circumstances. This is another example of the necessity of considering all factors involved, which as an operating man, I can appreciate very much.

A piece of apparatus is installed, designed and expected to do certain things; it fails to do so, perhaps due to secondary effects, not previously realized; the operating company suffers severe inconveniences and losses, and the manufacturer may be compelled to change it. So, therefore, it seems that if such facts as are brought out in this paper are not taken as merely adverse criticism but as an intended help, for all concerned, both manfacturer and user will be benefited.

The Physical Nature of the Electrical Breakdown of Solid Dielectrics

BY KARL WILLY WAGNER

Telegraphen-Technisches Reichsant, Berlin

WHILE the physical phenomena in connection with the electrical rupture of gaseous insulators have been thoroughly investigated by J. J. Thomson, J. Stark, J. Townsend, J. B. Whitehead, F. W. Peek, Jr., and many others, the nature of the breakdown in solid and liquid insulating materials has up till now remained in complete obscurity.

According to the prevailing opinion the rupture takes place at the moment when the density of the electrical field exceeds a certain limit at any point in the insulator. This is called the electrical strength of the material and is based on a reasoning analogous to that which gave rise to the theory of mechanical resistance against a breakdown.

However, there are recorded observations about the rupture of insulating materials which one is unable to reconcile with the general opinion that the rupture takes place as soon as the electric field strength exceeds the critical point. I made such an observation during the year 1905, and as it made me at that time doubt the correctness of the existing theories I shall endeavor to discuss it here.

Fig. 1 shows the cross-section of a concentric cable. A number of these cables, with various ratios of R to r, that is the ratio of the outside diameter of the insulation to the inside diameter, were measured for breakdown voltage. From this the maximum field density E,

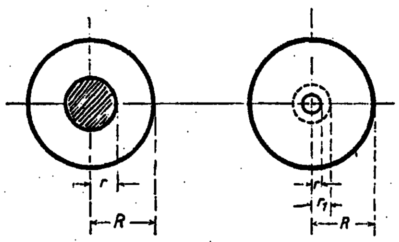

FIG. 1

existing along the radius r was calculated. The result was that as long as the ratio $R:r$ did not exceed a certain limit, approximately 2, the maximum field density was equal to that which existed when rupture took place on flat plates of the same material, namely $E = 10{,}000$ volts per mm. For large values of R to r, however, the rupture took place after E had increased to about 15,000 volts per mm.

Some one immediately suggested as an explanation that the inner layers of the insulation had been ruptured after E had exceeded 10,000 volts, and that as a result the diameter of the conductor had in effect increased from r to r_1, with a consequent decrease in the maximum field density even while the tension remains the same.[1]

In order to test this assumption a cable-section was subjected a certain length of time to a tension nearly reaching the limit, so that at least the inner part of the insulation from r to r_1, was subjected during this period to a field density far in excess of the rupture limit. Then the paper insulation was unwound till the supposedly ruptured part from r to r_1 was reached. What remained of the cable section was then provided with a metal cylinder, and subjected to an electrical tension. The test showed it to be perfectly intact and it ruptured only at the normal limit, (10,000 volts per mm.). It was thereby proved that such a material can be subjected without disadvantage to an electrical field density far above the normal.[2] This one and other tests show, therefore, that the analogy generally assumed between electrical and mechanical strength does not exist. Moreover I dare claim that this assumed analogy has not in the least promoted a clear understanding of the electrical phenomena; on the contrary it has been an obstacle in the way of understanding the true nature of things.

I observed during the numerous rupture tests which I conducted some years previously that the material prior to rupture heated up considerably in some places, while other parts remained comparatively cool, and that the rupture always took place at such a spot after it had become hot. If the current is interrupted before the rupture has taken place, and the heated spot is examined after cooling down, it is found that the electrical qualities of this spot do not differ materially from the spots which remained cooler.

Why then does the rupture occur at the heated spot?

It is a well known fact that the resistance of the insulation decreases rapidly with increasing temperature. The hot spots therefore take up a larger current than the adjoining cooler spots, which are subjected to the same tension. It is evident that the hot places receive more energy than the cooler ones, with the result that the temperature difference further increases. It is easy from this to picture that at a certain tension an

1. Similar experiments were undertaken later by M. Klein, E. T. Z. 1913 p, 851.

2. A. Russel, in a paper in the JOURNAL of the I. E. E., Vol. 40, 1907, p. 6 has developed a theory based upon the same assumption.

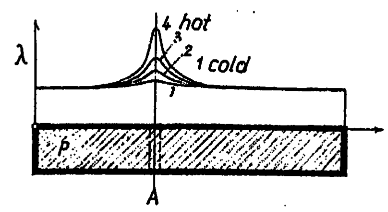
Presented at the A. I. E. E. Spring Convention, Chicago, Ill., April 20, 1922.

unbalanced condition takes place, and the hottest spot finally burns.

This is my theory of the physical occurrences at electrical ruptures of solid insulators.

It could be said that although this analysis is apparently simple, at first it seemed difficult to draw comprehensive conclusions as to the occurrence of ruptures depending on various factors. However, this did prove possible, and I will show in the appendix how by making certain simple assumptions this proved to be the case.

For the present time I wish to point out only the general lines of the theory and the most important



A = spot with higher conductivity

Fig. 2

conclusions drawn from it, and at the same time to show in just what manner I have endeavored to disclose the nature of the rupture phenomena by experiment. The work is not as yet concluded, but the data already obtained are sufficient to support the conception represented in this paper.

Take a plate P of insulating material (Fig. 2) provided on both sides with electrodes. This plate will not possess the same electric conductivity all through its section, but on the contrary, due to the lack of homgeneity in the material the conductivity will be higher in some places than others. Let A be such a place.

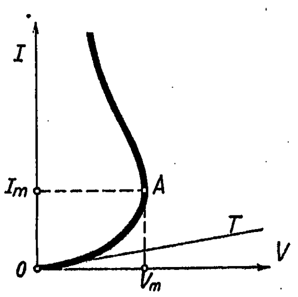


Fig. 3

Curve 1 may represent the original distribution of conductivity in the plate section. Subject the plate now to a certain potential, and a current will traverse the plate. The current density will be a little higher in A than elsewhere. The insulating plate is heated by the current, and to a larger degree in A than elsewhere. Now as the conductivity increases directly with increasing temperature, the conductivity distribution of the plate under electrical tension, will be represented by curve 2. Note the increase at A over curve 1. If, at the increased temperature at A, the heat conducted to the surroundings of A is equal to the heat created in A, curve 2 will remain stable. If the opposite is true, then the curve will become still more pointed. This also may happen, (curve 2 representing a stable distribution) if the electrical tension V is increased (curve 3). Finally a condition occurs represented by curve 4, during which the created heat grows faster than the heat conducted to cooler parts, and the temperature grows more and more rapidly and similarly the conductivity, and the current, until the rupture takes place at A.

The above leads to consideration of a thin thread of the insulating material.

The initial resistance of the thread may be R. As long as the voltage V remains small, the heating according to Joules law remains small and the resistance constant.

The current voltage characteristics (Fig. 3) are thus a straight line $O\ T$. With increasing tension the thread heats up and the resistance decreases, consequently the current increases more rapidly in proportion to the tension. Finally a point will be reached when the resistance decreases further, without a corresponding increase in the voltage. This is the rupture point and the voltage V_m, is the breakdown voltage.

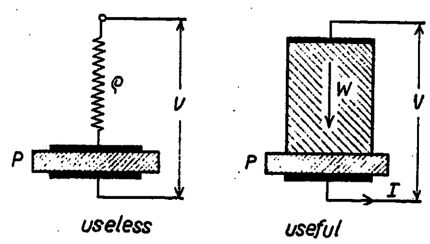

Fig. 4

It is easy to determine by experiment the characteristics up to point A. The portion above A represents the unstable condition, and this is passed at an immense speed and can therefore not be observed.

After I had made the above analysis, I was, of course, tempted to make an experimental test. At first I could see no possible way of determining the portion of the curve above A. Other work took up my time and interest and it was not until I began investigations on the nature of dielectric losses and their laws, that my attention was again directed to the rupture problem. In 1914 when these investigations were concluded[3] I found time to experiment again with the rupture phenomena.

I had previously tried to disclose the characteristics of the curve above A by means of connecting a high

3. The theory of imperfect dielectrics, "Annalen der Physik, Vol. 40, 1913, p. 817. "Dielectric Viscosity," *Elektrotechn. Zeitschr.* 1913, p. 1279. "Explanation of the Dielectric After-Effect according to "Maxwell's Theory," *Archiv. f. Elektrotechnik*, Vol. 2, 1914, p. 371. Dielectric properties of some insulating materials," *Archiv. f. Elektrotechnik*, Vol. 3, 1914, p. 67.

resistance in circuit with the plate of insulating material (Fig. 4, at the left.)

I hoped that this resistance would perform in a manner similar to the stabilizing resistances of electric arcs, and thus allow an observation of the points of the curve above A. This, however, proved futile.

Even when using very high resistances and corresponding high tensions V_o, it was impossible to reach beyond point A. Always a complete rupture took place, as soon as A was reached.

The following explanation was found for this unexpected result:

The insulating body with its two metal electrodes forms a small plate condenser.

At point A, where the insulating material begins to give way, an amount of energy $1/2\ CV_m^2$ is stored in this condenser, C being the capacity of the condenser. This stored energy jumps at once at the weak spot and feeds during a short time a much stronger current than the ordinary source of current, could supply over the resistance.

In other words the energy required for rupture *i. e.*, local burning, is supplied by the electrical field energy of the condenser. I found the following way out of this difficulty.

The resistance should form part of the electrode itself, *i. e.*, make the latter of poorly conducting material. The best material would be such as to lead the current only in one direction through the electrode that is in the direction of the arrow (Fig. 4, at the right). With such an electrode each thread of the material would be fed with current independently of all others through a constant resistance.

The current supply of a weak thread, could not come from adjoining parts, as occurs with metallic electrodes just before rupture.

The material which, most nearly meets the desired specification, is wood although it is not quite perfect.

Its conductivity across the grain is not zero, but it is considerably smaller than in the direction of the grain.

By means of impregnation and the choice of suitable kinds of wood the required range of resistances can be procured.

Thus, in the beginning of 1914, it was possible, after overcoming several experimental difficulties, to plot curves for the rupture characteristics of different kinds of paper, gutta percha and rubber. They showed the expected form of Fig. 3. Unfortunately the experiments had to be discontinued when the war broke out and could not be resumed until 1919. Since then I have been graciously assisted by Messrs. Stahl, Kupfmuller, Mitzel, Dr. Dieterle and Ludwig in carrying out the experimental work.

The method of recording the characteristics was as follows:

The VI curves were taken with the arrangement shown in (Fig. 4, at the right) both with the wood electrode alone and with plate P inserted.

The difference of the tensions read for the same current in both cases is the tension of the insulating plate P belonging to this current.

As source of current we used partly a rectifier fed with 500 cycles alternating current, and partly an electrostatic induction machine.

In order to avoid using too high tensions, V, the insulating material was tested in the form of thin plates (in some cases down to a few hundredths of a millimeter). The tests covered so far include different kinds of paper,

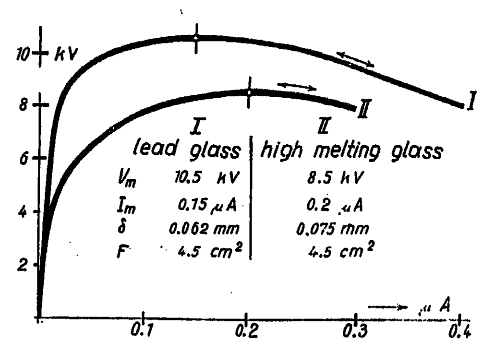

Fig. 5

oiled paper, paraffined paper, gutta percha, vulcanized rubber, cellon and similar materials, glass and mica.

Due to lack of space, I can give only a short report of the tests. Therefore, I shall confine myself to a description of the most important results in general.

In Fig. 5 there are represented the breakdown characteristics of two different kinds of glass (lead glass and high-melting glass). Fig. 6 shows the characteristic of mica; Fig. 7, those of cellon (two plates of different thickness); Fig. 8, that of another product manufactured from

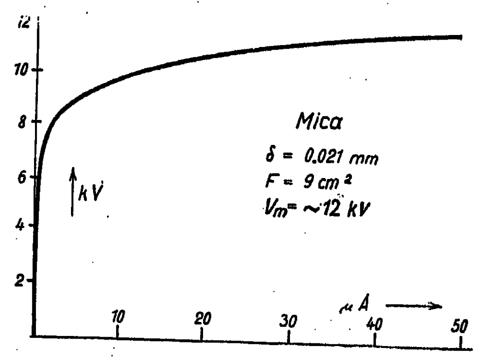

Fig. 6

cellulose. In the latter case, the wooden electrode had been covered with tinfoil. This experiment therefore relates to an arrangement as represented at the left of Fig. 4. According to the remarks formerly made, we observe the current suddenly increasing as soon as the breakdown voltage V_m is reached, while the tension diminishes to a small fraction. A hole burnt into the sample was found by inspection after the experiment.

The following statement has been proved to be of general validity:

The rupture voltage is in direct proportion to the thick-

ness of the tested material and independent of the size of the plate.

As an example, the data from a series of tests with gutta percha are shown in Fig. 9.

Of course, the particular characteristics of different samples of the same material do not coincide exactly due to the lack of homogeneity of any dielectric, and therefore the preceding statement relates to the mean voltage obtained from a number of equal tests.

When testing for ruptures with the usual metallic electrodes, the rupture voltage, as we know, grows

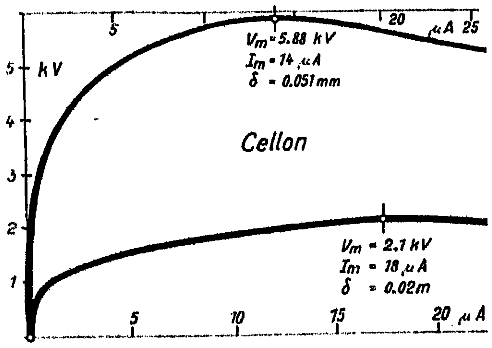

Fig. 7

slower than proportional to the thickness of the plates. This results from the distortion of the dielectric field on the edges of the plates. On the other hand with the method herein described the edge effect has very little influence, because the current flowing at the edges is only a very small portion of the total current, plotted in the characteristic curve.

If the characteristic curve of a transparent material is carried on to currents beyond the rupture point, and the material is inspected under a magnifying glass or a microscope, it is often found disturbed at a large number

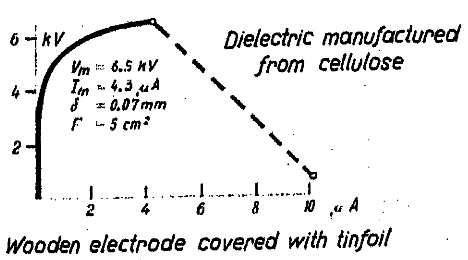

Fig. 8

of points and rendered dull. The characteristic obtained is therefore, the *mean* characteristic of all these "spoiled" paths. It may be understood that the material at these places has been spoiled by excessive current. When decreasing the tension from point B downward (Fig. 10, at the left), the curve 2 is obtained. This curve however, contains also the current of those paths, which were heated only and thus made better conductors, but not burnt.

By waiting until the material has cooled off, and then again taking the characteristics, curve 3 is obtained.

On the other hand if the characteristic is taken for the first time up to a point B, below the maximum, and then down again, the two characteristics practically come together. (Fig. 10, at the right). The fact that they do not cover each other entirely, demonstrates that several particularly bad spots had already undergone damage during the rising curve.

The characteristic shown in Fig. 11, relating to a thin sheet of vulcanized rubber may be taken as an example, representing the case just mentioned.

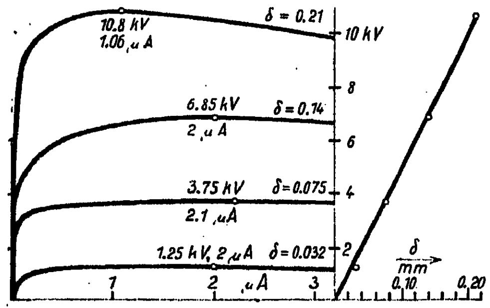

Fig. 9

The hump on the characteristic curve of oiled paper (Fig. 12) is by no means due to an error in the test, but has been regularly observed with numerous tests with the said dielectric if the whole of the characteristic curve was passed in a short time. If, on the contrary, the characteristics were taken slowly the regular shape was obtained as represented by the dotted curve in Fig. 12.

With most of the glasses the rising branch of the characteristic does coincide with the descending branch (see Fig. 5). In such cases the characteristic

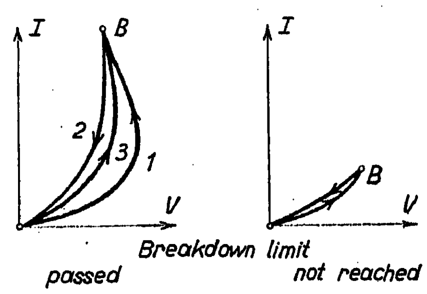

Fig. 10

curve may be passed several times up to points far beyond the rupture point without doing any damage to the dielectric. Part of the glass plates cracked when some point of the curve beyond the breakdown voltage was reached; that was obviously due to overheating of particular spots of the plates.

As a result of the lack of homogeneity of the material, the rupture voltage determined as usual with *metallic electrodes* is evidently depending on the electrode area. Each rupture test only gives the rupture voltage of the worst spot of the tested sample.

If the same number of tests is made on small and large areas, the chances of finding bad spots in the latter case is greater, and consequently with large areas a lower mean value of rupture tension is arrived at.

Geweeke & Krukowski[4] have proved the correctness of this assertion. They made n times as many tests with small electrodes of area f as with large electrodes of area $n \times f$; then they took from each series of n successive tests with small areas the lowest rupture voltage. The mean value of all these minimum voltages was found equal to the mean value of all the rupture voltages with large areas.

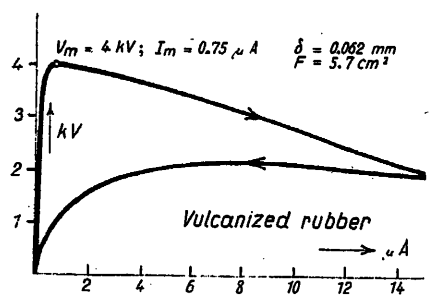

Fig. 11

I repeated these tests together with Mr. Stahl and found the same results. Mr. Stahl worked out a method of calculation, to determine the mean rupture voltage for any larger area from the distribution curve of the rupture voltages with small areas. Mr. Stahl's method is based upon the calculation of probabilities, and his results were also found in conformity with the test results. With the wood electrode test the mean breakdown voltage is determined, and this, of course, is independent of the area of electrodes except perhaps for very small areas.

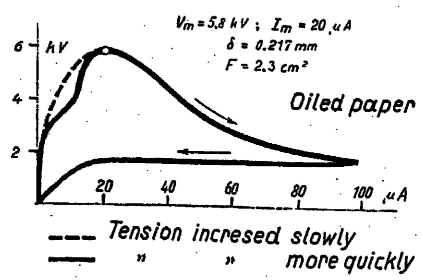

Fig. 12

It appeared desirable to follow through mathematically the thought that an insulating plate is ruptured by the overheating of the material caused by the current flowing through a weak spot. It could be hoped to find in this way certain relations which could be tested experimentally.

I do not wish to take up much of your time by producing here mathematical deductions,[5] but shall briefly give my considerations and the conclusions derived.

If we increase the voltage slowly so that thermic equilibrium is maintained in the material, the electrical energy delivered to one fibre $R\,I^2$ must equal the amount of heat energy per second conducted from that fibre to the cooler surrounding parts of the material.

If we know the relation of the resistance R of the fibre to the temperature, we are able to calculate the characteristic current-potential curve of the fibre (V = function of I) by means of the mentioned equilibration condition.

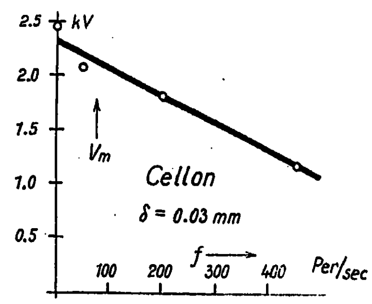

Fig. 13

It is well known that the resistance of insulating material decreases rapidly with increasing temperature, and that we can easily express this relation through some exponential or other function of the temperature.

With these and similar assumptions I have succeeded in calculating the characteristics of a material I. E., to determine the curve by means of the electrical and thermal constants of the material.

It is remarkable that the result of these calculations and the considerations mentioned further on depend very little on the specific assumption which has been made about the decrease of the resistance with increasing temperature. The shape of all these calculated characteristics conforms fairly well with the observed ones; and the theory is proved that the rupture voltage is proportional to the plate thickness.

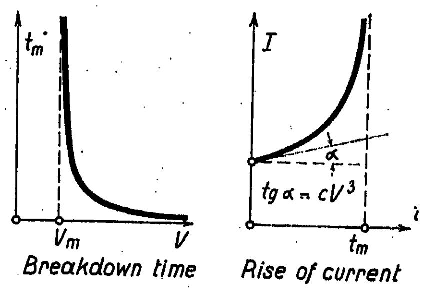

Fig. 14

Insulating material subjected to *alternating voltage* is heated not only by the current, but also by the dielectric losses. These are approximately proportional to the frequency and the square of the tension. If we consider these dielectric losses in the heat equilibrium condition,

4. *Archiv. f. Elektrotechnik*, Vol. 3, 1914, page 63.
5. See the Appendix.

we find that the rupture voltage with alternating current must be smaller than with direct current. With low and medium frequencies it decreases in a linear function of the frequency (Fig. 13). This law was corroborated by our tests, which up to now covered frequencies from 0 to 500 cycles.

Until now, it has been generally assumed that the maximum or peak value of the voltage curve would be responsible for the rupture. According to the overheating and burning theory of rupture, it is the *effective tension* which might be expected to be mainly responsible for the breakdown. There would exist, therefore, a very distinct difference between gaseous and solid dielectrics. This is a highly important conclusion of the theory, and it had to be borne out by test. By elimination of parts of a sine wave, a tension curve with a low effective value but a high peak was generated. The effect of this tension on the insulating material was very approximately proportional to the effective value and the short-lived high peak could be a considerable multiple of the rupture voltage, without causing a rupture.

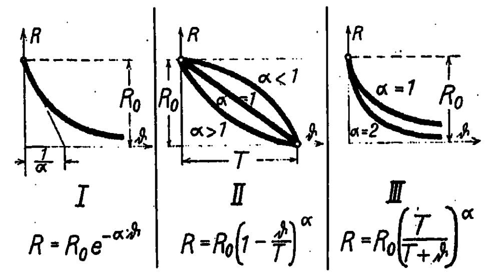

FIG. 15

Following these tests, we made tests with short single shocks, similar to those used by Mr. Peek in testing spark gaps. These shocks were created by a non-periodic condenser-discharge. In this case the effective value of the impulse, $\int_0^\infty V\, d\, t$ apparently governs the effect on the insulating material. These tests, however, are not concluded as yet.

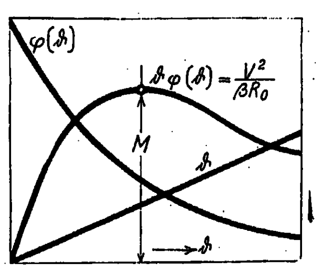

FIG. 16

If the tension exercised on a piece of insulating material is increased rapidly, the breakdown does not occur instantaneously, as soon as the rupture voltage is reached. We can, therefore, subject the material for a short time to a tension V, which exceeds the normal rupture tension without a rupture taking place.

For each voltage V, exceeding the breakdown voltage we find a time t_m, which elapses before the rupture takes place. (Fig. 14, at the left). The retarding of the rupture comes from the fact that with each temperature increase, heat energy has to be stored in the insulating material. This of course requires time.

The theoretical treatment of this problem showed the remarkable fact that the form of the curve (Fig. 14) does not depend on the kind of the tested material, if the scales of time and voltage are properly chosen. This means that the ratio of the heat capacity to the heat conductivity of the material has to be taken as unit of time and the breakdown voltage as the unit of voltage.

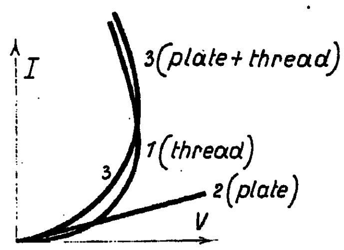

FIG. 17

The current traversing the insulating material increases with the time as shown in Fig. 14, at the right. This is another relation which may be calculated theoretically.

An interesting conclusion of such calculation is that the increase of current in the beginning is proportional to the third power of the tension V, namely: $\tan \alpha =$ const. V^3. The truth of this relation was proved by our tests.

According to the common theory, *i. e.* the so-called maximum electrical strength theory an insulating material exposed to a non-uniform electrical field should rupture as soon as the field—strength has passed a certain limit anywhere within the dielectric. But this conclusion has proved to contradict experience in many cases and may also not be justified by the author's theory. The dielectric is capable of withstanding an overstraining without damage, supposing that the less strained parts of the dielectric contained in the path of the current prevent the latter from increasing excessively. Rupture does not occur before the condition of the *whole* path of the current has become unstable.

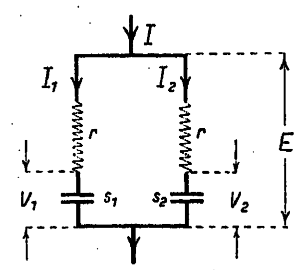

FIG. 18

The conformity of all these theoretical conclusions to the observed tests, may, I believe, serve as a strong support, for the correctness of the idea that the electrical rupture of solid dielectrics is a phenomenon of overheating by current.

By this explanation the breakdown phenomena, mysterious as they have been hitherto, are shown to be the consequence of well-known physical laws and at the same time are opened to numerical treatment.

Appendix

1. Calculation of the Breakdown-Characteristics

As explained before, breakdown occurs as soon as the condition in a thread-shaped channel through the insulating material has become unstable. This idea, as represented by Fig. 2, leads to a numerical calculation by the following assumptions.

a. Only the resistance of the thread-shaped channel shall vary with the voltage while the resistance of the remainder of the dielectric is supposed to be independent of the voltage variations.

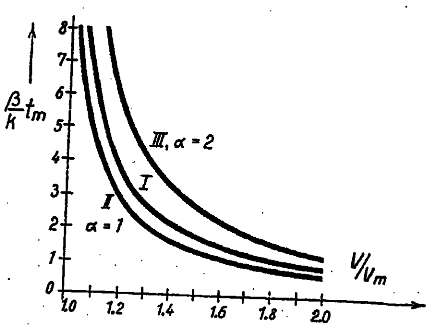

Fig. 19

b. The resistance of the thread is a function of the temperature. The calculations are based upon the following resistance laws:

$$R = R_0\, e^{-\alpha\theta} \qquad \text{(I)}$$

$$R = R_0\,(1 - \theta/T)^{\alpha} \qquad \text{(II)}$$

$$R = R_0\left(\frac{1}{T+\theta}\right)^{\alpha} \qquad \text{(III)}$$

θ = temperature of the thread above that of the surrounding parts of the insulator; R_0 = resistance of the thread at the initial temperature ($\theta = 0$), R = resistance of the thread at the temperature θ, α, T = constants.

By the Law I the resistance R decreases with increasing temperature according to an exponential function (Fig. 15, at the left), but does not vanish for any finite value of the temperature.

By the resistance Law II, R vanishes at a finite temperature T, which may be called the burning temperature of the insulating material. According to the value of the exponent α, the resistance decreases in a linear manner ($\alpha = 1$), or with slackening ($\alpha > 1$), or with increasing speed ($\alpha < 1$), see Fig. 15.

According to Law III, the resistance decreases continuously with the temperature, the rate of diminution being the larger the higher the exponent α is chosen (Fig. 15, at the right).

For most of the dielectrics investigated until now, the resistance Law III seems to give the best approximation to the actual variation of the resistance with the temperature.

c. If the voltage V be increased so slowly that the stationary condition is reached for any value of V, the power $V\,I$ absorbed in the thread must be equal to the quantity of heat carried off to the surroundings. This quantity increases with the temperature θ. If we suppose the heat to be carried mainly by conduction, the flow of heat will be in proportion to the temperature, and the condition of equilibrium is expressed by the equation

$$V\,I = \beta\,\theta \qquad \text{(IV)}$$

β being the coefficient of heat conduction. In the case that radiation of heat is to be taken into account, the flow of heat from the thread to the surroundings will increase with a higher power of the temperature, according to the equation

$$V\,I = \beta\,\theta^n \qquad \text{(V)}$$
$$n > 1$$

The following considerations are confined to the equation (IV), the results obtained in this way being in sufficient agreement with the observed data.

The equation of the $V\,I$—characteristics is obtained by eliminating the temperature θ from (IV) with the aid of the resistance law.

By Law I:

$$1/R = I/V = 1/R_0\, e^{\alpha\theta} = 1/R_0\, e^{\frac{\alpha}{\beta} V I}$$

or

$$f(V, I) = I/V - 1/R_0\, e^{\frac{\alpha}{\beta} V I} = 0 \qquad \textbf{(1)}$$

The characteristics computed from (1) have the shape represented by Fig. 3. The breakdown voltage V_m and the corresponding current I_m are obtained from the maximum condition

$$\frac{\partial f}{\partial I} = 0, \text{ for } V = V_m,\ I = I_m \qquad \textbf{(1a)}$$

in connection with the equation of the characteristic curve

$$f(V_m, I_m) = 0 \qquad \textbf{(1b)}$$

From (**1**), (**1a**), (**1b**), we get

$$\begin{cases} 1/V_m - \alpha/\beta\, V_m/R_0\, e^{\frac{\alpha}{\beta} V_m I_m} = 0 \\ I_m/V_m - 1/R_0\, e^{\frac{\alpha}{\beta} V_m I_m} = 0 \end{cases}$$

and further

$$\left.\begin{aligned} V_m &= \sqrt{\frac{\beta R_0}{\alpha e}}\,;\quad I_m = \sqrt{\frac{\beta e}{\alpha R_0}} \\ R_m &= V_m/I_m = R_0/e = 0{,}36\, R_0 \end{aligned}\right\} \qquad \textbf{(2)}$$

β and R_0 are both in direct proportion to the length of the thread, *i. e.* to the thickness of the insulating material. Consequently the *breakdown voltage* V_m *is in direct proportion to the thickness of the dielectric,* and the current I_m is independent of the thickness.

Supposing the *resistance law II,* we get

$$1 - \theta/T = (R/R_0)^{1/\alpha} = \left(\frac{V}{I R_0}\right)^{1/\alpha}$$

But from (IV) $\theta = \frac{V I}{\beta}$ and

$$f(V, I) = 1 - \frac{V I}{\beta T} - \left(\frac{V}{I R_0}\right)^{1/\alpha} = 0 \qquad \text{(3a)}$$

(3a) is the equation of the characteristics. By a reasoning similar to that given above, we find

$$\left(\frac{\partial f}{\partial I}\right)_{V_m, I_m} = -\frac{V_m}{\beta T} + (V_m/R_0)^{1/\alpha} \cdot I_m/\alpha^{\frac{1}{\alpha}\alpha} = 0$$

$$(V_m, I_m) = 1 - \frac{V_m I_m}{\beta T} - \left(\frac{V_m}{I_m R_0}\right)^{1/\alpha} = 0$$

$$V_m = \frac{\alpha^{\alpha/2}}{(1+\alpha)^{\frac{1+\alpha}{2}}} \sqrt{R_0 \beta T};$$

$$I_m = \frac{(1+\alpha)^{\frac{\alpha-1}{2}}}{\alpha^{\alpha/2}} \sqrt{\frac{\beta T}{R_0}} \qquad \text{(3b)}$$

$$R_m = V_m/I_m = R_0 \left(\frac{\alpha}{1+\alpha}\right)^{\alpha}$$

As before with the resistance law (I) V_m is in direct proportion to the thickness of the dielectric, while I_m is independent of it.

With the special value $\alpha = 1$ (linear decrease of resistance).

$$V_m = 1/2 \sqrt{R_0 \beta T}; \quad I_m = \sqrt{\frac{\beta T}{R_0}} \qquad \text{(3c)}$$

With the *resistance law III,* the equation of the characteristic takes the form

$$(V, I) = V (\beta T + V I)^{\alpha} - R_0 (\beta T)^{\alpha} I = 0 \qquad \text{(4a)}$$

By proceeding in the same way as before, we obtain the expressions

$$V_m = \frac{(\alpha-1)^{\frac{\alpha-1}{2}}}{\alpha^{\alpha/2}} \sqrt{R_0 \beta T} \qquad \text{(4b)}$$

$$I_m = \frac{\alpha^{\alpha/2}}{(\alpha-1)^{\frac{\alpha+1}{2}}} \sqrt{\frac{\beta T}{R_0}} \qquad \text{(4c)}$$

As a very remarkable fact we note that V_m and I_m are depending on the thickness of the dielectric, on the initial resistance and on the heat conduction coefficient β by the same functions as in the cases of the resistance Laws I and II.

The special value $\alpha = 1$ gives $I_m = \infty$ and $R_m = 0$; the characteristic approaches asymptotically the value V_m with increasing current. The values of α below 1 are without physical meaning in the theory developed here, as they lead to imaginary values of V_m.

As the three resistance laws *I, II, III* lead to quite similar results, we may imagine the existence of a general law

$$V_m = \text{constant} \sqrt{R_0 \beta},$$

which is independent of the particular resistance law. That this assumption is true can be shown as follows.

From (IV) we get

$$\beta \theta R = V^2$$

Now R is a function of the temperature, and we may put

$$R = R_0 \varphi(\theta)$$

φ being a function of θ with the initial value $\varphi(o) = 1$ and continuously decreasing with increasing temperature (Fig. 16).

From the preceding equations we obtain

$$\theta \varphi(\theta) = \frac{V^2}{\beta R_0}$$

Now the expression on the left side means the product of the ordinates of the curve $\varphi(\theta)$ and the straight line θ and is represented by the curve shown in Fig. 16, having an apex.[6] As the ordinate M of the apex does not depend on β or R_0, we have

$$V_m = \sqrt{M \beta R_0} = \text{const} \sqrt{\beta R_0},$$

q. e. d.

By determinating the breakdown characteristics *experimentally,* the current I observed is composed of the current through the breakdown channel and the current through the remaining part of the dielectric. If we suppose, that there is only one breakdown channel, *i. e.* one thread, the resistance of which depends on the voltage, while the resistance of the remainder is constant, the characteristic of the whole dielectric may be plotted by the following construction (Fig. 17). The characteristic of the breakdown channel is given by the curve 1, and the characteristic of the healthy parts of the dielectric by the straight line 2, the characteristic 3 of the whole of the dielectric is found by adding the ordinates of the curves 1 and 2.

If there are existing more than one weak channel the total characteristic is composed of the individual characteristics in a rather complicated manner. Fig. 18 represents the conditions with two weak channels s_1 and s_2. In series with each one we have the resistance r. With the same total voltage E applied, the two channels take different currents I_1 and I_2 and in

6. The existence of an apex is bound to the condition that, with θ increasing, ϕ decreases ultimately faster than $1/\theta$ does, which condition is fulfilled in all practical cases.

consequence are stressed with different voltages V_1 and V_2. But by the experimental determination of the characteristics the total current $I_1 + I_2$ is obtained as a function of a *mean* voltage, V, which is taken as the tension acting upon the weak threads. As the connection of V to the V_1 and V_2 is not known, we may say nothing but that the total characteristic must be an intermediate curve between the individual characteristics.

2. Dependence of the Breakdown Voltage on the Frequency

In the preceding considerations the weak thread is supposed to be heated only by the current according to Joule's law. With alternating voltages an additional heating occurs by dielectric losses. These are in direct proportion to the frequency of the current and to the square of the tension. The power produced in a thread of the capacity C amounts to

$$N = \omega C V^2 \cos \varphi = G V^2,$$

ω being the circular frequency, $\cos \varphi$ the power factor of the dielectric and G the dielectric leakance of the thread, $G = \omega C \cos \varphi$. In order to simplify the corrections in the preceding considerations required by the dielectric losses, we shall suppose the dielectric power factor to be independent of the temperature. In consequence G is a constant quantity for any given frequency.

The combined resistance, composed of the variable ohmic resistance R of the thread and the leakance G has the value

$$\overline{R} = \frac{R \cdot 1/G}{R + 1/G} = \frac{R}{1 + R G}.$$

$\overline{R}$ determines the proportion V/I, V being the voltage acting on the thread and I the component of the total current being in phase with V[7]. I is the sum of the ohmic current V/R and the leakage current $G V$. In the equation.

$$V/I = \frac{R}{1 + R G}$$

the resistance law (either I, or II, or III) has to be introduced, the temperature θ being determined according to (IV) by the power $V I$ and the heat conduction coefficient β.

With the resistance Law I, we get

$$V/I = \frac{R_0 e^{-\frac{\alpha}{\theta}}}{1 + G R_0 e^{-\alpha \theta}} = \frac{R_0 e^{-\frac{\alpha}{\beta} V I}}{1 + G R_0 e^{-\frac{\alpha}{\beta} V I}} \tag{6}$$

or

$$(V, I) = V + V G R_0 e^{-\frac{\alpha}{\beta} V I} - I R_0 e^{-\frac{\alpha}{\beta} V I} = 0 \tag{7}$$

7. The capacitive component of the current does not contribute to the heating of the thread and may therefore be left out of consideration.

This is the equation of the characteristic. If we apply the maximum condition

$$\frac{\partial f}{\partial I} = 0, \quad \text{for } V = V_m, \quad I = I_m,$$

$$I_m = \beta/\alpha \, 1/V_m + G V_m \tag{8}$$

The expression at the right of (8) has to be introduced into (7) in order to eliminate I_m. This done the factor

$$e^{-\frac{\alpha}{\beta} V_m I_m} = e^{-1 - \frac{\alpha}{\beta} G V_m^2} = 1/e \, e^{-\frac{\alpha}{\beta} G V_m^2}$$

appears. At tensions of the order of V_m the power absorbed by dielectric losses comes only to a small fraction of the power absorbed according to Joule's law. Therefore the exponent $x = \alpha/\beta \, G V_m^2$ is small as compared with unity, and in consequence

$$e^{-x} = 1 - x$$

holds very approximately, i. e.:

$$e^{-\frac{\alpha}{\beta} V_m I_m} = 1/e \, (1 - \alpha/\beta \, G V_m^2) \tag{9}$$

With (8), (9) and (7):

$$V_m^4 - \frac{e \beta (1 + R_0 G/e)}{\alpha G^2 R_0} V_m^2 + \frac{\beta^2}{\alpha^2 G^2} = 0$$

$$V_m^2 = \frac{e \beta (1 + R_0 G/e)}{2 \alpha G^2 R_0} \pm \sqrt{\frac{e^2 \beta^2 (1 + R_0 G/e)^2}{4 \alpha^2 G^4 R_0^2} - \frac{\beta^2}{\alpha^2 G^2}}$$

Only the root with the negative sign has a physical meaning as it gives for $G = 0$ the correct value of V_m according to equation (2), while the root with the positive sign leads to $V_m = \infty$ for $G = 0$. Therefore

$$V_m = \frac{e \beta (1 + R_0 G/e)}{2 \alpha G^2 R_0} \left[1 - \sqrt{1 - \frac{4 G^2 R_0^2}{e^2 (1 + R_0 G/e)^2}} \right]$$

With G small, as supposed, the root may be expanded according to the binomial formula, and nothing but the first term of the expansion need to be retained. By this procedure we get the final expression

$$V_m = \sqrt{\frac{\beta R_0}{\alpha e}} \left(1 - \frac{G R_0}{2 e} \right) \tag{10}$$

The first term on the right is the breakdown voltage with $G = 0$ (see equation 2), *i. e.* for direct current. The second term shows the decrease of the breakdown voltage with increasing frequency. In particular it is seen from (10) that V_m is a linear function of the frequency[8], as the same is true for G.

If we start from the resistance Law II or III, the same procedure as before may be followed. The mathe-

8. Of course the linear law holds only for low frequencies, for which G is small, as supposed.

matical derivations being of rather little interest only the results are given here.

Resistance law II, $\alpha = 1$:

$$V_m = 1/2 \sqrt{\beta R_0 T} \left(1 - \frac{R_0 G}{4}\right) \quad (11)$$

$$I_m = \sqrt{\frac{\beta T}{R_0}} \left(1 + \frac{R_0 G}{2}\right) \quad (12)$$

Resistance law III:

$$V_m = \frac{(\alpha - 1)^{\frac{\alpha-1}{2}}}{\alpha^{\alpha/2}} \sqrt{\beta R_0 T} \left[1 - \left(\frac{\alpha - 1}{\alpha}\right)^{\alpha} \frac{R_0 G}{2}\right] \quad (13)$$

As before with the Law I, we find a linear decrease of the breakdown voltage with increasing frequency, caused by the dielectric losses (see Fig. 13).

3. Influence of Time on the Breakdown Phenomena

According to the hypothesis (c) in part (1), we have assumed the voltage to be varied so slowly, that a stationary condition is reached for any value V of the voltage. This assumption shall be abandoned now. As an example we shall consider the case of a voltage V larger than the breakdown voltage V_m being suddenly applied to the dielectric at a certain moment $t = o$. We know from experience that the current passing through the dielectric increases continually (see Fig. 14, at the right) until the dielectric breaks down. The time t_m elapsed from the beginning of the phenomenon is obviously the shorter, the larger the voltage V has been chosen in proportion to V_m.

At any time between o and t_m the power $V\,I$ respectively V^2/R absorbed from the thread in which the rupture shall occur has to cover the flow of heat to the surroundings and the amount of heat stored up in the material forming the thread.

As the flow of heat equals $\beta\,\theta$ and the amount of heat stored up per second is expressed by $k \frac{d\,\theta}{d\,t}$, k being the heat—capacity of the thread, the law of conservation of energy takes the form

$$\beta\,\theta + k \frac{d\,\theta}{d\,t} = V^2/R \quad \text{(VI)}$$

R is a function of temperature, as per example, given by (I), (II) or (III).

Before we base further calculations upon one of the particular resistance Laws I, II or III, a general theorem shall be deduced, which is independent of the assumption of any special resistance law.

By differentiating Ohm's equation $I = V/R$ we get

$$\frac{d\,I}{d\,t} = -\frac{V}{R^2} \cdot \frac{d\,R}{d\,\theta} \cdot \frac{d\,\theta}{d\,t} \quad (14)$$

From this expression we may calculate the *initial gradient of current, i. e.* the slope of the tangent on the curve at the right of Fig. 14 at $t = 0$. In this point we have $\theta = o$ and therefore, from (VI)

$$k \frac{d\,\theta}{d\,t} = V^2/R_0 \quad (15)$$

The coefficient of resistance—variation with temperature $\left(-\frac{d\,R}{d\,\theta}\right)$ has, for $\theta = 0$, a certain positive value, say c.

With these terms we get

$$\left(\frac{d\,I}{d\,t}\right)_{t=o} = \frac{c}{k\,R_0^3} \cdot V^3 \quad (16)$$

In words: *The initial current gradient is in proportion to the third power of the voltage applied.*

By using the resistance Law I, we get from (VI) the differential equation

$$\beta\,\theta + k \frac{d\,\theta}{d\,t} = V^2/R_0\,e^{\alpha\theta} \quad (17)$$

We may separate the variables in (17) and then integrate both sides:

$$t = k \int_o^{\theta} \frac{d\,\theta}{V^2/R_0\,e^{\alpha\theta} - \beta\,\theta} \quad (18)$$

From (18) the time t that elapses until a certain temperature θ in the thread is reached may be numerically computed without difficulty. With θ the resistance R is obtained from (I); R gives $I = V/R$. In this way the curve at the right of Fig. 14 can be theoretically calculated.

The breakdown time t_m follows from (18) by putting $\theta = \infty$:

$$t_m = k \int_o^{\infty} \frac{d\,\theta}{V^2/R_0\,e^{\alpha\theta} - \beta\,\theta} \quad (19)$$

Write (19) in the form

$$t_m = k/\beta \int_o^{\infty} \frac{\frac{\beta\,R_0}{V^2} e^{-\alpha\theta}}{1 - \theta \frac{\beta\,R_0}{V^2} e^{-\alpha\theta}} \cdot d\,\theta$$

and develop the denominator according to the formula of the geometrical series

$$\frac{1}{1-x} = 1 + x + x^2 + x^3 + \ldots$$

$$t_m = k/\beta \int_0^\infty d\,\theta \left[\left(\frac{\beta R_0}{V^2} \right) e^{-\alpha\theta} + \theta \left(\frac{\beta R_0}{V^2} \right)^2 e^{-2\alpha\theta} + \ldots \right]$$

By the application of Euler's well-known Integral we get

$$t_m = k/\beta \left[\frac{\beta R_0}{\alpha V^2} + 1 \left(\frac{\beta R_0}{2\alpha V^2} \right)^2 + 2 \left(\frac{\beta R_0}{3\alpha V^2} \right)^3 + \ldots \right]$$

According to (2), we have $\beta R_0/\alpha e = V_m^2$. We introduce this term in the foregoing equation and obtain the final expression

$$t_m = k/\beta\,[e\,(V_m/V)^2 + 1\,!\,(e/2)^2\,(V_m/V)^4 + 2\,!\,(e/3)^3\,(V_m/V)^6 + \ldots] \tag{21}$$

The expression within the brackets depends on (V_m/V) exclusively and may be easily calculated as the series converges rapidly. (21) is represented by Fig. 14 at the left.

A very remarkable result follows immediately from (21): *If we plot $\beta t_m/k$ against V/V_m, we obtain the same curve from any kind of insulating material.* In other words: *The breakdown curve $t_m = f(V)$ for a certain dielectric may be transferred into the curve for any other dielectric simply by changing the scale.*

The theorem just mentioned has been obtained by assuming the resistance Law I. But we shall find it true with each of the other resistance Laws II and III too.

With the Law II the deductions shall be confined to the case $\alpha = 1$, according to

$$R = R_o\,(1 - \theta/T)$$

The calculations are omitted, as they do not show anything of interest; the result is

$$t_m = k/\beta \frac{2 \arcsin (V_m/V)}{\sqrt{(V/V_m)^2 - 1}} \tag{22}$$

By (22) $t_m\,\beta/k$ is, as before, *a function of V/V_m only.*

In the case of the resistance Law III we have

$$\beta\,\theta + k \frac{d\,\theta}{d\,t} = V^2/R_0\,(1 + \theta/T)^\alpha$$

We put, for abbreviation

and $$\theta/T \tag{23a}$$

$$\frac{\beta T R_0}{V^2} = A \tag{23b}$$

By introducing these terms, separating the variables and integrating:

$$t_m = k/\beta \int_0^\infty \frac{A\,d\,\eta}{(1+\eta)^\alpha - A\,\eta} \tag{23}$$

By (4g):

$$A = (V_m/V)^2 \frac{\alpha^\alpha}{(\alpha-1)^{\alpha-1}} \tag{23c}$$

Again we find, according to (23) $\beta t_m/k$ to be a universal function of the proportion V/V_m.

For arbitrarily given values of α, the integral on the right of (23) can only numerically be computed. But for $\alpha = 2$ it may be expressed by known functions:

$$\left.\begin{aligned} t_m &= k/\beta \frac{A}{\sqrt{A - 1/4\,A^2}} \left[\pi/2 - \arctan \frac{1 - 1/2\,A}{\sqrt{A - 1/4\,A^2}} \right] \\ A &= 4\,V_m^2/V^2 \end{aligned}\right\} \tag{23d}$$

In Fig. 19 the relations given by equations (21), (22) and (23d) are represented for the purpose of comparison. Table I contains the numerical values within a larger range.

TABLE I

V/V_m	$\beta t_m/k$ — Resistance Law: I	II	III
1	∞	∞	∞
1,11	5,805	4,625	9,26
1,25	3,133	2,473	4,95
1,43	2,055	1,520	3,12
1,67	1,310	0,965	1,93
2,00	0,823	0,604	1,21
2,50	0,490	0,359	0,7186
3,33	0,261	0,192	0,3844
5,00	0,1115	0,0822	0,1642
10,00	0,0274	0,0201	0,0403

The values below III are very nearly twice as large as the corresponding values below II, while the values below I differ from those below II approximately by the factor 1.35. According to these relations, each of the 3 curves in Fig. 19 may be turned into the other one simply by changing the time-scale. In consequence it is impossible to decide only by breakdown trials which particular resistance law holds good. This would require an independent determination of the thermical constant k/β.

With a proper time scale the theoretical curves represent the observed data as well as might be expected if the heterogeneousness of the dielectrics and the corresponding dissemination of the breakdown voltages are taken into account.

Discussion

D. W. Roper: As I understood Dr. Wagner's remarks, he says that practically all dielectric stress failures are dielectric loss failures. That is, the rupture of the insulation is preceded by a localized heating of the insulation due to the passage of the current through the insulation, and that occurs always, except in the case of a very high voltage suddenly applied.

There is one other point about which I would like to inquire. I understood him to state as one of his conclusions that the rupture voltage was proportional to the thickness of insulation. At that time he was discussing tests between plates. Does that also apply to the insulation in cables or in case of a round conductor? And if not, what is the law connecting the rupture voltage to the thickness of insulation on a round conductor?

R. E. Hellmund: We are certainly indebted to Dr. Wagner for the new idea regarding the cause of electric breakdowns. As he himself mentioned, there is hardly anything in the electric art about which we know as little as about the breakdown of solid materials. I surely hope that the various representatives of universities that are present will take up this subject and study it, so that we may obtain a better knowledge of insulation breakdowns.

I might mention that Dr. J. C. Shrader made numerous tests in the Westinghouse Research Laboratory regarding the law between voltage and the currents flowing through the insulation. They practically agree with Dr. Wagner's except that Dr. Shrader's tests go only up to the point of breakdown. In all cases he gets a straight line and a bend just before the breakdown. These tests have been made for a great many different materials and check out in all cases. It has been proposed to apply such curve tests carefully to electrical machines, in order to determine their breakdown point. That is, instead of going to the actual burn-out or breakdown, it is proposed to simply go to the bend in the curve and thus determine, approximately, the breakdown point, without destroying the machine insulation.

K. W. Wagner: I made the experiment with cables and at that time I didn't have much care for the time taken for breakdown. As I mentioned before, these experiments will be carried out later, and I will study the influence of the time on the breakdown.

This curve showing the time required for breakdown at a certain voltage is, as I mentioned, a universal one. If we take both a unit of time and a unit of voltage, of course the shape of this curve depends somewhat on the assumption made if the law governing the insulating resistance depends on the temperature. But it depends, in fact, on a very little proportion of this, and I made several assumptions on the dependence of the resistance on the temperature and exponential function and several others containing powers of the temperature, but all of these if the testing plates are put in give the same shape of the curve.

On the question of the breakdown voltage depending on the thickness of the insulation of concentric cables or three coil a-c. cables, I am not able to answer that question at this time. My experiments on the thickness were only made for plates.

Charles P. Steinmetz (by letter): The pyro-electric theory of insulation failure described by Dr. Wagner is fully corroborated by the conclusions from Mr. Hayden's and my investigations on insulation, and it therefore was of great interest to us to compare notes with Dr. Wagner during his visit. His ingenious method of carrying the volt-ampere characteristic of solid insulation beyond the so-called "breakdown point," by using wooden terminals, was new to us. We secured the required distributed current limitation by testing the sample between thin sheets of an insulation of higher dielectric strength and smaller temperature effect, such as mica, or by calculation from the temperature resistance curves of the material taken at high voltage, or by using a filamentary thread of insulation. The last method has the advantage of giving the true voltage characteristic, while the other methods give only an average characteristic. It has however the disadvantage to be limited to those few insulators, which have a relatively low resistivity, such as the material of the Nernst lamp glower.

In the mathematical appendix Dr. Wagner shows that, under certain conditions, the breakdown voltage is proportional to the thickness of the insulation, if the breakdown is a pyro-electric effect. This, however, does not mean that the breakdown cannot be a pyro-electric effect, if the breakdown voltage is not proportional to the thickness of the dielectric, but, as commonly the case, increases at a slower rate.

Dr. Wagner's conclusions are based on the assumption of the "hot spot" as a filament connecting the terminal (Fig. 2 of his paper) and conducting its heat away exclusively tangentially, into the dielectric, but not towards the terminals. With wooden terminals of low heat conductivity, this would be the case.

With metal terminals of good heat conductivity however, considerable heat conduction might occur also towards the terminals, especially if the hot spot is not filamentary, but its diameter of the same magnitude as the thickness of the dielectric, as would more probably be the case in a laminated dielectric. In such case, most of the heat may be conducted towards the terminals.

Assuming therefore, as the extreme case, that all the heat produced at the hot spot forming in the insulation, is conducted towards the terminals. Then by similar calculation as those given by Dr. Wagner for the extreme case, we find that *the breakdown voltage is proportional to the square root of the thickness of the dielectric.*

In general, heat will be conducted away transversely, towards the terminals, as well as tangentially, into the dielectric, and depending on the proportion of the heat conducted tangentially and heat conducted transversely, the breakdown voltage would vary with the thickness somewhere between the first power and the square root.

In concluding, I wish to say that the pyro-electric theory of insulation breakdown does not mean that the effect and the importance of dielectric hysteresis and ozonization losses, with alternating voltage, are overlooked. The conductivity of the insulation, which progressively increases by the temperature rise at the hot spot, must be understood as the effective conductivity, including the dielectric hysteresis, ozonization effect, etc.

Selection of Electrical Apparatus for Cranes

BY R. H. McLAIN

Associate, A. I. E. E.

Engineering Department, General Electric Company, Schenectady, N. Y.

Review of the Subject.—*This paper is intended to assist crane designers and electrical engineers in mills and factories to select the proper size and kind of motor by mathematical calculation from given data, and refers particularly to the electric overhead traveling crane. The paper does not apply to heavy duty cranes which undergo regular duty cycles, nor to very small hoists such as the monorail hoist. It is hoped that at some future date someone else will write papers on these two kinds of cranes to supplement this paper.*

Cranes are classified here for purposes of reference within the paper. It is then shown how to calculate the power required of a motor for hoisting and how to select the particular kind of motor needed; the same information is given for bridge travel with particular reference to the live loads or accelerating loads, and also for trolley travel.

The paper discusses direct-current motors separately from alternating-current motors. The calculations for each are also given separately.

This is the first of a series of papers covering the field of applications of electrical equipment. This paper is on application of motors to cranes. One will follow by Mr. H. W. Eastwood on auxiliary electrical equipment such as magnetic friction brakes, overload protective panels, and limit switches. To complete the series it is planned to have the third paper on the subject of controller equipment.

CONTENTS

IN the selection of electrical apparatus for crane drives, it is first necessary to consider the various classes of cranes. For reference later, these classes are enumerated below:

Class 1. Stand-by or service cranes which are used in emergencies, and at rare intervals. A typical example is the power-house crane which is used during installation and thereafter only when repairs are made. The apparatus on such a crane should be simple and should be worked to the limit of its capacity. The control should be very accurate for placing large machines even when used by unskilled operators, as this kind of crane is so rarely used that there is no regularly trained operator for it.

Class 2. Machine-shop and foundry cranes, which are always in service and moderately busy. The apparatus on them should be simple but not worked so nearly to the limit of its capacity as in Class 1. There is always a regular operator in attendance and, therefore, the control apparatus does not necessarily have to be so accurate as in Class 1. In this same class belong loading cranes which serve storage yards where infrequent movement of the stock occurs.

Class 3. High-duty cranes such as are used for moving material in steel mills and for loading material into cars from storage yards where stock is frequently moved. On these cranes very strong apparatus is required, and complications are warranted to some extent in order to secure long life of the apparatus. All apparatus should be very conservatively rated.

Class 3*A*. Magnet Cranes. On these cranes the hoist motion must be especially chosen so as to stand two times normal load because sometimes two times normal load sticks to the magnet for an instant while it is separating bars from their neighbors. The bridge and trolley motions must be chosen for frequent round trips, probably 60 trips an hour.

Class 4. Soaking pit, charging and stripper cranes. On these cranes fire-resisting insulation is required on motors, and apparatus should be designed to be mechanically strong, conservative in size and exceptionally safe in operation.

Class 5. Hot metal ladle cranes. These cranes should have fire-resisting insulation and should be extremely conservatively designed.

This article will not discuss various small foundry jib cranes and others of this same kind which are operated by a man on the floor rather than by an operator who rides with the crane.

General Selection of Electrical Equipment. To assist in selecting the general type and arrangement of electrical equipment, Table I has been compiled, in which all the various features to be considered are pointed out.

Calculation of Power for Hoisting. The horse power of the lifting motor depends upon the work done on the load, and the power absorbed in the resulting friction of the gearing, journals and pulleys. This quantity varies to some extent with the number of reductions and the type of gearing. The efficiency of a crane is generally lowest at the test, improving somewhat as the journals and teeth wear down.

Presented at the Spring Convention of the A. I. E. E., April, 19-21, 1922.

The efficiency of the first or motor reduction with well-made machine-cut spur gears, running in an oil-bath, has been found by trial to be as high as 97 per cent, and may be taken at 95 per cent under ordinary practical conditions. The average efficiency of one reduction of cut spur gears, running dry, is 92 or 93 per cent, and of cast spur gears, running dry, 90 per cent. The loss due to journal friction is generally about 2 per cent for each axle, when properly lubricated. The only other loss in efficiency of any importance is in the snatch block, if there is one fitted to the crane. This quantity is always reduced by using large pulleys and, preferably, small hardened pins, the pulleys being bushed with gun-metal, under which condition the efficiency works out to about 97 per cent.

$$\text{h. p.} = \frac{W \times S}{33{,}000 \times e} \qquad (1)$$

where h. p. = horse power to hoist at full speed. (All starting resistance short-circuited) (2)

W = weight of suspended load in pounds including tackles (3)

S = speed of hook in feet per minute (4)

e = necessary factor to allow for friction losses in the crane (5)

The value of e varies from 0.25 on low-speed (10 ft. per minute) cranes which use worm gears, to 0.70 for high-speed (75 ft. per minute) cranes which use good cut gears. The over-all mechanical efficiency of a crane can be determined, if the number of reductions and the other particulars are known. Small high-speed cranes have a higher efficiency than larger ones, owing to there being less gearing; thus, in the case of a trolley lifting three tons on a single rope and having two reductions of machine-cut gearing, the first of which runs in oil, the over-all efficiency will be about:

$$\frac{95 \times 92 \times 98 \times 98}{100} = 84 \text{ per cent.}$$

As another example, take a 50-ton trolley having four reductions, the first three of which are machine-cut, the motor reduction running in oil. Then the over-all efficiency will be about:

$$\frac{95 \times 93 \times 93 \times 90 \times 98^4 \times 97}{100} = 66 \text{ per cent.}$$

$$T = \frac{5250 \times \text{h. p.}}{\text{r. p. m.}} \qquad (6)$$

T = Torque on motor shaft required to hoist as in (1) expressed in pounds at one foot radius (7)

r. p. m. = Speed of motor shaft in revolutions per minute with all resistance cut out of the circuit (8) (This corresponds to S in (4))

$T_1 = T \times e^2$ if no friction brake is used for lowering (9)

where

T_1 = braking torque in pounds at one foot radius required to lower the weight W (10)

The torque to hoist an empty hook or drive it down is about 5 to 30 per cent of the torque required to hoist maximum rated load of the crane. This is due entirely to crane friction.

In addition to the work of hoisting (1) there is the work of accelerating. Most of this work, on cranes lifting at less than 150 ft. per min., is expended on the motor armature and brake wheel. An approximate rule is to assume that the horse power input to accelerate an armature and brake wheel to full speed in one second is equal to the 30-minute horse power rating of the motor for alternating-current induction motors (11); and is equal to one-half the 30-minute horse power rating of the motor for series-wound direct-current motors (12).

A more exact rule is to obtain from the motor manufacturers the weight and radius of gyration of the armature. Then, horse power input to start =

$$\frac{M \times \text{r. p. m.}^2}{1{,}612{,}800 \times t} \qquad (13)$$

where

M is given in (19)

r. p. m. = speed of motor shaft as in (8)

t = seconds used in acceleration (usually not over 2 sec.) (16)

Selection of D-C. Hoist Motors. The general requirements are that the motor shall be enclosed to protect its commutator from dirt, that it shall be as light and easy to start as is consistent with necessary mechanical strength, that it shall be accessible and its parts easily replaceable. The power requirements are for a large torque sustained for only a short time—therefore an especially designed motor for crane service is needed. It differs from a motor which is used for continuous drive in that it requires the mechanical strength of a large motor, the commutating capacity of a large motor, but needs to have only the active electrical material of a small motor. The smaller the active electrical material and the closer it can be located to the armature shaft, the better the motor, because of the lightness and small flywheel effect which are advantageous for a motor that starts frequently and quickly.

Manufacturers of crane motors have given especial attention to the question of commutation either by using large brush area and narrow commutator bars with many windings or by using commutating poles.

When required to meet the modern requirements of dynamic braking control, the motor must be stable and have good commutation when separately excited and when run at a high speed delivering about 50 per cent

of the rated torque; and it must show equally good commutation in either direction of rotation without shifting the brushes.

It is advantageous for these motors to have split frames, easily accessible connection cables and brushes, so that the motor can be readily dismantled and repaired in a small cramped space in the quickest possible time.

To select the proper size of motor for crane hoist, determine (a) the maximum horse power to be delivered by the motor, and (b) the usual horse power. The horse power value obtained by adding h. p. (**1**) for a maximum load to h. p. (**13**) (or, for approximate results to h. p. (**11**) or (**12**)) should always be less than the motor's commutating limits. This may be the five-minute rating of the motor if commutating poles are used. By formula (**1**) the horse power delivered under usual operating conditions should be determined. This usual value of horse power determines the ordinary rating of the motor and it should be:

For Class 1 cranes, the 15-minute rating of the motor.

For Class 2 cranes, the 15- or 30-minute rating of the motor.

For Class 3 cranes, the 60- or 90-minute rating of the motor.

For Class 3A cranes, the 90-minute rating of the motor (because of the uncertainty of the load when the magnet attracts too large a piece).

For Class 4 cranes, the 60- or 90-minute rating of the motor.

For Class 5 cranes, the 30-minute rating of the motor.

On large cranes of Class 5, it is customary to use two hoist motors, each of which alone can hoist the total load without exceeding its commutating limits. This excess capacity is warranted on account of the great value of the metal and the necessity of hoisting the load even if one motor is broken down.

Example of Selection of Direct-Current Hoist Motors. Take a crane which usually hoists 10,000 (W) lb. at 20 (S) feet per minute and which has gear efficiency (e) of 0.55. Take the extreme load to be 15,000 lb. Substitute in (**1**).

$$\text{h. p.} = \frac{10{,}000 \times 20}{33{,}000 \times 0.55} = 11 \text{ h. p. to hoist usual load.}$$

Let t in (**16**) be 2 seconds

Then $$\text{h. p. } (\mathbf{12}) = \frac{11}{2 \times 2} = 2.75.$$

When the motor has to hoist 15,000 lb. occasionally this will require approximately

$$\frac{15{,}000}{10{,}000} \times 11 = 16.5 \text{ h. p.}$$

Therefore, the usual horse power required will be 11 and on extreme loads $(16.5 + 2.75 = 19.25)$. Choose a motor which will start at 19.25 h. p. and whose 15-, 30-, 60- or 90-minute rating, according to class of crane, is 11 h. p.

Approximate Rule. An approximate rule is as follows:

$$\frac{\text{Tons to be hoisted} \times \text{ft. per min.}}{10} = \text{30-min. rating of motor.}$$

Selection of D-C. Bridge Motors. The general characteristics of these motors should be the same as those described for hoist motors. They should be series wound, totally enclosed and have good commutating characteristics, etc.

Calculation of Power for Bridge Motors. Rolling friction is caused by axle friction and wheel friction. With good lubrication, axle friction in pounds

$$= \frac{0.10 \times (\text{axle radius in inches}) \times (\text{load in pounds})}{\text{Radius of wheel in inches}}$$

With good track, wheel friction in pounds

$$= \frac{0.002 \times (\text{load in pounds})}{\text{Radius of wheel in inches}}$$

The cross shaft runs in several bearings and its efficiency may be around 95 per cent.

The efficiencies of the gears will be as defined above for hoist motions.

The work done by the bridge motor consists of three parts; first, overcoming track resistance and journal friction—sometimes, together, called rolling friction; second, accelerating the crane with load; third, accelerating the motor armature and brake wheel. The first and second items of work above are done through a train of gears and involve gear losses. In the majority of busy cranes, the rolling friction is a small part of the total work and acceleration is the main work. Usually a draw-bar pull of from 20 to 30 lb. per ton will move a well made crane along a good level track. A new stiff crane or a poor track may require 50 or 60 lb. per ton. Acceleration of the crane and armature may require anywhere from 50 to 300 lb. per ton draw-bar pull, depending on circumstances.

Actual tests show that rolling friction may, for different cranes and tracks, vary anywhere from 5 to 50 pounds per ton. However, when a building sags, the draw-bar pull to move a crane may be almost any value and there is no use of trying to calculate it.

Let C = Weight of crane without load in pounds (**17**)

W = Weight of suspended load in pounds (including tackle) (**3**)

N = Revolutions of motor armature which correspond to one foot travel of the bridge along the track (**18**)

in other words $N = \dfrac{\text{r. p. m. of motor}}{\text{f. p. m. of crane}}$

M = The effective weight of the armature and brake wheel plus an allowance of 5 per cent for gears, expressed in pounds at one foot radius on the armature shaft, *i. e.* the flywheel effect **(19)**

$$e = \frac{\text{Efficiency of gearing expressed in per cent}}{100} \qquad \textbf{(20)}$$

D = Rolling friction in pounds per ton **(21)**

V = Free running speed in feet per minute when fully loaded crane is completely accelerated **(22)**

The easiest way to choose the proper motor is to cut and try. Gear ratio is of vital importance and must be selected to conform to the speed-torque characteristics of the motor.

First determine:

Horse power to propel loaded crane

$$= \frac{V \times D \times \dfrac{C + W}{2000}}{33{,}000 \times e} \qquad \textbf{(23)}$$

As a first trial select a motor whose 30-minute rating is about 30 to 50 per cent above horse power in **(23)**. Determine from the motor manufacturer's speed-horse-power curve the speed of the motor when delivering horse power in **(23)**. Then determine N in **(18)**.

Next determine whether the assumed motor with the assumed gear ratio can accelerate the loaded crane and also the empty crane as rapidly as desired or needed, without exceeding the commutating limits of the motor. The rate of acceleration of empty crane will never need to exceed three feet per second per second; and of a loaded crane two feet per second per second.

Let F = torque in lb. at one foot radius at motor shaft corresponding to horse power in **(23)**.

Then $\dfrac{C}{C + W} \times F$ = torque at motor shaft to propel empty crane.

Let A = maximum torque which motor is recommended (by manufacturer) to exert during starting. Commutation and strength will be the limitations rather than heating.

Rate of acceleration in feet per second per second which the empty crane can attain without torque exceeding A

$$= 32.2 \frac{A - \dfrac{C}{C + W} F}{\dfrac{C}{2 \pi N e} + 2 \pi N M} \qquad \textbf{(24)}$$

Rate of acceleration in feet per second per second which loaded crane (load being rigid) can attain without torque exceeding A

$$= 32.2 \frac{A - F}{\dfrac{C + W}{2 \pi N e} + 2 \pi N M} \qquad \textbf{(25)}$$

It is interesting to note that when the load is hung from the crane by a flexible rope, the motor does not have to start the load as soon as the crane starts. This relieves the motor somewhat. At the first instant of starting, the motor has to overcome rolling friction of total weight of crane and load, and it has to accelerate the crane and armature. As the crane moves away from the load, the load begins to accelerate at a rate far below that of the crane and finally when the crane has moved far enough away from the load, the load is accelerated as rapidly as the crane.

Rate of acceleration in feet per second per second which loaded crane attains at instant crane starts to move (before suspended load begins to move), without torque exceeding A

$$= 32.2 \frac{A - F}{\dfrac{C}{2 \pi N e} + 2 \pi N M} \qquad \textbf{(26)}$$

There are four things which tend to limit the rate of acceleration of a bridge motor:

1. Automatic magnetic control can absolutely limit it.
2. Slipping of wheels can practically limit it.
3. Swinging of load can limit it in some cases.
4. Comfort of operator may limit it.

When automatic magnetic control is used, the current-limit devices may be set to a value of current just sufficient to start the crane under the severest working conditions, and if the current is within the working limits of the motor no trouble need be expected on the crane. Of course, trouble can arise if the controller fails to function properly or if the operator "speeds up" the crane by setting the relays for higher current. To safeguard against this last difficulty, it is, of course, necessary to select a motor large enough to make all the speed actually needed. An average acceleration of something like 1 to 1½ ft. per sec. per sec. will be fast enough for cranes which travel at less than 500 ft. per min. or make infrequent starts. Cranes which make regular frequent trips of 50 or 60 ft. every minute or so may need an *average* acceleration of 2 to 2½ ft. per second per second. Cranes which do "stunts" with swinging loads like some bucket cranes, which swing a bucket into a hopper, or hot metal ladle cranes, may need even 3 feet per second per second *peak* acceleration.

When a motor is powerful enough to slip the wheels under full load without exceeding the working limits

of the motor, it is out of danger. A simple calculation[1] shows that if one-fourth of the wheels are driven and if these wheels carry one-fourth of the total weight, an acceleration peak of 2 ft. per second per second will just about slip the wheels. Of course, the average acceleration will be less than the peak and will depend on the number of controller steps.[2] If one-half the wheels are driven, the rates of acceleration could be double the above values. Of course, it is possible for a vicious operator to turn his controller on so rapidly after the wheels slip, that the power required to spin the wheels and accelerate the armature will exceed the motor limits; but this is hardly to be expected. Where it is possible for a crane to do its work with only one-fourth of the wheels driven, this drive makes a very practical way of protecting the motor, but where one-half of the wheels must be driven, the motor is not so protected from overload.

Cranes are frequently used for dragging cars and consequently the bridge motors must be large enough to do extra work, when so used. This problem would be something like an electric locomotive problem and will not be discussed in this paper.

Usually when an enclosed crane bridge motor is properly chosen so far as torque and strength are concerned, it is big enough so far as heating is concerned; but this is not necessarily true on rapid-duty cranes. If the crane is running with power on the motor, more than 35 seconds in 100 seconds continuously for 5 hours at a time, heating is liable to be a limitation and the motor manufacturer should be consulted or past experience with similar work should be used.

Selection of Trolley-Motion, Direct-Current Motors. The type of motor should be the same as for hoist and bridge motions and since this motor is "plugged" (or reversed by power when running at high speed frequently) its commutation must be good at double speed and 150 per cent current. Its commutator and windings must be insulated for at least double normal voltage.

Calculation of Power for Trolley Motors.

Let B = weight of trolley carriage less load (27)

V = free running speed in feet per minute when fully loaded trolley is completely accelerated (28)

Horse power to propel loaded trolley

$$= \frac{V \times D \times \dfrac{B + W}{2000}}{33{,}000 \times e} \qquad (29)$$

Choose a motor whose 30-minute rating is not less than horse power in (29).

Selection of Alternating-Current Polyphase Hoist Motors

For the usual factory crane an open-type motor should be used.

Where metal dust cinders, furnace fires, acid alkali and such unusual conditions are present, motors should be specially insulated and, in some cases, enclosed.

For cement plants the bearings should be enclosed. It has seemed desirable to enclose also the collector rings but there is a considerable physical difficulty in enclosing collector rings on a motor which is equipped with a solenoid brake at one end and gearings at the other end. These difficulties, together with the inaccessibility of enclosed collector rings, have made it a better practical proposition to use open collector rings. It is necessary to clean out the brushes frequently in order to prevent them from sticking.

The slip-ring wound-rotor induction motors are generally used where reduced-speed operation is needed. The single-speed squirrel-cage-rotor type of motor, with high-resistance rotor windings, is best suited to cranes which handle rough material where no reduced-speed operation is required and where size does not exceed 25 horse power. Under this class would come ice hoists, lumber cranes at not over 50 or 75 ft. per minute, cranes for boxed or baled goods at not over 100 feet per minute, machine shop cranes at not over 15 or 20 feet per minute. The multi-speed motor with squirrel-cage rotor offers many possibilities where reduced-speed operation is required, such as foundry hoists; but this type has not been generally exploited commercially.

There are two important differences between the alternating-current and the direct-current, series-wound motor: (1) Power supply voltage and frequency must be maintained fairly uniform for the alternating-current motor because its maximum starting torque varies as the *square* of the voltage impressed, and inversely as the *square* of the frequency. Voltage has, in practise, no effect on the maximum starting torque of a direct-current series-wound motor because starting torque is a function of current only and even if voltage is abnormally low the controller can be manipulated to give maximum current. It is therefore, necessary to choose

1. Assume a coefficient of friction between the wheels and the rail of 25 per cent. Then the available draw-bar pull from one-fourth of the wheels will be 25/4 or 6.25 per cent of the weight of the crane. Gravity (or the total weight of the crane) will accelerate the crane at 32.2 ft. per second per second—therefore 6.25 per cent will accelerate it at 0.625 × 32.2 or 2 ft. per second per second. This calculation omits some niceties about rolling friction but they are relatively unimportant.

2. Three blocks of accelerating resistors produce an average of approximately 72.5 per cent of the peak rate of acceleration; four blocks 78.5 per cent; six blocks 85 per cent; nine blocks 89 per cent; and thirteen blocks 92.5 per cent.

a motor whose maximum-minimum[3] starting torque is, at least, twice and for squirrel-cage motors 2.5 or 3 times the torque required for hoisting the maximum load. Consider, for example, a crane where power supply voltage is 90 per cent of rated motor voltage and where static friction is such as to add 25 per cent to hoisting torque at the instant of starting. Then if motor could exert 200 per cent normal torque at starting under normal voltage, it could exert 162 per cent of normal torque under 90 per cent voltage; and it would be called on to exert 125 per cent of normal torque. The difference between 125 per cent and 162 per cent represents the margin, and it is none too great. This margin is not sufficient for squirrel-cage motors because if they stall they are almost sure to burn out the rotor.

In order to make the same number of trips per day with an a-c. crane as with a d-c. crane, it is frequently necessary to gear the a-c. crane for a higher full-load hoisting-hook speed than would be used with d-c., and this means that the rating of the a-c. motor must be relatively greater than that of the d-c. motor. To explain, let us assume that a round trip consists of hoisting full load 20 feet, lowering it 20 feet, hoisting an empty hook 20 feet and lowering it 20 feet. If a d-c. motor were used and geared for 40 feet per minute full-load hoisting speed, it would hoist in 30 seconds, lower (where lowering speed is 190 per cent hoisting speed) in 16 seconds, hoist in about 15.5 seconds (where 20 per cent hoisting torque corresponds to 195 per cent speed), lower in 20.5 seconds, making a total of 82 seconds. An a-c. motor would have to be geared to hoist full load in about 20.5 $\left(= \frac{82}{4}\right)$ seconds in order to keep up with the d-c. motor because the a-c. motor can never run above its synchronous speed. This means that the a-c. motor would have to be $\frac{30}{20.5}$ ($= 1.46$) times as large as the d-c. motor for the particular case illustrated. This ratio does not come as high as 1.46 for ordinary practical cases where there is a good deal of creeping speed work in the typical round trip of the crane hoist. However, in order to meet the requirements of an occasional extremely high load, an induction motor may have to be considerably larger than a d-c. motor because a d-c. motor can exert more overload torque.

Use of Permanent Resistance in the Rotor Winding of Slip-Ring Motors. When manual control is used and service is severe and abusive, *a permanent block of resistance* should be wired in series with the slip rings of the motor and should be of such value that the slip at full-load torque on the motor will be about 15 per cent after the controller has been turned to the "full on" position. To accomplish this, the permanent resistance should contain about 10 per cent as many ohms as are required to give 100 per cent slip (or standstill) with full-load torque on the motor. This sounds like wasting power but power is only one of the small considerations in the operation of the crane. The following tabulation of performance values on a certain typical motor shows the advantage of permanent resistance:

Max. stalling* torque in per cent of full-load torque	Stalling amps. in per cent of full load	Per cent slip when motor is delivering full-load torque	Heating when motor is stalled, expressed in per cent of the heating when full-load current is flowing
175	484	5	2340
265	419	10	1750
290	360	15	1300
286	311	20	960
272	278	25	775
255	250	30	625
236	229	35	522
220	208	40	434

*These are maximum-maximum values; not maximum-minimum values.

Operators seem to make a practise of turning these manual controllers on as fast as possible and it is best to plan that the controller will be full on before the motor starts. The above table shows that the most starting torque can be obtained when a resistor is set for 15 per cent slip and that there is a big saving in motor heating at this resistor setting. A careful study of practical operation from all angles will show that with this resistor setting more can be gotten out of the motor than with any other setting, and at less expense in the way of motor and control trouble.

When magnetic control is used, no permanent resistance is necessary because current-limit relays prevent all of the resistance from being short-circuited while the motor is at standstill.

When permanent rotor resistance is used, it is not necessary, in comparing an a-c. motor with a d-c. series motor, to make the full-load hoisting speed for alternating current as much higher than for direct current as was indicated in a foregoing paragraph. In the example used, the full-load lowering speed will be enough above synchronous speed to average up the lower full-load hoisting speed; and, consequently the full-load hoisting speed need be only 129 per cent above

3. Maximum-minimum starting torque is a term which applies to slip-ring type, wound-rotor induction motors. With the external resistance which is connected to the rotor adjusted for obtaining the maximum starting torque, the currents are so high as to set up a magnetic distortion between the poles of the stator and of the rotor. At some positions of the rotor, this distortion causes the torque to increase and at other positions to decrease. Maximum-maximum starting torque means the torque when rotor is in most favorable position; *Maximum-minimum*, the most unfavorable.

full-load d-c. hoisting speed in order to make the round trip in 82 seconds.

Calculation of Power for Alternating-Current Crane Hoist Motors. Calculate the hoisting horse power as per equation (1) and choose a motor whose 30-minute rating is equal to or greater than this value. Where the motor is to be started frequently, calculate starting horse power to start from equation (13), choose a motor such that horse power from (1) plus horse power from (13) does not exceed 150 per cent of the 30-minute rating.

Sometimes, on very rough service, it is advantageous to connect a permanent resistor in the rotor circuit of such value that speed under full load is about 85 per cent of the synchronous speed. When this is done the motor rating is reduced about 10 per cent and, therefore, select the motor so that its 30-minute rating is 110 per cent of the horse power in equation (1). Also it is, of course, necessary to gear the motor so that when running at 85 per cent of synchronous speed, the load will be hoisted at rated crane hook speed.

Heating is not usually a limiting feature on open motors when motors are selected as above described except on bucket or similar cranes. When enclosed motors are to be used, or buckets are to be handled, the duty should be referred to the manufacturer for selection of the motor.

Selection of Alternating-Current Bridge-Motion Motors. Wound-rotor motors with slip rings are best suited to this work.

Motors should be open, enclosed or specially insulated to correspond with hoist motor.

Permanent rotor resistance is generally advantageous.

Calculation of Power for A-C. Bridge-Motion Motors. Try a motor such that the horse power to propel, in equation (23) does not exceed 75 per cent of the 30-minute rating. The maximum instantaneous torque during starting should not exceed 200 per cent of the full-load rated torque of the motor. Refer to equations (24), (25) and (26); substitute for A a value of torque in pounds at one foot radius which is not over twice full-load rated torque. Then see that a satisfactory rate of acceleration can be attained, cut and try until a suitable size of motor is obtained. On some high-speed cranes, horse power in equation (23) may have to be as low as 30 per cent of the 30-minute rating of the motor in order to obtain satisfactory acceleration without overloading the motor.

Selection of Alternating-Currnet Trolley Motors. Use the same type of slip-ring motor as on hoist and bridge.

Choose a motor such that the horsepower in equation (29) does not exceed the 30-minute rating of the motor.

On certain small trolleys which do not exceed 250 ft. per minute speed nor 5 h. p., it is possible to use a simple squirrel-cage motor with high-resistance rotor. Such a motor must have a starting torque at least twice the torque required to propel the maximum load as per equation (29).

Starting torque in pounds at one foot radius must at least =

$$2 \times \frac{(\text{horse power in (29)}) \times (\text{full load r. p. m.})}{5{,}250}$$

Special heating requrement must be met and special control precautions taken.

Discussion

For discussion of this paper see page 323.

Auxiliary Electrical Equipment for Motor-Operated Cranes

BY H. W. EASTWOOD

Associate, A. I. E. E.

Cutler-Hammer Mfg. Co., Cleveland, O.

Review of the Subject.—*This is one of a series of papers on the selection of electrical apparatus for cranes and deals with the brakes, overload protective panels and limit switches. Other papers of the series cover the requirements as to motors and control.*

A magnetic friction brake is needed for every crane hoist, in addition to what may be provided in the way of dynamic braking or mechanical brakes, but its required characteristics are very definitely affected thereby. In selecting a magnetic brake the character of the service must be well understood, and the part that it plays therein, and it must possess an adequate energy dissipating capacity. A definite formula for such selection is given.

The paper discusses the various service requirements and describes the several available types of magnet brakes and their particular fields of application.

Limit switches, while occasionally employed to limit the travel of the trolley or bridge motions of a crane, are universally used to limit the upward travel of the hook block. Hoist limit switches may be geared to the machine or directly operated by the block. The former do not take into account the stretching of cables and require complete readjustment when new cables are installed. Switches operated by the hook block are the surest.

The paper describes the various forms of geared and direct-operated limit switches and points out their relative advantages. Considerations of safety often demand that the operation of the switch not only disconnects the motor but simultaneously closes a dynamic braking circuit for quick stop.

The history is given of the evolution of the modern crane overload protective equipment and devices. Fuses and railway type circuit breakers have been tried, but up-to-date equipment employs overload relays in each motor circuit operating in conjunction with magnetic switches. In the interests of safety it is possible to cut off all power instantly by tripping a switch that causes the magnetic switches to open. Safety locks are provided that permit of locking the entire crane equipment against operation.

The best results are secured by properly inspected time-element overload relays in each motor circuit and a common-return instantaneous relay.

CONTENTS

In addition to motors and controllers, modern cranes also require auxiliary electrical equipment, namely; magnetic friction brakes, overload protective panels and limit switches.

D-C. Magnetic Friction Brakes

Every crane hoist requires a magnetic friction brake for the purpose of stopping and holding loads in suspension. If the crane is equipped with dynamic lowering control, a large part of the work of retardation is absorbed electrically, in the dynamic braking resistance. In the case of a crane equipped with a well-adjusted mechanical load brake, the magnetic brake is called upon to absorb only the energy of the rotating armature. In the case of a crane without either dynamic lowering control or mechanical load brake, the magnetic brake is called upon to absorb in friction and dissipate in heat, all of the stored energy in the moving load, gearing and armature. The amount of energy expressed in foot-pounds per minute or per hour which a brake of given type and size may safely dissipate without exceeding a reasonable rise in temperature, is a definite quantity. In selecting a brake for severe duty, the above factors should be considered in connection with the severest probable duty cycle, and a brake should be selected whose energy-dissipating capacity provides some margin of safety above anticipated requirements. A failure to observe this simple precaution in the past has often resulted in serious trouble, especially with brakes of poor heat dissipating capacity.

On a crane without mechanical load brake, the magnetic brake is the sole means of holding a load in suspension. It is, therefore, an important factor in the safe and efficient operation of the crane and care

Presented at the Spring Convention of the A. I. E. E., Chicago, Ill., April 19-21, 1922.

must be exercised to select a brake having sufficient torque to hold, and, in case of emergency, to stop the heaviest load which the crane may be called upon to handle. Some manufacturers rate their brakes in horse power, corresponding to the ratings of the motors with which they recommend their brakes to be used. The horse power rating has arisen from the fact that hoist brakes are usually, though not always, mounted on the armature shaft of the hoist motor, and from the fact that the coils for series-wound brakes must be designed on the basis of the motor rating. The torque rating of a brake is, of course, a perfectly definite quantity determined by actual test. The horse power rating is the calculated horse power which the brake would absorb when exerting its rated retarding torque at an assumed speed. The speed is determined by averaging the full-load rated speeds of various makes of hoist motors. As a guide to the approximate size of brake required, the horse power rating is, no doubt, useful but as a basis for the selection of a brake, it may prove positively dangerous. A calculation of the actual torque required to hold the maximum load in suspension should therefore be made and a brake whose torque rating is at least equal to this amount should be selected. This torque can be quickly calculated from the formula:

$$T = \frac{L \times D \times E}{24\,R}$$

where T = Torque in lb-ft.
L = Maximum load in lb.
D = Diameter of winding drum, in inches.
E = Efficiency of gearing.
R = Gear reduction including ropes, between load and the shaft on which the brake is mounted.

Brakes selected in accordance with this plan will, in general have less torque than the motor in connection with which they are used; this is because of the fact that the inefficiency of the gearing is of assistance to the brake whereas it is a handicap to the motor. In order to provide a margin of safety it is therefore customary to select a brake on the basis of motor torque. If the torque rating of the motor is not at hand, or if the brake is to be mounted on some shaft other than the armature shaft the torque can be calculated from the formula:

$$T = \frac{33000 \times \text{h. p.}}{2\,\pi\,N} = \frac{5250\,\text{h. p.}}{N}$$

where T = Torque in lb. ft.
h. p. = Horse power rating of motor
N = Rev. per min. of shaft to which brake is to be attached.

As above stated the hoist brake is usually mounted on the armature shaft of the hoist motor. This is not universally the case, however, and not infrequently brakes are mounted on intermediate shafts. In the case of ladle and hot metal cranes, for example; when dynamic lowering control is used, in view of the great responsibility imposed on the brakes, it is customary for safety reasons, to install brakes both on the armature and on intermediate shafts. Either of these brakes alone should be capable of stopping and holding the load. A brake on an intermediate shaft as compared with a brake on the armature shaft, in order to hold the same load, must develop a greater torque in proportion to the gear reduction.

Intermediate shaft brakes are, not infrequently, too large, or of improper design for the real purpose they are intended to serve. By far the greater part of the stored energy in the system is in the rotating armature. If this energy is absorbed by a brake on the armature shaft, the only parts subjected to stress are the armature shaft and bearings, the motor supports and the brake itself. If this energy is suddenly absorbed by a brake on an intermediate shaft, this shaft, together with its bearings and the gearing, are also subjected to severe stresses. There is always some back lash in the gearing and in consequence, every time the intermediate shaft brake stops the armature, a hammer blow is delivered to the gearing and transmitted to the shafts and bearings. In one direction of rotation this hammer blow is delivered downward and in the other direction, upward, so that the mechanism is continually subjected to alternating stresses of great intensity. On ladle cranes this hammer blow is particularly noticable when hoisting without load, because in this event the motor operates considerably above normal speed. In various installations this effect has been so severe as to break bearing cap bolts, bend shafts, strip pinions and break motor feet. In all such cases, where two brakes are required it is a wise precaution to use a quick acting brake operated by a short stroke magnet, on the armature shaft and a more sluggish brake, operated by a long stroke solenoid on the intermediate shaft. Since this trouble is most likely to occur in hoisting the light hook, it can be almost entirely eliminated by using a dead-end band brake as an intermediate shaft brake, as this type of brake is practically ineffective when the brake wheel rotates toward the anchored end of the band.

The operating coil of a magnetic brake may be series wound, for connection in series with the motor, or shunt wound for direct connection to the power circuit in parallel with the motor, or compound wound, *i. e.*, having both shunt and series windings. Compound wound brakes are rarely used on electric cranes, though their use may be advisable in special applications in connection with compound wound motors, where the load may approach zero. Shunt brakes are sometimes used on standard crane hoists due to the preference of the individual user, but in general shunt brakes constitute an evil to be avoided where possible in crane service. If wound for full voltage their inductive effect makes them sluggish in action and destructive

to insulation. If wound for fractional voltage in order to reduce the inductive effect, the additional complication of a fine wire resistor for connection in series with the coil is required. Their use involves the use of additional trolley conductors. If used in connection with a dynamic lowering controller they are a menace to safety because they may be held released by any one of a variety of causes when it is very necessary that they be applied. From the standpoint of safety it is especially desirable to provide some assurance that the brake will automatically set in case of accidental failure of the dynamic braking circuit. This feature can be secured with the shunt brake only by means of the additional complication of a series relay, whose coil is connected in series with the motor precisely as the coil of a series brake would be connected, and whose contacts are connected in series with the shunt brake-control circuit. Shunt brakes must be used where it is desired to provide a drift point, as on bridge and trolley motions and in some special applications. For crane hoist service, however, the series-wound brake has been all but universally adopted, because of its simplicity, reliability, and suitability, for the work. The sole objection raised against the series winding in the past has been that its operating range is too narrow. Following the introduction of dynamic lowering control, it was found that few brakes in service could be depended upon to release at less than 75 per cent of full-load current. Another objection was that series brakes would not hold released to a sufficiently low value of current. However, these objections do not apply to brakes of modern design which will release at 40 per cent and hold released as low as 10 per cent of full-load current or less.

As regards the mechanical arrangement of their friction surfaces, commercial brakes are of three general types, namely, band brakes, shoe brakes and disk brakes.

The most extensively used type for crane hoists is the dead-end band brake. It consists of a flexible sheet steel band, lined with leather, asbestos composition or other friction material, one end of which is firmly anchored by means of a cast or forged ear, riveted to the band. The other end of the band is attached through a suitable adjustable fitting to a lever, which is operated by a long-stroke solenoid. In most designs the weight of the solenoid plunger, assisted perhaps by an adjustable weight on the lever, is made to apply the brake. In other designs the brake is applied by means of a spring. Very considerable improvement has been made in recent years in band brakes as manufactured by the various crane builders by refinement of the structural details and by the adoption of a well-designed single-coil solenoid instead of the old two-coil horse-shoe type operating magnet formerly used. For some purposes, as for example, on an intermediate shaft, the band brake has decided advantages, and for such applications it will, no doubt, long continue to be used. It possesses, however, inherent defects which no amount of refinement in design can eliminate. The most important of these defects is that it is effective in only one direction of rotation. In lowering, the friction between the brake wheel and band tends to wrap the band more tightly around the wheel, and this together with the fact that almost the whole circumference of the wheel is used gives high braking torque. But in the opposite direction the friction between wheel and band simply tends to raise the operating lever, and the retarding torque developed is practically nil. In hoisting the light hook, therefore, an excessive amount of drift is experienced and many accidents, usually unjustly blamed on the failure of limit switches, have resulted in consequence.

Another defect of the band brake is that it is difficult to make it as strong mechanically as other types. The band must possess a degree of flexibility which limits its thickness and therefore its strength, and the ends where the ears are attached are especially apt to fail. Every one with steel mill experience has seen these bands fail, perhaps with disastrous results. In actual practise the band nearly always drags more or less, imposing a friction load which detracts from efficiency. The long-stroke solenoid is sluggish in action as compared with a short-stroke electromagnet, so that in hoisting a heavy load, when the controller is brought to the off position the load may start to drop before the brake sets. When somewhat out of adjustment and operating through an excessively long stroke the hammer blow developed when the plunger drops, gives for an instant an excessive braking torque which throws severe stresses on brake band and gearing, sometimes resulting in damage to both.

These various defects of the band brake are rapidly forcing the more general use of shoe and disk brakes. The shoe brake consists of a brake wheel and a pair of shoes lined with friction material, and operated through the proper mechanism by either a short-stroke electromagnet of the clapper type or a solenoid. When a clapper type magnet is used, the brake is set by means of a spring. When a solenoid is used, the weight of the plunger is usually assisted by a spring. The only serious defect of the shoe brake is that it is practically impossible to use much more than one-half of the circumference of the brake wheel as a bearing for the shoes. Therefore, if the pressure per square inch is kept down to a value which will allow long life to the friction material, a considerably larger brake of the shoe type than of the band type will be required for the same torque. As compared with the band brake, the shoe brake has the following definite advantages; it gives the same braking torque in either direction of rotation; it is a stronger mechanical structure, when operated by a short stroke magnet it is much

quicker in action and yet has less instantaneous excessive braking; it is easy to keep it so adjusted that the brake shoes do not drag.

The disk brake consists of a set of one or more rotating disks, feather keyed to a hub which is in turn keyed to the shaft to be retarded and a set of stationary disks feather keyed to the frame of the brake. Either the rotating or stationary disks may be faced with friction material. The armature plate of the short-stroke operating magnet is moved forward by a spring, pressing the friction plates together when the brake is applied. When the magnet is energized the spring is compressed, and the friction plates float apart. The positive advantages of the disk type construction are that it gives equal braking torque in either direction of rotation; it provides plenty of friction surface and, therefore, gives relatively high torque in a relatively small and compact structure; because its friction surfaces are enclosed it gives a very constant torque, regardless of weather, splashing, oil or other untoward conditions. Its positive disadvantages are that on account of its compact structure it will dissipate relatively little heat; on account of the necessarily small bearing of rotating and stationary disks on the feather keys, the wear in both keys and keyways is excessive in severe service; the operating magnet simply relieves the pressure on the disks, when the brake is released and does not positively disengage the disks. This aggravates the trouble from heating; if it is desired to replace the armature or other shaft to which the brake is attached, it is necessary to entirely remove the brake.

To sum up, then, each type of brake has its advantages and its particular applications. The band brake should be used where a holding brake is desired. Its excellent torque characteristic in one direction of rotation is a positive advantage in such service. The shoe brake is a general service brake and should be used for all severe duty applications. The disk brake is also a general service brake which will give excellent satisfaction in light duty applications. Its use is frequently dictated by space limitations.

All of the three types of brakes above described are subject to the same objection, namely, that their torque is either all on or all off; in other words, they do not permit any graduation of braking torque. For most applications, this is not a grave disadvantage. Where dynamic braking control is used, the load is retarded by a nicely graduated braking torque and the fixed torque of the magnetic brake is of no consequence. In many cases where no great nicety of control is required, even without dynamic braking control, no difficulty is experienced if the brake is reasonably well proportioned with reference to the motor and the load. In special applications, however, the fixed torque characteristics of the ordinary brake is a very serious disadvantage. For example, take the case of the bridge motion of a gantry crane which it is desired to hold against any probable wind pressure. In such a case, the torque required of the brake bears no definite necessary relation to the motor torque. If a brake sufficiently powerful for safety in emergency is used, entirely too severe braking for ordinary service application will result. The swinging motion of a jib crane or a hammer head crane presents a similar difficulty. A too severe application of the brake produces objectionable and even dangerous swinging of the load, and, sets up excessive stresses in the structure. Various attempts have been made to properly take care of these difficulties. One method is to use a dash pot to secure gradual application of the brake. This is open to the objection that the brake must always be gradually applied, even in emergency when it may be necessary to apply it instantly in order to avert a wreck. A more satisfactory solution is the use of a multiple solenoid or multiple magnet brake.

The multiple solenoid brake consists of practically two brakes in one, one solenoid being arranged to release the greater part of the total braking torque and the other solenoid arranged to release a smaller part of the total torque. Both solenoids may be shunt wound or one may be shunt and one may be series wound, depending upon the convenience of control. There are various methods of controlling these brakes depending upon the particular application in which they are used. Both magnets may be released at once when the controller is thrown to the off position, and the action of the more powerful one delayed by a dash pot so that the smaller brake does practically all of the work of bringing the structure to rest, and the more powerful brake is then effective as a holding brake. A second method is to release the more powerful brake on the first point of the controller and the less powerful on the second point. This scheme permits the operator to secure full braking torque in emergency. A third method consists in releasing the large solenoid on the first point, the small solenoid on the second point and in providing a drift or coasting point on the third control notch at which point neither brake nor power is applied. Many applications where a drift point is very desirable will occur to the reader. It must be kept in mind, however, that with this scheme both solenoids must be shunt wound, involving at least two additional trolley conductors, and this feature may be very objectionable.

The second scheme mentioned above has a special application in connection with dynamic lowering hoist controllers which deserve particular mention. A defect of the standard dynamic lowering systems of control is that it is difficult or impossible to secure creeping speeds in lowering heavy loads. If reference is had to a dynamic braking speed torque curve (See paper by James A. Jackson, *General Electric Review*, June 1917, page 462) it will be noted that for the motor to develop a dynamic braking torque equal to full load torque it is necessary that the armature rotate at about

35 per cent of full load hoisting speed. In other words, it is difficult to secure more than 65 per cent speed reduction in lowering a heavy load, without dangerously overloading the field windings, whereas 90 per cent speed reduction is not infrequently required. This defect of dynamic lowering control is due to the fact that the retarding torque is proportional to the product of the currents in field and armature. The maximum safe field current must be assumed to be full-load current. In order to develop full-load torque the armature must therefore generate full-load current and it will accelerate to the speed necessary to enable it to generate sufficient voltage to force full-load current through the resistance of the dynamic loop. The minimum safe value of resistance in the dynamic loop is also quite definitely determined by considerations apart from speed control. It is evident, therefor, that the only safe way to reduce the minimum lowering speed with heavy loads is to relieve the motor of some of the overhauling torque. This can be very effectively accomplished by means of the multiple solenoid brake. If the smaller brake remains applied, as outlined in the second scheme of operation mentioned above, on the first point of the controller, excellent speed regulation may be secured, even with the heaviest loads the crane may be called upon to handle.

A-C. Magnetic Friction Brakes

Alternating-current brakes are either of the band or shoe type operated either by solenoids or clapper type magnets, or by small torque motors. In general, what has been said above with reference to d-c. brakes applies with equal force to a-c. brakes. It is to be constantly kept in mind, however, that alternating current cranes are rarely found in exceedingly severe duty, so that defects which may be quite serious in d-c. equipment may be unimportant in similar a-c. equipment. Furthermore, on account of the synchronous speed characteristics of the wound-rotor induction motor, the brake is relieved of all danger of excessive stresses and wear because of the excessive speeds often encountered in severe duty d-c. equipment. On the other hand there is no system of dynamic lowering control for a-c. hoists and many a-c. cranes are installed without mechanical load brakes. In consequence, a-c. brakes must usually absorb all of the energy of stopping the load, and usually they constitute the sole means of holding a load in suspension. A strong and reliable brake is therefore essential.

The constant speed characteristic of the wound-rotor induction motor makes a mechanical brake unnecessary for limiting the lowering speed of an overhauling load. The motor is simply accelerated to synchronous speed and above this speed true regenerative braking is secured and power is returned to the line. On the other hand, if no mechanical brake is used, it is impossible to secure a nice speed regulation in lowering an overhauling load, since no system of control for a-c. motors comparable to dynamic braking control for d-c. motors has been designed. This has led to the development of the solenoid load brake, which eliminates many of the inherent disadvantages of the mechanical load brake and secures effectively the desired accuracy of speed control.

The solenoid load brake consists of a single brake wheel and a single pair of brake shoes mounted in an appropriate frame and operated by two solenoids. One solenoid which is connected in the primary circuit is arranged to entirely release the brake when energized. The second solenoid is connected across one phase of the secondary or rotor winding with some variable resistance in series with it. Since the voltage generated by the secondary of an induction motor varies directly as the slip and since the pull of the solenoid can be made to vary almost exactly with the voltage across its coil, the pull can be made almost exactly proportional to the slip or inversely proportional to the speed. This solenoid is of course arranged so that the pressure on the brake shoes is relieved by the pull of the solenoid, so that when the pull is a maximum, that is when the rotor is at standstill, the braking torque is almost entirely relieved, whereas at high speeds, where the slip approaches zero approximately full torque is developed. The braking torque at low speeds can be increased by increasing the variable resistor in series with the solenoid coil. This resistor is controlled by the contacts of the hoist controller, so that operation very similar to that of a dynamic lowering d-c. controller is secured. In hoisting, the solenoid in the primary circuit is energized and this entirely releases the brake so that there is no braking friction in hoisting. On the first three or four points lowering only the solenoid in the secondary circuit is energized, so that on these points accurate speed control is secured by means of the solenoid load brake. On higher speeds the solenoid in the primary circuit is energized and the braking torque of the solenoid load brake is entirely relieved and the load may be lowered at high speeds by pure regenerative braking. The brake is therefore relieved of wear except when operating at low speeds and in slowing down from high speed to low speed. As compared with a mechanical load brake, very much less wear due to friction is encountered and much less frequent adjustment is therefore necessary. The solenoid load brake will give as good results on creeping speeds when lowering loads as the mechanical load brake, assuming equivalent adjustment; especially accurate control is secured in lowering a heavy load a very short distance, usually called "jogging".

In conclusion it seems advisable to emphasize the importance of substantial and capable braking equipment on electric cranes. A good dependable hoist brake is perhaps more important from the standpoint of safety than any other item of electrical equipment on a crane. This subject deserves more consideration

than has hitherto, in general, been given to it. The brake is an insignificant item of cost in the total price of a crane, so that even a cheap crane could well afford a good brake, but it has been very largely overlooked by the purchasers of cranes and many unsatisfactory and even unsafe brakes are in daily use. If this paper serves in any degree to direct more careful consideration to the matter of magnetic brakes for cranes, the author's object will have been accomplished.

Limit Switches

The function of limit switches as applied to electric cranes is to limit the travel of either hoist, trolley or bridge motion in either one or both directions. Their most common use is to limit the upward travel of the hook block.

Hoist limit switches are of two general types; first, geared; second, direct-operated by the hook block. Geared limit switches consist of a contact mechanism connected to the drum shaft through some such reduction gear as a traveling nut, worm and gear or interrupted gear. This contact mechanism is usually designed to handle a control circuit only, so that in addition to it, a magnetic switch or circuit breaker to break the motor circuit is required. Direct-operated limit switches are of either the control circuit or the main circuit type. The control circuit type consists of a simple normally closed contact opened directly by the hook block, and a magnetic switch. The main circuit type consists of a more substantial contact mechanism, capable of handling the motor current, operated directly by the hook block. It may simply open the motor circuit, or it may in addition provide some form of dynamic braking to secure a quick stop.

As mentioned above, geared limit switches are supplied with either a magnetic switch or a circuit breaker, of the shunt trip type, to open the motor circuit. A sharp distinction must be drawn between these two types. If a shunt trip circuit breaker is used, the geared contact mechanism must have normally open contacts. When the hook approaches the limit of travel, the contacts are closed, the shunt trip coil energized and the circuit breaker thus opened. It is therefore dependent upon the integrity of its circuits for its operation. Its contacts may be out of commission, a shoe may fail to make contact with a trolley bar, or a connection may be loose and the limit switch is inoperative. The important point is that it gives no previous warning or indication of its condition and the hoist may continue to operate until the hook block over-travels and an accident results.

The device with normally closed contacts and a magnetic switch, on the other hand, is normally safe. The magnetic switch will be opened by any failure of the limit switch circuit and the hoist cannot be operated until the fault is repaired. The magnetic switch may of course be held closed by a grounded circuit, independent of the action of the limit switch contacts and thus cause a wreck. However, the danger of grounds is small as compared with the many possibilities of open circuits and the closed circuit device is therefore a much safer and more dependable limit switch than the open-circuit device.

The magnetic switch may be mounted either upon the trolley or in the operator's cab. There is some advantage in mounting upon the trolley. It may not be so easily tampered with and the control wiring runs only a short distance so that there is less danger of grounding. If the magnetic switch is mounted in the cab, it is a wise precaution to put it in a locked enclosing case, so that it cannot be tampered with by unauthorized persons.

The method of resetting the limit switch is important. Any method, such as the use of a push button, which will permit further hoisting after the limit switch has operated, is to be condemned. A control circuit wire, energized by a finger in the hoist controller is often used, and is an excellent method if the necessary contact finger in the controller is available. This connection simply short-circuits the limit switch contacts when the controller is thrown to the lowering position, and the limit switch is reset automatically when the hook has lowered a short distance. A still better method is to connect the main contacts of the magnetic switch in a part of the circuit which is used only in hoisting. It is possible with most reversing controllers and with all dynamic lowering controllers, to make this connection and with this arrangement no control circuit connections whatever are required for reset. It is needless to say that careful and constant inspection is necessary if such limit switches are to be depended upon. The mechanical parts of the contact mechanism require especially close inspection. A flexible coupling of some sort is required between the drum shaft and the operating shaft of the limit switch, because of difficulty in securing accurate alinement. The couplings in general use at the present time are of poor design and are sure to give trouble unless frequently inspected and replaced when necessary. The bearings of the operating shaft require thorough lubrication. Accidents occur because these bearings become so badly worn that the reduction gears fail to mesh and the contact drum is therefore not driven.

All geared limit switches are open to the very serious objections that they take no account of the stretch of the cables and require complete readjustment whenever new cables are installed. If the limit switch is set with a new cable, to stop the hook travel at the proper level, it quickly develops as the cables stretch that it is impossible to hoist to the desired height, and readjustment is necessary. The direct-operated control circuit type limit switch avoids this difficulty and in addition has the advantage of being a very simple and strong device, and of being subjected to very little wear, because it operates only when the hook reaches the limit of travel. The contact mechanism hangs

under the trolley and at least a superficial inspection of it can be made from the floor. For cranes equipped with shoe or disk brakes, giving full braking torque in the hoisting direction and where from twelve to eighteen inches of variable drift may be permitted, this type of limit switch makes very satisfactory equipment. It provides a very considerable degree of protection at very little expense. It is important to remember, however, that a good disk or shoe type brake is very necessary for the reliable operation of such a limit switch.

The extensive use of band brakes, which provide almost no retarding torque in the hoisting direction, and the close limits within which many crane hoists have to work, has lead to the development of direct-operated main circuit limit switches, which in addition to opening the motor circuit, establish dynamic braking connections, in order to secure a quick and accurate stop.

The first devices of this kind were developed in the steel industry which is still their principal field of application. The first development, known as the 2 by 4 limit switch consisted simply of two pieces of 2-in. by 4-in. lumber from two to four feet long connected together at one end by a common door hinge and having mounted upon them at their other ends a pair of carbon blocks. This device is swung under the trolley with its contacts normally open, in such position that the contacts will be closed by the hook block lifting the lower two by four as the hook approaches its limit of travel. The electrical contacts are connected to short-circuit the armature when closed. The tremendous rush of current in the field and the heavy circulating current in the armature brings the hook almost instantly to rest. At the same time the circuit is supposedly opened by the blowing of the circuit breaker in the cab. To reset this limit switch it is necessary to pry the 2 by 4's apart while the hook block is lowered out of the limit.

This limit switch which is extremely effective in securing a quick and accurate stop, is cheap, strong and easily inspected. But it is evident that the operation of such a limit switch must be considered a serious emergency. In addition to the time and trouble required for resetting, the damage accruing to the motor is a serious matter. A flash-over almost inevitably results and after a very few operations of the limit switch the motor must be sent to the repair shop. Furthermore, under certain conditions of operation it is ineffective. If the hoist controller is not in the full on position, that is, if the current in the field circuit is limited by a portion of the starting resistance, the armature will be slowed down but will not be brought to a stop unless the circuit breaker happens to blow. If power fails, or if the hoist controller is brought to the off position at the instant the hook strikes the limit, the switch is absolutely ineffective. This latter contingency is more than probable since an operator will instinctively throw his controller to the off position when he sees the hook approaching the danger point. Very frequent failure of this type of switch may therefore be anticipated and has actually resulted in practise.

This device scarcely deserves consideration here except for the fact that it has served to direct the attention of control manufacturers to the need for a limit switch designed to give quick and accurate stops. The first development along this line consisted of a switch built along the lines of a drum controller, arranged to break the line connections and reconnect the motor with armature reversed as a series generator with a current-limiting resistor in circuit. By adjusting the resistor, practically any degree of braking and therefore any quickness of stop desired may be secured. In the interest of reliability it is wise to use a resistor of non-breakable material, since it must be mounted upon the trolley and since the quick dynamic braking stop depends upon the integrity of this resistor. This type of stop is widely used and gives excellent satisfaction. The objection to it is that it must be reset by hand, and for this purpose a reset rope is provided. The trolley must be run back toward the operator's cab so that the operator can reach the rope which results in some inconvenience and delay. To escape this objection, self-resetting, direct-operated switches have been designed. These switches secure dynamic braking in the manner described above, but in addition, close contacts which establish connections for lowering when the controller is thrown to the lowering position. The hook is lowered at low speed with a shunt around the motor until the hook is out of the danger zone, when the limit switch is automatically reset by a weight and the hook may be lowered at full speed.

If it is necessary to secure a very quick stop, say within four to six inches of drift with the light hook, the dynamic braking resistance will have to be so small and the braking current so heavy, even with this type of limit switch, that the commutator will be pitted and flash-overs may result. If the resistance is so proportioned as to allow a dynamic braking current equivalent to full-load current, only full-load braking torque is generated initially, before the motor begins to slow down and the average braking torque will be only about half full-load torque. Since the dynamic braking torque is proportional to the square of the current it is evident that about 150 per cent full-load current must flow on the dynamic braking peak in order to secure even as quick a stop as would be secured with a full-torque magnetic friction brake without the assistance of dynamic braking. It is evident, therefore, that by far the best results will be secured by using a good brake of the shoe type in conjunction with the dynamic braking limit switch where very accurate stops are required. Thus with a dynamic braking peak of 200 per cent and a full-torque magnetic brake, an armature

rotating at twice full-load speed should be brought to reset in about two-thirds of a second. If the hook speed is fifty-feet per minute, the drift will be about six inches.

As may be seen from the foregoing, the whole matter of hoist limit switches is in a rather chaotic condition at the present time. There is no conclusive and definite opinion among operating men as to what constitutes a good limit switch. Some operating engineers take the position that no limit switch is thoroughly dependable and that a limit switch which is not dependable is worse than none at all. Some maintain that the operator should not be permitted to depend upon the limit switch and that he should be put to some trouble to reset it, so that he will avoid using it if possible. Others maintain that such loss of time in resetting is not permissible and that automatic reset is positively necessary. Still others consider the matter of slight importance and accept without question anything in the way of a limit switch which the crane builder may provide. New cranes are being installed every week with every type of limit switch mentioned herein, from the open-circuit geared type, which the author frankly believes to be worse than no limit switch at all, to the most elaborate form of dynamic-braking direct-operated, self-resetting type. There is literally no standard specification for limit switches either as regards structure, as regards functions or as regards what they shall accomplish. In the hope, therefore, of assisting in the formation of a definite sentiment on this subject, the author ventures to submit his own opinions as follow:

Hoist limit switches should be operated directly by the hook block and should preferably open the motor circuit without the intervention of a magnetic switch or circuit breaker. On cranes equipped with disk or shoe type magnetic brakes and on which the drifting space is ample, a limit switch which merely opens the circuit is sufficient. On cranes equipped with band brakes and on cranes operating with very small head room dynamic braking limit switches should be used. The head room used by upward drift of the hook when retarded from three times rated speed by a full-torque brake, amounts to about three feet when full load speed is 60 feet per minute, 18 inches for 30 feet per minute, and so on in proportion. The above applies when high-speed motors of the so-called crane type are used; about one-half the drift would occur with the lower-speed so-called mill type motors. Hoist limit switches should always be considered emergency devices. Their use for service stops should be discouraged. The most obvious method of discouraging their continual use is to put the operator to some inconvenience in order to reset. It should not be necessary, however, for the operator to climb upon his trolley or endanger himself in any way, and it should not be possible for him to reset and continue to hoist either by accident or intention. It should be effective regardless of power failure or the position of the controller at the instant of operation. The operating mechanism should be positive, and no dependence should be placed upon springs or other mechanism exerting a definitely limited operating force. Direct operation through push rods or steel cable is preferable. In the limit switch itself, simplicity and strength are of the utmost importance. In the purchase, installation, operation and upkeep of a limit switch it should be constantly kept in mind that it is primarily a safety device upon which the safety of human life may very frequently depend and that therefore the best is none too good.

The foregoing has all been with reference to limit switches for limiting the upward travel of the hook. Where a lower as well as an upper limit is required, commercial types of direct-operated stops are not easily applied. In such cases it is customary to use two complete geared limit switches, or a single geared mechanism, such as is used with elevators, containing two adjustable sets of contacts working in conjunction with magnetic switches.

Limit switches are sometimes required to prevent the collision of trolleys on double trolley cranes, or of the cranes themselves when several cranes are mounted upon one runway. Direct-operated dynamic-braking switches have been applied to some extent for this purpose. Another method is to equip the trolley or bridge motors with magnetic friction brakes, normally held released by shunt-wound magnet coils and automatically applied by means of a direct-operated contact device when the machines come into dangerous proximity to one another. This problem, however, does not often arise.

For alternating-current cranes, the same remarks which have been made regarding direct-current cranes apply insofar as they refer to the method of mounting, of operating and of opening circuits. Dynamic braking cannot be secured with an alternating current motor, independent of an outside source of power and the remarks made regarding the use of dynamic braking limit switches therefore do not apply to alternating-current cranes. Fortunately the a-c. motor does not run at a very much higher speed on no-load than it does on full load. The amount of drift is therefore quite constant independent of the load on the hook, so that, if reliable brakes are used, quite accurate stopping may be secured with direct-operated limit switches which merely open the circuit.

Direct-Current Crane Protective Panels

It has always been the practise to equip electric cranes with some form of protective panel, mounted in the operator's cab, provided with a service knife switch for disconnecting all of the circuits on the crane from the power lines and with some form of individual overload protection for each motor. A vast improvement has been made in recent years in the character of this equipment as offered by the electrical manufacturers, but cranes are still sometimes provided

with protective panels of the crude original type. We will, therefore, take up the various types of crane protective panels in the order of their development since even the crudest type is still sometimes furnished on an otherwise modern crane.

The simplest form of crane protective panel consists of a main knife switch with open link fuses and a link fuse in one side of each motor circuit. The unsatisfactory and unsafe character of this equipment scarcely requires comment. The first step in advance from this type is, naturally the use of enclosed fuses instead of link fuses and in this form the fused crane protective panel is very widely used. The protection furnished by this equipment, however, is not very great, and in the case of severe duty cranes is, in fact almost negligible. On severe service cranes heavy momentary over loads are a necessary incident of normal operation. It is, therefore, necessary to use fuses of such large capacity that they afford no protection to the motor or mechanical equipment against continuous overload. For example, a bearing cap in the bridge drive may be pulled up too tight, imposing an overload of 25 or 50 per cent on the bridge motor. In such an event, a fuse, as ordinarily used, in the bridge motor circuit would be unlikely to afford any protection to either the motor or bearing. The panel may be properly fused when new, but it is unlikely to remain so very long. Proper replace fuses often are not at hand when required, and in this case a piece of copper wire is commonly used as a re-fill, which may be replaced at some distant date or not at all. If rigid inspection is enforced and an attempt is made to use fuses of the proper capacity to afford real protection, the replacement of enclosed fuses on a severe duty crane is a considerable item of expense. These disadvantages all indicate the fundamental unsuitableness of fuses for the protection of crane motors and have to some extent forced the adoption of circuit breakers.

Railway type circuit breakers have been used to some extent in this service, in various combinations, and it is rather remarkable that their use is not more general. They constitute a strong and simple protective equipment at comparatively small expense. They avoid the two most important defects of fuse protection, because they may be quickly reset at no expense. The sole serious objection to them is that they must be set too high to give any protection against continuous overloads.

The modern crane protective panel, now almost universally used in the steel industry, has been developed with the view of providing safety protection for the operating force as well as electrical and mechanical protection for the crane. In the interest of safety in emergency it is often desirable that the operator be able to cut off power instantly. This is best accomplished by push button operation of the circuit breakers with the push button mounted within easy reach of the operator. In the interest of safety of workmen engaged in routine inspection and repairs it is desirable to provide means for making it impossible to accidently start any motion of the crane. This is accomplished by providing a safety plug, which the workman takes out of the panel and carries with him in his pocket, while he is on the crane and the absence of which from the panel makes it impossible to close the main circuit breakers; or by providing a safety lock clip on the service knife switch by means of which the workman locks the knife switch in the open position with a safety padlock, the key of which he carries in his pocket. Overload protection is secured by means of overload relays in each motor circuit operating in conjunction with magnetic switches. Various combinations of overload relays are used, depending upon the preference of the user. However, a quite definite standard specification seems to be forming and the type now most generally used has one overload relay in one side of each motor circuit and one common or totalizing relay in the opposite side of the main circuit.

On account of the ease and quickness with which this magnetic contactor type of circuit breaker can be reset it is possible to set the overload relays so that they will trip at a comparatively small overload without interfering too greatly with normal operation. Such a protective panel, therefore, affords some protection against continuous overloads. A much greater degree of protection is secured by the use of inverse time element overload relays. It has become quite common practise to use one inverse time element overload relay in each motor circuit to protect the individual motors against continuous overloads and an instantaneous trip relay in the common or return side of the circuit. This arrangement undoubtedly provides the ideal protection if the equipment is kept in good operating condition, but with the care which such equipment commonly receives in service, it is not wise to put too much reliance upon it. The inverse time element characteristic is usually secured by means of an oil dashpot and its accurate operation depends upon the use of a specific oil having very definite physical characteristics. If some other oil is used the inverse time element feature becomes unreliable or useless. The use of oil moreover tends to assist in the accumulation of dust and grit on the apparatus, which tends to destroy not only the reliability of the inverse time element feature but in addition may retard or actually prevent the operation of the relay itself. The author does not wish to be understood as condemning panels which make use of inverse time element overload relays. If carefully inspected and kept up they certainly provide a very valuable protection, which can be secured in no other way. Our desire is to emphasize the necessity for this inspection with existing types of equipment, and further to present the problem of securing the time element feature in some more simple and more reliable way.

The selection of the proper sizes of knife switches and magnetic contactors for crane protective panels is of

importance. In general it is impossible to calculate with any degree of accuracy the current which, flowing continuously would produce a heating effect equivalent to the varying loads on the several motions. Each motor is operated intermittently but usually not in any definite cycle. Two or even three motions may be operated at the same time. There are so many variables depending upon the infinite variations of actual service that an attempt to standardize at first seems hopeless. However an examination of heating curves on a standard line of 30-min. rated enclosed crane motors shows that they can work at their rated load less than 20 per cent of the total time; also that they will, with rare exceptions, and that on small sizes only, carry no more than 35 per cent of their rated load continuously. This indicates that no matter how the currents flowing to the several motors on the crane are superimposed on one another, the root-mean-square value of the current passing through the main knife switch and magnetic contactors, could not exceed 35 per cent of the sum of the rated currents of the several motors, provided the motors were of such capacity as never to be overheated themselves.

Actual experience, quite independent of the consideration of motor ratings, has evolved a standard which is now in general use. The rule is to use magnetic contactors and main line knife switches whose continuous rating is equal to 50 per cent of the sum of the half-hour current ratings of the several motors on the crane. This rule may be used with confidence in making specifications for crane protective panels for all general purpose cranes having three or more motors. Discretion must of course be used in connection with unusual cases. The arc rupturing capacity of the magnetic contactors, should not be less than three times the normal current of the largest motor on the crane.

Alternating-Current Crane Protective Panels

The problem of overload protection for alternating-current cranes is entirely different from that presented by direct-current cranes. In the first place, an alternating-current motor does not need to be protected against exerting too great a torque instantly. It will inherently stall at somewhere between 2½ and 3½ times full load torque, whereas with a d-c. crane motor, torque can be developed to the destruction of motor or gearing unless a protective device of some sort intervenes. An overload device is therefore required in connection with an a-c. crane motor almost solely for the electrical protection of the motor, and not as on d-c. cranes for the mechanical protection of the motor and gearing. In the second place, in an a-c. crane motor greater starting peaks of current are required for the same motor output than in a d-c. motor, so that any overload device which is unable to differentiate between excessive peaks and continuous overloads of lesser magnitude, is even less useful for the protection of an a-c. crane motor than for a similar d-c. motor. In addition to these considerations, the use of fuses is especially to be condemned in connection with a-c. crane motors because of the danger of single phasing, which might easily result in serious accident.

The satisfactory protection of an a-c. crane therefore depends upon the use of reliable inverse time element overload relays. These relays are usually of the duplex type, that is, with two coils operating upon one control contact. One such relay should be used in the primary circuit to each two- or three-phase motor and in addition, a totalizing relay, connected in series with the wire or wires not protected by the individual motor relays may be used if desired.

Discussion

Electric Crane Controllers

BY J. F. SCHNABEL
Associate, A. I. E. E.
Electric Controller & Manufacturing Company, Cleveland, Ohio

Review of the Subject.—*Other papers in the series on electrical apparatus for cranes deal with the requirements as to motors and auxiliary equipment; the latter comprising brakes, overload protective panels and limit switches. This paper on controllers reviews its subject in a general way, without going into any details of the devices employed, presenting a clear view of the fundamental considerations involved.*

The controlling apparatus of an electric crane is responsible for the prompt and proper accelerating of the several motions; their speed control; the safeguarding of the motors from abuse; the convenience and economy of operation; and the elimination of many dangers due to carelessness. The author touches indirectly on these points but concerns himself chiefly with the character of the controllers best suited to the bridge, trolley and hoist under various conditions.

The paper deals fully with the problems concerning the selection of ohmic values for the resistors and also covers very completely the connection arrangements and resistance values involved in the dynamic braking control of lowering loads.

CONTENTS

INTRODUCTION

THE controlling apparatus of an electric crane is to the machine on which it is used as the nervous system is to the human body.

The best designed and most scientifically selected motors or brakes would be practically useless without the proper means for controlling the energy that must be applied to them to do the work intended. Furthermore, the dissipation of the energy stored in the crane bridge or trolley during acceleration, or in the loads that have been lifted by the hoist, in order to bring these structures to rest, or to lower the loads, is of as great importance as the application of energy in the first place. Friction devices can be used for this purpose, but the resulting wear on the friction surfaces requires frequent replacements and adjustments, particularly on hoists. It has been stated by some one that the energy given up in lowering 20 tons through 50 feet will generate sufficient heat to raise the temperature of 10 lb. of iron 1000 deg. fahr.

It is well-known that friction brakes for lowering were long a source of trouble on crane hoists. Due to the ability of a direct-current motor to convert mechanical energy into electrical energy, as well as to perform the primary function of translating electrical energy into mechanical energy, the motor, in many cases, can be used for retarding also and thus relieve or replace the friction brake for this purpose. The energy is not all radiated from the motor itself, but mostly from resistors connected in the motor circuit. In the resistors the electrical energy is changed into energy in the form of heat, and is transmitted to the air. It is easy to design and proportion resistors to do this without any great depreciation, and the energy can be radiated into the air wherever it is most convenient. There is some additional heating in the motor when used for both applying power and retarding, but on crane work this is not enough to exceed the safe limits of a motor that is large enough to meet the other requirements of starting torque and commutating ability. However, on hard worked cranes and hoists, performing a definite cycle of operations, such as the hoist of an ore bridge, or special cases where loads are hoisted and lowered through long distances, the heating due to the dynamic braking current should be taken into account in figuring the size of motor required. On account of the twofold function of the motor, we will consider the question of control in two parts. The first will relate to controllers which are used only where energy is applied to the motor to accelerate and move a load, and which we will call *plain controllers*, and the second to those in which, in addition to accelerating and moving a load, the motor is also used to retard and stop a moving load, and these we will call *controllers with dynamic braking.*

APPLICATION OF PLAIN CONTROLLERS

Plain controllers are used for either direct or alternating-current motors, and on cranes are usually of the reversing type. The bridge and trolley motions of cranes require controllers of this description. On hoist motions of cranes, with friction brakes for lowering, either reversing or nonreversing controllers will be required, depending on the design of the brake. The first crane hoists were doubtless made with hand-operated brakes for lowering, and if the load on the hook would overhaul the motor, the speed in lowering was regulated by hand or foot, no power being required in the motor during lowering. Mechanical load brakes have been used for a number of years for hoists which are so designed that if the speed of the lowering load exceeds that of the motor, friction is applied to retard it. This form of brake requires the use of a plain reversing controller, but on account of the advantages of controllers with dynamic braking on hoists, it is now used only in special cases.

Direct-current motors are most commonly used for cranes, for the reason that better starting conditions and better speed control can be obtained by their use.

Presented at the Spring Convention of the A. I. E. E., Chicago, Ill., April 19-21, 1922.

Alternating-current motors, usually of the slip-ring type, must sometimes be used because the power supply available is alternating current, and the expense of converting it to direct current may not be warranted. On direct-current cranes the motors for all motions are usually series-wound on account of their strong construction, high starting torque and their characteristic feature of adjusting their speed to the load. Due to friction of gearing, bearings, ropes, etc., there is always sufficient load on the motor to prevent over-speeding, except on overhauling loads on hoists, for which a system of control using a series motor will be described later. Shunt field windings are seldom used, except for bridge or trolley motions where dynamic braking is sometimes required.

Plain controllers for bridge, trolley or hoist motions may be either of the manual or magnetic contactor type. In general, it may be stated that for small motors, or large motors not frequently operated, manual controllers are satisfactory. For motors that are operated very frequently, or for motors of large sizes, magnetic controllers are more desirable for the reason that the small and easily operated master switch relieves the operator of considerable manual labor, and enables him to do more work. Magnetic contactor controllers can also be provided with current limit acceleration, and the motors, as well as the machinery, can thus be protected from damage due to a careless or too ambitious operator attempting to accelerate the motor too rapidly.

The functions of a controller in connecting a motor to the line for operation in either direction are well understood. The controller, either manual or magnetic, should be designed to open or close the circuits with the least amount of wear, and ample provision for taking care of the arc should be made. The wearing parts should be easily accessible for renewals.

On magnetic contactor controllers it is important to have at least two independently operated contacts for opening the motor circuit, so that failure to stop, due to sticking of contactors, will be minimized. This is particularly necessary on hoists, and the addition of a hoist limit switch for positively opening the motor circuit when the hook block reaches the upper limit of travel is desirable from the standpoint of safety to workmen below the crane. Failure to stop the hoist motor often results in breaking the hoisting cables when the hook block strikes the drum or a cross member on the trolley, and the hook block falls to the ground. Even with no load on the hook, men have been killed from this cause.

Calculation of Resistor Ohmic Values

An important point in connection with controllers for cranes is the ohmic value of the resistors used with them. It is well-known that a direct-current motor can not be connected directly across the usual source of power until it has developed a suitable counter e. m. f. Several factors determine the value of the resistor in addition to the requirements for accelerating the motor, gearing and load:

(1) The starting torque required.

(2) The speed control desired.

(3) The protection on reversing controllers when "plugging," which is reversing the current in the armature while running in order to make a quick stop.

On bridge motions the torque, and consequently the current, required to start the motor is usually close to the full-load torque of the motor. On most cranes the ratio of hook load to the total weight of the crane is small, so that the load on the hook does not greatly affect the starting current required. The fact that the load is suspended by ropes also reduces the effect of the hook load in starting. On account of uneveness in the crane runway, even greater current may be required at times. If the resistor for a bridge controller allows less than full-load current to flow, the operator may be obliged to move the controller several points before the motor will start, and there will then be fewer points remaining for speed control. A bridge motor is seldom "plugged," the motion usually being checked by a foot brake, so that a resistor allowing full-load current is satisfactory.

On trolley motions the starting torque and current vary more in proportion to the load, and a resistor allowing less than full-load current is desirable. The trolley motor is usually "plugged" for making quick stops, and the resistor should limit the current to a safe value for the motor under this condition. Low speeds with light loads are also necessary on some trolley motions where it is necessary to place loads accurately. A resistor that will allow half full-load current on the trolley motion is desirable from all three points of view, viz., starting, speed control and "plugging."

On the hoist motion the resistor should allow at least sufficient current on the first point in hoisting to release the brake, and also to give sufficient torque to prevent the maximum load from overhauling, especially where there is no mechanical lowering brake.

The efficiency of a well designed crane may be as high as 70 per cent. The torque and current required to hoist the full load on this crane will be 1/0.70 or 143 per cent of that which would be required to hoist the load if friction were not considered. In lowering, only 70 per cent of the torque, due to the actual load, will be available, so that the lowering torque is about one-half of the total hoisting torque. (70/143 = 0.49 or 49 per cent). While the current required on a series motor to give one-half full-load torque will be somewhat more than one-half full-load current, it is found in practise to be satisfactory to use this value of current on the first point hoisting, as the motor rating should be somewhat more than that required for merely hoisting the maximum load of the crane, in order to allow for acceleration.

This value of the resistor will give a fairly low speed when hoisting a light load, which is an important con-

sideration in a hoist controller. Assuming the light load hoisting current to be about one-quarter of the full-load current of the motor, and referring to the characteristic curve of a Westinghouse No. 7-K d-c. series-wound motor rated at 27½ h. p., 230 volts, the current required would be about 28 amperes. The speed of the motor at full voltage with this current would be 1200 rev. per min. The value of the resistor to allow half full-load current, neglecting the resistance of the motor itself, which is comparatively small, is about 4 ohms. The voltage drop in the resistor is then 28×4, or 112 volts, leaving 118 volts on the motor. The speed will then be $1200 \times 118/230 = 615$ rev. per min. The full speed of this motor is 535 rev. per min. This will be satisfactory in most cases, though there are cases where a much lower speed than this may be necessary, as in the case of foundry controllers where light flasks, or moulds, must be carefully lifted to prevent shaking out the sand. For such service a higher ohmic value of the resistor may be necessary, but if there is danger of the heavy loads overhauling, other provisions, which will be referred to later, will be required. It is of course possible for the operator to move the controller over several points in hoisting the heavy load, but in so doing the number of speed control points remaining is thereby reduced.

As a compromise value for the ohmic value of the resistor, where the manufacturer may not always know the service in which the controller and resistor will be used, about three-quarters of full-load current can be allowed to flow on the first point. This will give sufficient protection if the motor is "plugged" by bringing the controller to the first point in the reverse direction while the motor is still rotating. If the efficiency of the motor is 85 per cent, the back e. m. f. of a motor wound for 230 volts will be nearly 200 volts ($230 \times 0.85 = 195.5$). At the moment current is applied to the motor in the opposite direction, the line voltage will be added to the back e. m. f. of the motor, and there will be a total pressure of 430 volts to force current through the motor and resistor. The value of the resistor to allow three-quarters of full-load current is about 2.7 ohms for the motor to which reference has been made. The current that will flow will be about one and one-half times full-load current ($430/2.7 = 159.3$ amperes. $159.3/112.5 = 1.43$). It is true that on account of the high speed which a series motor will reach on light load, there is a tendency for the voltage to go to a higher value when the field strength is increased by the current that flows when plugging; but the speed of the motor will be reduced about as fast as the field magnetism will build up, so the above voltage may be considered to be about the maximum, and it is the voltage that exists at the moment of reversal. This current will not damage the motor as it must be designed to withstand acceleration peaks as high as this.

The speed reduction obtained with a resistor as just described can be stated as being about 50 per cent for average load conditions. In the case of the Westinghouse motor to which reference has been made, a resistor of about 2.7 ohms would be used. A drop of 50 per cent in the resistor means that the current would be $115/2.7 = 42.6$ amperes. $42.6/112.5 = 37.8$ or about 40 per cent of full load, which may be considered average load conditions. The motor would run at 850 rev. per min. at this load with full voltage, so that the actual speed would be 425 rev. per min., since there is only half voltage applied to the motor.

In order to secure lower speeds with light loads than can be had with a resistor in the motor circuit, another resistor is shunted around the armature. On manual controllers this can usually be done by adding another contact finger and segment. This has the effect of reducing the voltage applied to the armature and at the same time it increases the field strength. Reductions in speed as much as 90 per cent can be secured in this manner with light loads. Any value of resistor could be used as all of the regular starting resistor is also in the circuit, and any speed could be secured by adjusting the armature shunt. However, if it is made too low, there may be too high a current in the armature and this resistor if the controller is quickly brought to this point with the motor at high speed. As explained in connection with the current values in plugging, the back e. m. f. may be about 200 volts. It is customary to use a resistor value so that the current will not exceed one and a half times full-load current. For the Westinghouse motor already referred to, with a full-load current of 112.5 amperes, the resistance would be $200/168.75 = 1.18$ ohms. In practise it could be somewhat less than this, as the motor would have slowed down somewhat and the back e. m. f. would be correspondingly reduced by the time the armature shunt point was reached. Adjustment of this resistor in the field could be made to suit the actual requirements of speed, load and current allowable.

The resistor values just described are for manual controllers. On magnetic contactor controllers it is customary to allow three-quarters of full-load current to flow on the first point in order to provide protection to the motor when plugging. On most crane controllers full-speed control is used, but the acceleration relay for the first resistor contactor should be set to operate immediately upon closure of the circuit, so that if necessary to secure more torque to hoist a heavy load, or for any other reason, the operator can close this next contactor by means of the master switch. However, the first acceleration relay should be adjusted to prevent the closure of this first contactor in "plugging," if the current is much above the current in starting from rest, so that the "plugging" current will be limited to about one and one-half times full-load current as previously explained.

Resistor Carrying Capacity

The current-carrying capacity of the resistors is another point for consideration. While there is a number of classifications ranging from light starting duty with current on 15 seconds out of four minutes up to continuous duty, there are two classifications that meet the average crane service. The first is light intermittent duty good for one minute out of four minutes, and the second is heavy intermittent duty good for two minutes out of four minutes. These are both on the basis of allowing about three-quarters full-load current on the first point. The first is known as the Electric Power Club rating No. 53, and the second as No. 73. Special cases may require more or less capacity in the resistors. Little is saved on small motors by reducing the capacity below the heavy duty rating, and the use of the heavier duty resistor makes the controller safer for conditions of operation which cannot be foreseen at the time of installation.

On manual controllers there is considerable advantage in having the resistors mounted in the same frame with the controlling elements as there is less wiring required in the crane cab. In all such cases, however, the resistors should be easily removable, both as a unit and as individual units, so that replacements can be easily made.

Controllers with Dynamic Braking

There are two classes of controllers with dynamic braking, first, those used for heavy bridges or trolleys where in either direction it is necessary to dissipate the energy stored in them during acceleration, and second, hoist motions where only in the lowering direction must the energy stored in the load during hoisting be dissipated. In the first case the energy is represented by the well-known formula $\frac{M V^2}{2}$, where M is the mass and V the velocity or speed in feet per second. This energy is small, on ordinary cranes, in relation to the energy required to accelerate and drive these motions. "Plugging" is much used on trolley motions because of its effectiveness and absence of any additional control apparatus. On high-speed trolleys of ore bridges, the proportions of this energy to the energy for accelerating and running is much greater, and a controller with dynamic braking may be desirable to reduce the current consumption and provide graduated braking to give smoother operation. On hoist motions the energy to be dissipated is represented by the formula $W \times S$ where W is the weight of the load in pounds, and S the distance in feet the load has been lifted. In lowering, friction of the gearing, bearings, ropes, etc., absorbs part of the energy stored in the load. On a crane hoist having an efficiency of 70 per cent, it has already been shown that the torque in lowering is about one-half that required in hoisting, so the energy is in like proportion.

Direct-current motors are best adapted to all forms of dynamic braking control. A series-wound motor is not well suited for controllers of the first class, where the braking is required in either direction of travel. A series generator is not a very stable machine, especially when operating under widely varying speed and torque conditions. Furthermore, the switching of connections necessary to cause the current to flow in the armature and field in the proper directions for either running or braking, whether in the forward or reverse direction of the machine, makes a complicated controller. By using a compound motor the shunt field will give the initial magnetism in the field without regard to the speed of the armature, which is not the case with the series field. It is usually sufficient to use only the shunt field excitation, and the dynamic braking connections are simple, as it is only necessary then to connect a resistor around the terminals of the armature. This resistor may be variable to give graduated braking torque. If it is necessary to include the series field in the dynamic braking circuit in order to get increased torque in braking, the shunt field should also be used to give the initial magnetism in order to cause the dynamic braking current to build up promptly under all conditions of speed. It is of course possible to excite the series field separately from the line, and so to have the same advantage as

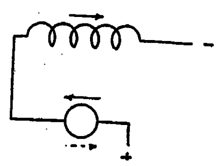

Fig. 1

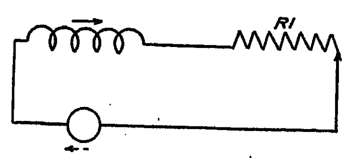

Fig. 2

if a shunt-wound field were used, but waste of power in the resistors necessary to do this is objectionable. Usually it is desirable to continue the dynamic braking action at the "off" position of the controller, and in such cases means must be provided for automatically disconnecting the series field from the line when the motor has about come to rest, which complicates the controller. Where a series motor must be used, a so-called "teaser" circuit can be applied to the series field, so that a small percentage of full-load current will flow that will enable the motor to build up the dynamic braking current. There is still the objection that such a controller is complicated, and simpler means are usually to be preferred.

A simple arrangement for securing dynamic braking with a series motor operating in either direction is to use a resistor shunted around the armature as described in connection with plain controllers. The armature will force current through the resistor across its terminals until it has slowed down to a point where its back e. m. f. is equal to or below the voltage applied to it, and it will then continue to run at a greatly reduced speed, so that it can easily be stopped by disconnecting

it from the line. A magnetic friction brake may be necessary finally to stop the motor, but on account of the greatly reduced speed the energy to be absorbed by the brake is small. Several points of shunted armature, obtained by varying the resistance, should be used to enable the speed gradually to be reduced without exceeding a safe current in the armature.

Alternating-current motors are not well adapted for use on motions requiring the motor to be used for slowing down and stopping. It requires direct current for energizing the primary circuit during braking, and where alternating-current cranes are installed, no suitable provision for direct current for this purpose would be available, nor would the braking action be as effective or as easily regulated as in the case of the direct-current motors.

It will be seen that this class of controllers with dynamic braking will usually require some application of power from a source outside the motor to give proper braking action. If failure of the power supply should occur at the moment the retarding action was to be applied, either in plugging, dynamic braking or applying a shunt to the armature, failure to stop the motor may cause an accident. Where a series field is connected in the dynamic braking circuit there would be a continued braking action, provided the conditions of speed had been such as to cause it to begin. But, especially in magnetic controllers, which require power to close the contactors, failure of the controller to close the proper circuits may also result. Therefore in all cases where there is any hazard involved if the motor cannot be stopped through its own action, it is advisable to use a friction brake also. A series-wound brake is always the safest, but if the fluctuations in current are too great to permit a series brake to be used, a shunt-wound magnetic brake should be used for safety. If this is connected across the line permanently, so that it sets only in an emergency, the wear on it will be negligible, and it will be in good condition to perform its function as a safety device if occasion demands it.

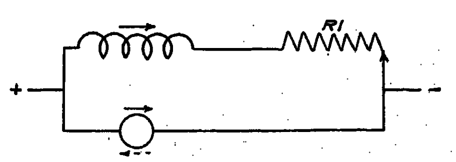

Fig. 3

Dynamic Braking Lowering

It is on the hoist motions of cranes and similar machines that controllers with dynamic braking find their greatest application. Since the advent of the present system of control here described, in which the controller applies power for lowering light loads, as well as enables the motor to regulate the lowering of heavy loads, the various forms of mechanical lowering brakes for direct-current cranes have been practically eliminated, together with the expense for their maintenance and adjustment. A series motor has always been considered ideal for the hoist motion. It lends itself readily to the requirements of dynamic braking in lowering, for the reason that its back e. m. f. is in the right direction for lowering without complicated switching connections in the controller.

In the simple diagram shown in Fig. 1, the current in hoisting flows in the direction of the full arrows. The back e. m. f. of the armature is, of course, in the opposite direction as shown by the dotted arrow. In

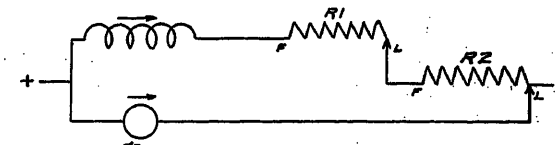

Fig. 4

lowering, the armature will rotate in the reverse direction, and the back e. m. f. will be opposite to that first mentioned and current will flow in the same direction as it would in hoisting. This fact helps to simplify the circuit connections required in changing from hoisting to lowering. The connection between one side of the armature and one side of the field is fixed, and this lessens the chances of an open circuit in the controller or wiring of the crane. To complete the dynamic circuit for lowering, we refer to the diagram in Fig. 2.

The circuit is closed through a variable resistor R-1, so that the speed in lowering may be regulated. The value of this resistance depends on the speed desired. The current in the circuit varies with the overhauling load. This circuit is not yet complete, as on an electric crane provision must be made for lowering the empty hook, which may not overhaul the hoisting mechanism. This requires application of power from the line, and we add to the circuit as indicated in Fig. 3.

The series field will now be separately excited from the source of power, and under any condition of load on the hook, a definite amount of field excitation will be assured to enable the armature to generate current. In starting from rest, current will flow in the armature in the direction indicated by the full arrow, and will continue in that direction until driven by an overhauling load sufficiently heavy to overcome the friction of the hoist, and to drive the armature at such a speed that its generated e. m. f. will be greater than that applied to it, when current will flow in the opposite direction. The field strength, and consequently the speed of the armature with any load, depend on the value of resistance R^1. In practise this is found to be about one-half full-load current to give the necessary speeds for light and heavy loads. This same resistor can be used in the hoisting direction, for it meets the requirements of starting and speed control as explained in connection with plain controllers mentioned in the first part of this paper. It will be easily seen that the essence of this system is to excite the series field sepa-

rately, and so obtain somewhat the characteristics of a shunt-wound motor, which is easily convertible into a generator. There is a great advantage, however, over a shunt motor in the fact that once the motor is started it can easily supply its own field excitation, even at low speeds, because of the variable resistor R^1, and thus failure of the supply voltage does not cause the loss of ability to slow down and stop the motor.

In Fig. 3, no provision is shown for limiting the current in the armature during acceleration. This is provided by another resistor, R^2, which is connected as shown in Fig. 4.

This is also a variable resistor, and by the connections employed it is cut out of the armature circuit and into the field circuit, thus giving greater variation in the speed control. The connections shown are for the last point of the controller, the arrows being considered as moving along the resistors from points marked "*F*" to points marked "*L*" as the controller is brought to the full-speed position. The ohmic value of resistor R^2 should be sufficient to limit the current at the start to suitable amounts in the two parallel circuits, viz., armature and field, to give enough torque to start the motor.

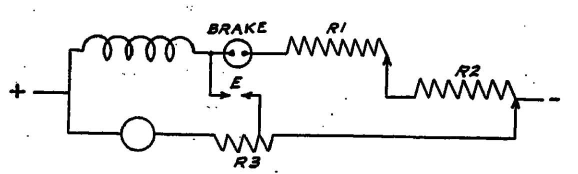

Fig. 5

It is necessary to use a magnetic friction brake for holding the load suspended, and also for bringing the load to a final stop.

Dynamic braking can reduce the speed of a lowering load to a low value, it is true, but never to a definite stop if there is an overhauling load. A series brake is used on most hoists because it offers the greatest protection if the motor circuit opens accidentally. It is also quicker acting than a shunt brake and requires no additional control wires. It is connected in the field circuit as shown in Fig. 5.

It will be noted that there is an unbroken circuit from one side of the armature through the series field and brake in either hoisting or lowering, so that the chances of losing the dynamic braking circuit by any failure in the circuit-closing contacts of the controller are limited to the connection between the other side of the armature and the brake. On magnetic controllers a spring or gravity closed contactor *E* is connected in the circuit so that any failure of voltage, or the failure of the hoisting or lowering contactors themselves, will cause the closure of a safety dynamic braking circuit independent of the regular controlling circuits. On manual controllers a similar connection is made in the controller at the "off" position.

It will be noted in Fig. 5 that another resistor R^3 has been added. This is necessary in order to secure the release of the brake under all conditions. On a manual controller especially, if the resistor R^2 were cut out too rapidly, the armature might not accelerate quickly enough, and being in a parallel path with the field and brake, would take most of the current if this resistor R^3 were not used. The brake would not release and with the low field current the armature current would reach a high value. The addition of resistor R^3 causes a more equal division of the current at the first point when starting, and insures the release of the brake even when the operator moves the controller on rapidly. This resistor R^3 also limits the current when the controller is brought to the "off" point quickly, and when the emergency circuit is closed. Theoretically this resistor should be gradually cut out of the circuit until at the full-speed position the armature would be directly across the line. If this were done, the speeds in lowering light and heavy loads would be very nearly the same, and on the heavier overhauling loads some current might be returned to the line. On manual controllers, however, the expense of the additional contact devices necessary is not warranted. On magnetic controllers such provision can more easily be made by the addition of the necessary contactors, and means can also be easily provided for insuring the release of the brake before the resistor is short-circuited. However, it has been found that unless a certain amount of resistor R^3 is left in the circuit, there will be a tendency for the motor to "hunt," or have an unstable speed for a time, due no doubt to the high armature current flowing at this time, while the field current is comparatively low.

If the current in the field on the last point is limited, by the combined resistors R^1 and R^2, to one-half full-load current, and the resistor R^3 adjusted to give proper operation of the series brake, the speed in lowering the light hook is about $1\frac{1}{2}$ times the rated full-load speed of the motor, while the speed in lowering the full load of the crane is about $2\frac{1}{2}$ times the rated speed. These values may vary with different conditions of friction, number of reductions in gearing and ropes, and the size of the motor with reference to the load upon it, but the ratios stated are for average conditions. The light-hook speed can be increased somewhat by using a weaker field and cutting out part of the resistor R^3 as indicated, but this adds considerable expense for the additional apparatus and is necessary only in special cases. A shunted armature connection can easily be added for the hoisting direction when necessary to secure unusually low speeds at light loads, as already explained in connection with plain controllers.

It should be noted that the combined action of dynamic braking and the friction brake at the "off" position gives double protection in preventing the load from lowering. This combined effect is had also with magnetic controllers in case of failure of voltage or failure of the hoisting or lowering contactors to close

and remain closed at the proper time. On manual controllers failure of the voltage will not cause the opening of the dynamic braking circuit as in the case of the magnetic controller. The fact that there is always a dynamic braking action at the "off" position relieves the friction brake of a great part of the work of bringing the motor to rest. In this system of control, the fact that the number of places is few at which it is necessary to open the circuit in changing from hoisting to lowering, makes it a very safe system of control for hoists. All these points have been well proved by the number of controllers of this type now in use. In fact, it has become the standard system of control for the hoist motion of direct-current electric cranes.

Discussion

SELECTION OF ELECTRICAL APPARATUS FOR CRANES (McLain)

AUXILIARY ELECTRICAL EQUIPMENT FOR MOTOR-OPERATED CRANES (Eastwood), and

ELECTRIC CRANE CONTROLLERS (Schnabel),

C. A. Bird: Referring particularly to Mr. Eastwood's paper on brakes, we might add the subject of weather-proof coils. Cranes at steel mills usually are used out of doors, and are subjected to weather conditions that are rather severe, and the design of the brake might be well considered along the same lines as those of the motor. This will refer to the linings as well.

On the limit switches, I have seen a lot of well-known 2 by 4 type short-circuit in the armatures and reduce the efficiency of the motor.

I cannot understand why the dynamic braking type is not used more than it is. It is certainly a device that will give the protection that is desired on crane hoists.

On crane protecting panels, there is no question but that they are being used more and more. They provide a very convenient means of combining all the devices for protection of cranes all in one unit. The practise now is to enclose the steel panels in a steel cabinet and lock it so the operator cannot interfere with the setting of the relay.

H. D. James: Mr. Eastwood states: "It is difficult to secure more than a 65 per cent speed reduction when lowering a heavy load without dangerously overloading the field windings." These data seem to be based on the assumption that in dynamic brake lowering not more than full-load current can be passed through the fields. Well designed motors will stand more current than this and in many cases 150 per cent full load may be used. The minimum speed obtained with any particular motor depends upon the combined design of the motor and controller. Where low speed is an important factor, it is very desirable for the engineers designing the control to work in close contact with the motor designers in order to obtain the best results.

Under the head of A-C. Magnetic Friction Brakes, the assumption is made that the lowering speed under load will not materially exceed the synchronous speed of the motor. This assumption is true only when the secondary of the motor is short-circuited. Much higher speeds can be obtained with resistance in the secondary if a load brake is not used. For ordinary shop cranes the most common and perhaps the best practise at the present time is to use a load brake.

Dynamic braking for a-c. hoist motors may be obtained in any of four ways: (a) Exciting the stator with d-c. power; (b) Using a two-speed motor; (c) Plugging the motor in the reverse direction with resistance in the secondary for varying the slip; (d) The use of a frequency changer in the primary.

All four of these methods are in successful operation but are not ordinarily applied to cranes.

The d-c. system of dynamic braking provides for motor operation at low speeds where power is required to lower the hook. As soon as the load changes from positive to negative, the motor speeds up and the braking operation automatically takes place without changing the motor connections. This arrangement permits the gradual lowering of the hook under all conditions of load. When a-c. motors are used the use of d-c. power in the field or of plugging the motor does not provide for the gradual lowering of the hook without changing the motor connections. The two-speed motor might be designed to give the desired minimum speed on the low-speed connection but ordinarily this connection gives too high a hook speed. The use of a frequency changer in the primary will give the desired low hook speed but involves additional machinery on the crane. In view of these limitations the load brake seems to be the most desirable practise at the present time.

I agree with the author that every crane should be equipped with a limit switch that opens the main motor circuit at the upper limit of travel and is operated by the block or hook. In many cases the head room under the crane is so limited that it is difficult to avoid running into the limit switch and I see no reason why this switch should not be designed in as durable a manner as the other portions of the control equipment so that it will withstand repeated operation.

I do not believe that the design should be arranged to cause inconvenience to the operator in resetting this switch, particularly where the head room of the crane is limited. We have crane equipments in our own factory where the limit switch must be operated on nearly every hoist motion. This is an extreme case but there are many other applications requiring the frequent operation of the limit switch. If we require the trolley to be run over to the cab in order that the operator may reset the limit switch we impose a hardship and where this operation has to be performed with a heavy load on the hook we may introduce a hazard out of proportion to the results obtained.

Elevators and other hoist devices similar to cranes are provided with a durable limit switch which may be operated every time the car reaches either limit of travel.

It seems to me that in condemning the use of springs the author is condemning all control apparatus. I do not know of any normal design of control where springs are not relied upon for maintaining contact pressure between the current carrying elements of the switching mechanism. A failure of these springs might result in serious accidents. The reliable operation of control apparatus is a proof that springs when properly designed are reliable. There is no mystery about the proper design of springs. They are composed of the same kind of material we are accustomed to using in other parts of the design and under other conditions. It is well known that if the fiber stress in the metal, whether it is a spring or some other part of the apparatus, is in excess of a safe limit that breakage may result. The spring failures can usually be traced to improper design. A great many springs are not accurately calculated but are the result of a cut-and-dried process. The calculations of a spring are more difficult than an ordinary beam and some designers have not had the necessary experience to properly determine their fiber stress.

I am a strong advocate of the use of springs instead of gravity as they have very little inertia, are compact and can be worked into a design to much better advantage. They are not affected by vibration. The magnet brakes we use for holding crane loads are set by springs. Why discriminate against the use of a spring as the actuating means of a limit switch when we use springs in the current carrying parts of this limit switch and we use springs for setting the magnet brake which is operated by the limit switch and use springs in all other portions of the equip-

ment including the motor brushes which form part of the dynamic brake circuit? I do not feel that I can express myself too strongly on this point.

P. Trombetta: I don't quite agree with the gentleman that just spoke in that a spring is like a beam. The making of a beam does not involve the process of hardening and proportioning the carbon, etc., while making a spring is almost a matter of art. There are only certain companies that make springs, and sometimes you cannot even rely on those springs. I know of an instance where a company tried to make springs by themselves for use in a certain truck; they tried for several years, and so far as I know, never succeeded in making two springs alike. Probably every one of them gave trouble when they were in use, and I can't see how the spring may be compared with a beam. I must agree with him, however, that perhaps too little attention is given to their design, and also that the spring in a good many cases is the only solution of the problem, because it does not introduce additional masses which have to be accelerated whereas balancing by gravity, by eliminating one difficulty, we insert another, which is inertia, and you often find that the cure is worse than the disease, and consequently we may state that the spring has certain places as well as gravity has certain places in engineering and there are certain applications where only gravity can be used, for instance, in elevators, springs would be the best thing there is for such services, but we can't hope to find a spring that would be as long as an elevator shaft. It must be understood however, even elevator balancing weights are very detrimental since they must be accelerated and retarded just as the elevator itself.

Albert J. Acker: Mr. Eastwood made a statement that a band brake doesn't exert a braking torque in the hoisting direction, that is, with the motor armature operating in the hoisting direction. That is true if the band is anchored at one end only, but it is possible to make a band brake with both ends attached to the lever and have it exert equal torque in both directions, and therefore stop the motor just as promptly when it is revolving in the hoisting direction as it does in the lowering direction. A further advantage in such an arrangement is that the same band can be put on the intermediate shaft brake or the second shaft brake, and anchored at one end and give interchangeable brake parts for both of those brakes.

About limit stops, Mr. Bird stated that he couldn't understand why the dynamic braking limit switch is not more widely used than it is. I think I can answer that question. The reason is because there are so many varieties of cranes, so many different numbers of parts of rope, two parts, four, six, eight, ten parts, and all the different styles of lowering blocks, and it is difficult to put on those dynamic braking limit stops in many cranes. That is, to find the room to put them. In two respects, it is difficult to find a place to put them on the trolley itself, and it is difficult to hang the operating or tripping mechanism above the lowering block.

Another difficulty with limit switches is that the crane hoist is so frequently used for something else besides hoisting; to pull a car or to drag something along the ground, and the rope is pulled off at a sharp angle, and any mechanism that is put above the lowering block is likely to be bent or broken when the crane is used in these unusual ways. You all know that that is done very frequently. In an attempt to make a limit switch that could be tripped by the lowering block and yet not be rigid, so when the rope is pulled off at an angle it won't break, the scheme of using a mercury tube has been tried, the idea originating from its application to rubber calendar work. You may know that a rubber calender is very dangerous to operate and there is usually a board across for a man to butt his head into for a quick stop if he catches his hands. This board trips a switch of some kind. Mercury switches have been used for that purpose, a little tube no larger than a 30-ampere fuse with contacts arranged in it, and a little puddle of mercury. If it is tipped one way it makes a contact, and if tipped the other way it breaks it. That same tube applied to a crane limit switch works out well in many instances. It can be put in a little box with an arm sticking out from it and hung so the lower block coming up must tilt that lever arm. Now that can be hung perfectly free and no matter how the ropes pull off, it cannot be bent or broken, yet when the lowering block comes up and tilts it, it will trip the limit switch. Of course that will have to operate on control circuits, not on the main circuits. For some cranes this is a valuable idea, because it is so difficult to bend or break.

It is possible to get on the market now a tube filled with inert gas so the contacts don't blacken after many makes and breaks.

Electric Power Application to Passenger and Freight Elevators*

BY HARRISON P. REED
Fellow, A. I. E. E.
Cutler-Hammer Manufacturing Co., Milwaukee, Wis.

This Committee has been requested to report on the application of electric power to passenger and freight elevators. An enormous amount of electric energy is used for the operation of elevators and it is therefore fitting that the problem be studied from a power economy standpoint as well as from the more important standpoint of protection to life and limb.

It is assumed that the reader knows little of this subject and that practically nothing up-to-date has been published. It is not believed that the reader will be particularly interested in accurate technical details, but that he will want to know the range of application of elevators, their motors, controllers and all safety appliances as represented by best present practise.

Included in this report are six chapters as follows:

I. History and service requirements.
II. Types of elevator machines and the limitation of each.
III. Charateristics and limitations of d-c. and a-c. motors.
IV. Elevator controllers.
V. Brakes and other safety accessories.
VI. Power consumption.

I—HISTORY—SERVICE REQUIREMENTS

Historical

THE history of the elevator dates back to 236 B. C. which date is mentioned by Vitruvius describing an elevator built by Archimedes in that year. This "elevator" was operated by man-power applied to a capstan revolving a drum on which hoisting ropes were wound.

According to Prof. Coburn, of Philadelphia, who has made extensive archaeological studies in Palestine, the palace of Nero had three elevators.

It is reported that Prof. Commadatore Boni, the celebrated Italian archaeologist, while exploring some underground passages near the north rostra of Caesar, discovered twelve small galleries which he claims are traces of a former system of elevators, as in each room there are grooves through which ropes passed and stone supports for wooden poles are fixed vertically inside the passages.

An early mention of an elevator is made in a letter of Napoleon I to his wife, the Archduchess Maria Louise.

A Brussels paper not long ago stated that the apparatus which takes an occupant from the ground floor to the top of a building in a few seconds is not a new invention, as an ingenious contrivance was constructed in the seventeenth century by Velayer of Paris who called his invention "the flying chair." It was not merely a toy but became very fashionable among the rich people on account of its utility. It consisted of a chair hung by a rope passing over a pulley and counter-balanced by a weight. It continued in operation until a serious mishap occurred to the King's daughter at Versailles.

No doubt the elevator as we know it evolved from the so-called "flying chair." Only since 1850 has real progress been made in elevator development. In that year George H. Fox made an elevator operated by the motion of a vertical screw, the nut being carried on the cage.

The steam elevator, now practically extinct, was introduced over half a century ago. This stimulated increased building heights but successful service was limited with this type of machine. About 1880 the hydraulic elevator came into use and it practically superseded the steam machine at that time. However, building heights were limited by brick bearing walls inasmuch as steel-framed structures were not known. The introduction of steel building frames made the limit of building heights a commercial rather than an engineering problem.

The electric elevator was invented about 1885 and the first installation was made in 1887, but it was not developed sufficiently for extensive use until approximately the year 1893. Still, many hydraulic elevators were installed, although many were equipped with electrically driven pumps. Even with this arrangement the hydraulic elevator consumes more power than the electric elevator. During the past ten years there has been a decreasing number of hydraulic elevators installed. The electric machine has practically superseded all other types. This is true because the electric elevator is more readily equipped with suitable safety features, it occupies less space in the building, its initial cost is less, it is more easily controlled, and the power consumption and repair bills are smaller.

It is estimated that in any large city more people are carried daily by passenger elevators than by all

*A paper prepared under the auspices of the Subcommittee on Elevators of the Industrial and Domestic Power Committee:
HARRISON P. REED, Chairman.
HENRY F. BEWLAY, Roth Bros. Co., Chicago, Ill.

DAVID L. LINDQUIST, Otis Elevator Co., New York, N. Y.
ERNEST B. THURSTON, Haughton Elevator & Machine Co., Toledo, Ohio

street cars and subways combined. It is extremely important therefore that elevator travel be safe. It is almost equally important that for the service required the electric power consumption be reduced to a minimum.

SERVICE REQUIREMENTS

1. *General Requirements.* The initial elevator problem is one of service. So many factors enter into this problem that each individual case must be considered as a separate problem in itself. However, some accepted general rules may be stated for the guidance of elevator selection.

The service to be rendered depends upon the number of passengers, or the weight and bulk of freight to be carried, and upon the number of floors served. It is limited by the time taken for loading and unloading as well as by the time consumed during acceleration and retardation, and by the time consumed during travel at full speed.

For many stops per car-mile the important factors are quick starting and stopping, and quick loading and unloading. For few stops per car-mile the more important factor is higher running speed. In many installations accurate stopping is also extremely important.

We can consider elevators as vertical railways, running express or local, as the service may require, and when they are so arranged that they carry the number of people that arrive at or depart from the building in a given time, and distribute them on the various floors, or bring them to the street level, the elevator service may be considered 100 per cent of that required. The same applies to material-carrying elevators relating to the service of delivering incoming and outgoing material so that it does not accumulate anywhere.

In order to give passenger elevator service in a building, it is necessary to consider the number of persons that enter and leave the building, morning, noon and night, and also the number of people that enter and leave between these times.

The building height and floor area are not the only things that are needed to determine elevator service, although they must be considered in connection with the local regulations with reference to speed.

The elevators must have a given capacity in pounds and should be capable of running at a certain maximum speed with this load.

The passenger elevator car should be constructed with reference to its opening towards the hall so that a number of persons can enter or leave at the same time, making a car rather shallow in depth, but wide. The dimensions of a freight elevator car depend much upon the material to be handled, but quick loading and unloading should be a consideration in the determination of the car size.

Elevators should be capable of accelerating and retarding as rapidly as local power conditions will permit with, however, due consideration of effect on passengers and power consumption during starting and stopping.

The number of elevators required of the express or local type should be determined from the number of people that it is necessary to carry per hour, and the grouping of these elevators should be considered with reference to the entrance to the street or streets so that the movement of traffic may be distributed to best advantage.

Elevators should be durably and economically constructed, so that if ordinary care is exercised in their maintenance, only small inexpensive, interchangeable parts need be replaced in order to keep the elevators in fit condition for continuous service. The major parts should last indefinitely without replacement.

The direct-current elevator was the first to be perfected because of the fact that we had no suitable a-c. motor for elevator service prior to 1905. Even after the development of the a-c. induction motor the d-c. motor was better suited to elevator service due to the ease with which speed control can be obtained under varying loads. However, it has been found difficult to obtain direct current in outlying sections of our cities especially, and in some cities direct current is unobtainable. It is therefore necessary to use such power as is available, and in the application of the alternating-current motor to elevator work of the higher speeds, it has been found that it cannot compete with the direct-current motor in the present state of the art due to the inherent characteristics of the single-speed induction motor. There are, however, several types of multi-speed alternating-current motors especially designed for elevator service that are performing very satisfactorily on speeds up to about 300 ft. per min. and when properly installed, the service given is comparable with the direct-current elevator of the same speed. However when applied to higher speeds, a number of complications arises because the alternating-current motor does not lend itself to the refinement of control possible with the d-c. motor.

2. *Speeds and Capacities.* Heights of buildings are not limited by weight and speed limitations in elevator equipment. Elevators have been built for speeds up to 700 ft. per min. for passenger service, up to 30,000 lb. lifting capacity for freight service, and up to 100,000 lb. for special forms of electric hoists such as car dumpers.

The speed of the elevator for any particular service is very difficult to determine satisfactorily to everyone as it is more often personal opinion than engineering judgment that decides this detail.

As a general guide for estimating, the following will serve as representative of present practise:

Passenger Service—Office Buildings, etc.

Total Travel	Maximum Car Speed
Feet	Ft. per min.
0 to 50	50 to 300
50 to 75	300 to 350
75 to 100	350 to 400
100 to 150	400 to 500
150 up	500 to 550

Express service—550 to 600 ft. per min.

The above is for direct current and for operator-controlled cars. For automatic push-button service 300 ft. per min. is usually considered the limit of speed, as the automatic elevator is inherently a time waster inasmuch as the person within the car has complete control and runs the car without regard to the floor demands. It should be noted that 700 ft. per min. is not given in the table principally due to the fact that many state and city codes limit the speed to 600 ft. per min. For alternating current 400 ft. per min. is considered the limit although very extensive developments are being carried out at the present time by many manufacturers, the results of which they hope will make it practicable to use a-c. motors in connection with elevators traveling at a higher rate of speed.

The values in the above table are entirely dependent upon the average number of stops per mile of car travel. For example, in department store service where stopping at every floor is required for sales reasons, 350 ft. per min. is the maximum desirable speed because above this the car would not attain full speed between floors and therefore would give very inefficient operation; 250 ft. per min. is about the accepted correct average speed for this service. In office buildings of eight stories or less, the number of stops per mile generally ranges from 150 to 200. In office buildings above eight stories the number of stops will range from 125 to 175 per mile for local service, while for express service we can expect 50 to 150 stops depending upon whether service is given to several upper floors or to only a club or restaurant on one floor.

The capacities of passenger elevators vary from about 1000 lb. in residences to 5000 lb. in department stores, and from 2000 to 3000 lb. in office buildings. The capacity determines the car size which should be of sufficient floor area to provide not over 75 lb. per square foot. This is an accepted standard throughout the United States.

The number of elevators required to supply a given service is very difficult to determine accurately because each building is an individual problem in itself, due to the large variation in the demands such as internal traffic, insurance office traffic, consulting office traffic, etc. Consequently we can use only similar buildings for estimating an approximate average. The following method may be used as a guide for determining the number of elevators required in a building of known dimensions.

The population can be estimated from the rentable area as follows:

New York City—75 to 100 square feet per person.
Other large cities—100 to 130 square feet per person.
Small cities—125 to 150 square feet per person.

Total travel in feet if not known can be estimated by assuming 17½ feet for the first floor and 12½ feet between other floors.

Floor area of car platform:

27 sq. ft. for 2000 lb. for medium height buildings.
33 sq. ft. for 2500 lb. for standard office building capacity.
40 sq. ft. for 3000 lb. for special service where a lift for safes is required or the time schedule of leaving the first floor is not a feature.

The normal capacity of a car in passengers without crowding is determined by allowing two square feet per person including the operator.

The estimated time for synchronizing the cars, loss in time due to accelerating and retarding, loading and unloading at the first floor is 27½ seconds. The estimated time for accelerating and retarding, loading and unloading for each floor above the first is 7 to 8 seconds, or if positive door locks are used, 8 to 10 seconds.

The estimated time required to empty the building above the first floor usually ranges from 40 to 60 minutes.

The following is an example of an office building calculation for New York City.

Rentable area above first floor	190,000 sq. ft.
Travel first to sixteenth floors—All local	192 ft.
Car capacity. 2500 lb. 33 sq. ft.	15 persons
Speed of car	550 ft. per min.
Positive door locks used	
Time required to empty building	45 min.
Estimated stops per mile of travel	150 stops
Estimated sq. ft. per person in building	80 square ft.
Population of building = 190,000 ÷ 80	2375 persons
Number of trips to empty building = 2375 ÷ 15	159 trips
Time lost. Stops at first floor = 27.5 + 2	29.5 sec.
Actual running time per round trip $= \frac{2 \times 192 \times 60}{550}$	42 sec.
Total round trip travel = 2 × 192	384 ft.
The average number of feet between stops = 5280/150	35 ft.
Number of stops above first floor = 384/35 − 1	10 stops
Stopping time above first floor = (7½ + 2) × 10	95 sec.
Total time of round trip = 29.5 + 42 + 95	166.5 sec.
Total time of round trip	2¾ min.
Time required for one elevator to empty the building = 159 × 2¾	437 min.
Number of elevators required to empty building in 45 minutes × 437/45	10 elevators

From the above it will be seen that during the rush hours ten elevators with a capacity of 2500 lb. at 550

ft. per min. will give approximately 17-second service leaving the first floor. For the other hours of the day eight elevators will handle the traffic and give 20-second service from the first floor. If 15-second interval service is required eleven elevators will be necessary. This question of time interval must always be checked before definitely determining the number of elevators.

These calculations can only represent average conditions as the human element enters into the problem to a considerable degree. For example, the time the car will be stopped at a floor varies from 4 to 12 seconds depending mainly on the characteristics of the people served.

On page 59 is given a table of speeds for various rises as representative of present practise. It is interesting to note the effect of a change in speed upon the passenger-carrying rate and upon the power consumption per car mile.

Since an elevator doing local service in an office building of fifteen stories or less spends nearly as much time in starting and stopping as in running at full speed, the energy consumed in accelerating and retarding becomes an important factor. The energy required to accelerate to full speed is present in the moving system in the form of kinetic energy, but with most methods of control in use very little of this energy is recovered in stopping. The energy that must be stored in the machine, car, counterweight, cables, etc. for each start depends upon their mass times the square of the velocity to which they are accelerated.

It is, therefore, evident that increased car speeds must be accompanied by a considerable increase in the power consumption per car mile. It remains to be seen what effect a change in car speed will have upon the carrying rate of the elevator.

For the sake of comparison the foregoing office building calculation will be analyzed for a car speed of 450 instead of 550 ft. per min.

All other values except the following remain the same as before:

Speed of car	450 ft. per min
Actual running time per round trip $= \frac{2 \times 192 \times 60}{450}$	51.3 sec.
Total time of round trip = 29.5 + 95 + 51.3	175.8 sec.
Total time of round trip	2.93 min.
Time of one elevator to empty building = 159 × 2.93	465 min.
Time required for 10 elevators to empty the building	46.5 min.
Interval of service	17.58 sec.
Estimated car miles per day (10 elevators)	120 car miles
Estimated car miles per year (10 elevators)	36,000 car miles
Estimated kw-hr. per car mile saving by using 450 ft. per min. instead of 550	0.8 kw-hr.
Kw-hr. per year saved = 0.8 × 36,000	28,800 kw-hr.
Dollars per year saved at $0.01 per kw-hr.	$288.00

The amount of saving per car mile due to the reduced speed may vary as much as two-to-one in individual cases. The above figures are merely given as an illustration and not as a guarantee in any sense of the word. The price of power at $0.01 per kw-hr. is given so that knowing the power rate in any locality the saving may be easily calculated.

The above analysis shows that the decrease in speed increases the time required for the ten elevators to empty the building from 43.7 to 46.5, or 2.8 minutes, and increases the time interval from 16.65 to 17.58 seconds, or less than one second.

The use of the lower-speed elevators increases the time required to empty the building by an amount that is probably much less than the errors that would be made in the original assumption.

This analysis is not submitted as a more nearly correct solution of the problem but is simply to illustrate the effect of changing the car speed. It is probable that if building owners fully realized how much they are paying for higher elevator speeds and how little they are really gaining by them, there would be a downward revision of elevator speeds for buildings of this class.

Freight Elevators. Freight service is extremely varied, ranging from 1000 to 30,000 lb. short and long travel, and at speeds of from 30 to 250 ft. per min. The determining of the correct freight speed is not so difficult because the service is usually fairly well known. The cost of installation increases very rapidly with increase of speed with the result that speed is often sacrificed for first cost which explains why very few freight elevators above 100 ft. per min. are in use except in plants where an enforced system of manufacture is maintained. This means really two different demands. First, for isolated installations, storage, small plants, etc., speed ranging from 30 to 100 ft. per min. and for large manufacturing plants requiring speed from 100 to 250 ft. per min.

It has been proved very conclusively that a speed above 250 ft. is not warranted except for special service because only a small fraction of the total time is running time.

The required capacity of freight elevators is usually known because the material to be handled is known. The tendency of large manufacturing plants is to use some type of power driven truck which is usually very heavy, so this demands elevator capacities from 5000 to 15,000 lb.

Service or capacity of elevators is affected by safety appliances such as door and gate interlocks inasmuch as the introduction of these devices increases the time for loading and unloading. Thus the extension of safety appliances tends to increase the number of elevators installed. This is unfortunate, but the safety

consideration is so vastly important that the reduction of service efficiency is not to be deplored.

II—THE ELEVATOR MACHINE

General

The electric elevator is made up of three principal parts:

1. The car, consisting of the car frame and enclosure with such control and safety apparatus as is necessarily attached to the car.

2. The shaft work, consisting of the guides, counterweights, buffers, limit switches, etc.

3. The hoisting engine, with motor, brake, controller and cables.

The car should be made as light as practicable so as to keep down the load on the machine bearings and also so as to assist in keeping down the power consumption.

The elevator guide rails are of great importance in connection with efficient and safe operation of the elevator, as the smoothness of operation in the car is largely dependent upon good elevator guides, properly installed. The guides must be uniform in size, straight and installed in exact alignment. It is best to have the guides machined and the ends tongued and grooved for accurate connections with fish plates.

The electric elevator hoisting engine is a simple mechanism consisting of a grooved drum or driving sheave over which the hoisting cables pass from the car to the counterweight, and a mechanical brake. In most cases a gear-reduction mechanism running in oil is incorporated between the electric motor and the driving sheave.

Location

Infrequently the elevator machine is installed in the basement of a building. Probably 98 per cent of all new installations in the United States use an overhead machine installed in a room called the "pent-house" at the top of the building. Basement installations are objectionable because they require much longer hoisting cables and more idler sheaves than for overhead machines; they occupy valuable space in the basement and in many cases the actual load on the building is greater. Placing the machine directly over the hoistway imposes a load on the building equal to the weight of the hoisting machine, plus the loads on the car and counterweight ropes, whereas placing the machine below, imposes a load on the building equivalent to twice the loads on the car hoisting and counterweight ropes. Therefore, if the hoisting engine weighs less than the combined loads on the car and counterweight ropes, placing the machine overhead reduces the load on the building. This relation of weights often occurs.

Roping

The different types of machines according to roping are: Winding drum, full-wrap traction, and half-wrap traction (generally known in this country as the "V" groove traction and abroad as the "wedge drive" traction.)

The winding-drum machine predominated in earlier elevator history, but for passenger service it is gradually being superseded by either the full-wrap traction or the half-wrap traction elevator. Even for freight service many traction-type elevators are now being used. The following will give a clearer idea of the three types of elevators.

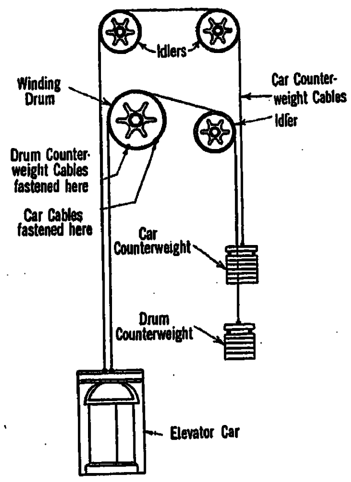

Fig. 1—Typical Roping for Overhead Drum-Type Elevator

Winding-Drum Machine. The method of roping is shown in Fig. 1. Three sets of cables are used. The first set or hoisting cables is attached at one end to the winding drum and at the other end to the car. The drum counterweight cables are also attached at one end to the winding drum but the other ends of these cables are fastened to the drum counterweight. The third set lead from the car, over idlers, to the car counterweight. The drum is machined with spiral grooves so that as the hoisting cables wind up, the drum counterweight cables unwind.

This type of elevator is limited to relatively short travels (not over about ten stories) due to the fact that the drum length becomes unwieldy on longer travels.

If the drum-type machine is installed overhead it will give remarkably long cable life because there is no possible cable creepage and the bending is always in one direction. However, if the machine is installed in the basement, reverse bends are necessary in the cables and this materially reduces the cable life. A car counterweight is used with the larger cars to reduce the load on the drum and drum bearings. One reason

for the decreased use of the drum machine is because it requires a modification of the machine for each installation, as the length of travel determines the length of the winding drum. Another bad feature is that should the terminal stops and overtravel limit switches fail to stop the car at the terminals, the machine may continue to travel and finally pull the cables from their sockets.

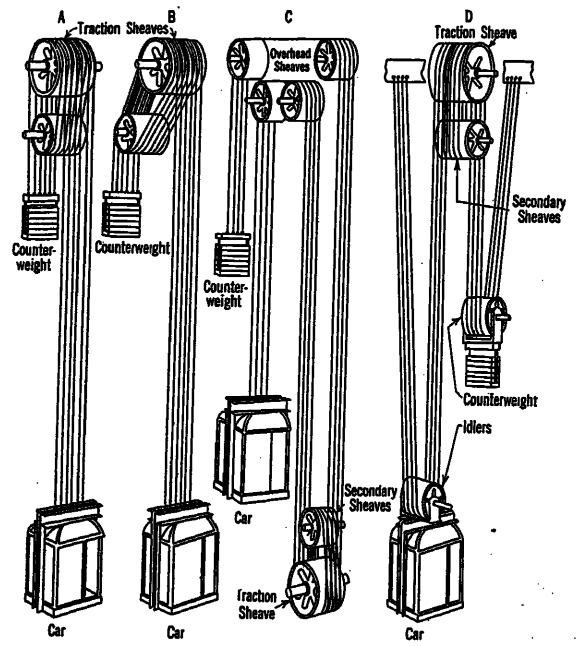

FIG. 2—ROPING FOR FULL-WRAP TRACTION ELEVATORS

Full-Wrap Traction Machine. The roping for various full-wrap traction machines is shown in Fig. 2. This machine, cabled directly one-to-one, or two-to-one, has the advantage of being a standard stock machine for all lengths of travel. The driving sheave has parallel round grooves, the driving of the car being dependent upon the friction between the cables and these grooves. To get sufficient traction an idler is necessary so as to get the equivalent of a full wrap around the traction sheave. A great advantage of the traction machine, both half-wrap and full-wrap is that if the limit switches fail to stop the machine at the terminals, the landing of either the car or the counterweights will slacken the cables and allow the machine to over-run without moving the car.

One possible objection to this type of machine is that the driving sheave bearing is required to take double load due to the double wrap necessary in this form of drive. This produces a somewhat lower efficiency than could otherwise be realized. Because of the round grooves the traction is limited but it does not change much with wear as it does in the case of the half-wrap traction machine.

Half-Wrap Traction Machine. For the method of roping used, see Fig. 3. It will be noted how simple the roping is, there being only two cable bends (one as the cable leads onto the driving sheave and the other as it leaves), where the driving sheave diameter is one-half the car width, although this is doubled when a deflecting sheave is necessary. However, for loads above approximately 15,000 lb. a two-to-one roping is generally used. As the car width increases to a point where it is impracticable to further increase the diameter of the driving sheave, the amount of "wrap" possible on the driving sheave decreases. Therefore in the case of wide freight cars it is sometimes necessary to use the full-wrap traction machine in order to get sufficient driving friction. The driving sheave bearing load is only one-half that of the full-wrap traction machine.

One criticism of this type of elevator is the wearing of grooves in the sides of the V, thereby reducing the pinching action, although sheaves properly machined are still in good operating condition after eight or ten years of constant regular service. Moreover the rim in which the grooves are cut can readily be made removable for replacement.

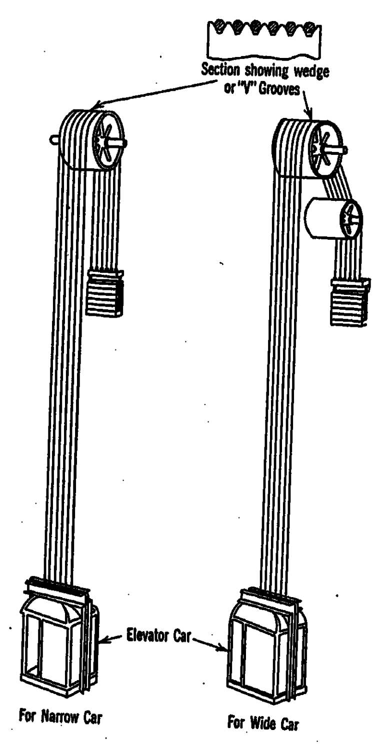

FIG. 3—ROPING FOR OVERHEAD HALF-WRAP TRACTION-TYPE ELEVATOR

The traction elevator has the advantage of being a standard or stock machine for all lengths of travel. If the limit switches fail to stop the car, the landing of either the car or the counterweights will slacken the cables and allow the machine to over-run without straining the hoisting cables.

It is still an open question whether the full-wrap

or the half-wrap traction machine is the better. Cable life is generally a little longer on the half-wrap machine, but the wear of the V grooves is still a problem.

Gearing

Elevator machines have been built gearless or with the following types of gearing: Single worm and gear, single herringbone gear, tandem worm and gear, single worm and gear with external spur back-gearing, single worm and gear with internal spur back-gearing and car leveling single worm and gear.

Gearless Elevator. The gearless elevator is shown in Fig. 4. It requires a very low-speed direct-current motor, because the driving sheave diameter is usually made not less than forty cable diameters in order to obtain reasonable cable life, and therefore to obtain the desired elevator speed a motor having a speed of 65 rev. per min. or less is used. Due to this limitation, car speeds with the gearless machine lie between 400 and 700 ft. per min. It is a very smooth and quiet operating machine and gives a high full-speed operating efficiency for long travels. As yet this machine is generally built in the full-wrap traction type which reduces the full-speed running efficiency somewhat.

The low-speed motor design inherently means a very large machine and therefore to keep the size down only a small range of speed is obtained by a change in shunt field. It is therefore necessary to use either series-parallel resistors in the armature circuit or multiple voltages applied to the armature in order to obtain adequate speed control. The series-parallel resistor method is a low-efficiency method of starting and stopping. Where alternating current only is available a synchronous converter may be used. Sometimes multi-voltage control is considered, which requires a motor-generator set to supply the multi-voltage. The stand-by losses of this set reduce the operating efficiency. If direct current is available, a storage battery may be used to supply the multi-voltage.

The gearless machine roped two to one, allows a motor of twice the speed of that of the one to one for the same elevator car speed and therefore a higher speed can be used and the motor built on a smaller frame. This type of machine is usually used for car speeds of 400 to 500 ft. per min. It is a smooth and quiet operating machine. Its speed is also controlled generally by series-parallel resistors. This machine has until recently been built in the round groove, full-wrap traction type, giving ten cable bends and a lower full-speed running efficiency. There has lately been installed a half-wrap machine, reducing the cable bends to six. The number of cable bends is then equal to the one to one, so the efficiency is doubtless about the same as the one to one.

Single Worm and Gear Machine. This machine (see Fig. 5) covers a wide field of application as it is used with drum, full-wrap traction, half-wrap traction and two to one cabling, for car speeds from 50 to 500 ft. per min. In car speeds up to 300 or 400 ft. per min. it has been a standard almost ever since elec-

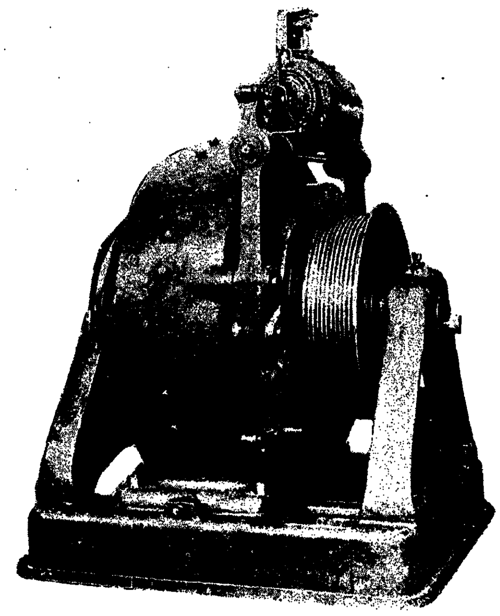

Fig. 4—Gearless Traction Elevator Machine

tric elevators were built. Due to special effort in the motor and controller design and special attention to design and workmanship of the machine and gears, some machines of this type are now working at car speeds of 600 ft. per min. with smooth and quiet operation.

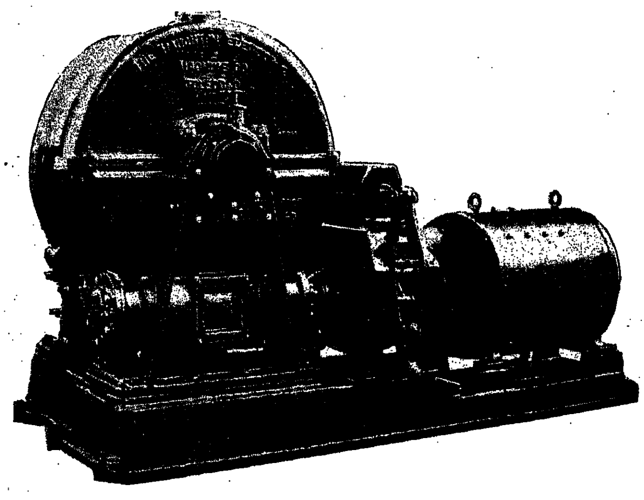

Fig. 5—Single-Gear Traction Elevator Machine

While the full-speed running efficiency is less than that of the gearless machine, its actual operating efficiency with the shunt field controlled motor is usually higher on any service requiring many stops per car mile. The better operating efficiency becomes more and more of a factor as the number of stops per car

mile increases. Another feature of value is that the winding sheave diameter is not limited and can in most cases span one-half of the car depth, thereby eliminating all idler sheaves and increasing the cable life.

A possible objection to this type of elevator for high car speeds is that it requires long experience and the highest class of manufacture to produce a smooth and quiet operating machine. Another objection, gear wear, has not proved to be a factor, as after six years of regular operation it is insignificant and promises to give twelve to fifteen years of continuous operation before any gear replacement is necessary.

Single-Gear Herringbone Machine. This machine has been tried extensively, giving very efficient operation, but it is understood that it is expensive to cut gears that insure quiet and smooth operation. This fact has limited its use.

Tandem Worm and Gear Elevator. The tandem-gear machine (Fig. 6) has been in use practically from the date of the earliest electric elevators and has stood its own, although at present there is a tendency to manufacture the single-gear machine roped two-to-one, which of course is relatively hard on cables. The field of the tandem-gear elevator is heavy duty continuous service since it minimizes gear pressure by using three points of gear contact. The majority of elevators used in rubber and automobile plants which demand the most severe service, is tandem geared.

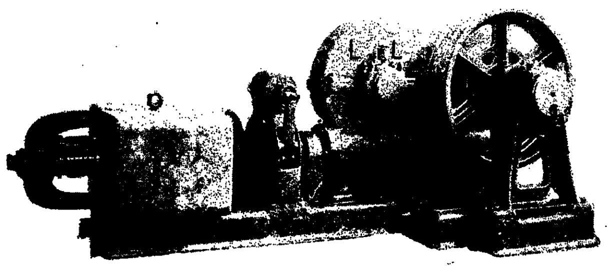

Fig. 6—Tandem-Gear Traction Elevator Machine

There seems to be an impression that a thrust gear is a poor thrust bearing, and so it would be were it not for the fact that this thrust gear delivers its thrust to lift one-half of the load.

Single Gear with External or Internal Back Gearing. This machine is like the standard single worm and gear machine shown in Fig. 5 except that between the gear and drum shafts is a spur gear reduction not ordinarily oil immersed. The reason for this is to enable a small machine to lift a heavy load where the service is intermittent and first cost is a determining factor. It is a question of judgment whether to use this type or the single-gear elevator roped two to one.

Car-Leveling Single Worm and Gear Elevator. The car-leveling elevator has a certain field where it is very essential that the landing stops be accurately within one-quarter inch, plus or minus, with the landing. This is accomplished with shunt field control of d-c. motors whereby a low enough speed with high enough torque can be obtained; or by applying a low-frequency to a regular a-c. elevator motor, or by the use of an additional small geared machine arranged to drive the regular hoisting motor and brake shoes at a low speed.

Counterweighting and Cable Compensation

To get best operating efficiencies it is essential that both of these subjects receive careful consideration. Many elevators are running today with insufficient counterweight, and with no cable compensation on jobs where the rise is great and therefore compensation should be used.

Counterweighting. It is obvious that an elevator without any counterbalance will be very inefficient because the motor horse-power required would be relatively large. It is customary therefore first to supply sufficient counterweights to balance equally the elevator car. Then enough additional weight is added to equal the estimated average load. This additional counterweight is generally known as "over-counterweight." The amount of over-counterweight is usually between 30 and 40 per cent of the maximum rated capacity of the elevator. In rare cases this amount is made 50 per cent, where full load is carried by the elevator nearly every trip. In any case the over-counterweight never exceeds 50 per cent of the rated load.

To illustrate the need of proper counterweighting, assume the following problem:

L = rated elevator load..... = 3000 lb.
S = rated elevator speed.... = 500 ft. per min.
W = over-counterweight in lb. = ?
E = per cent efficiency—Line to load.

$$\text{Then, h. p. required (theoretical)} = \frac{(L - W) \times 500}{33{,}000 \times E}$$

If there is no over-counterweight it will require $45\frac{1}{2}$ h. p. (at 100 per cent efficiency) to lift the full load at full speed. At 50 per cent over-counterweight, it will require just one-half of this power. However, with more than 50 per cent, it will take more power to lower the empty car than to hoist the maximum load.

If the over-counterweight is made equal to the average load, the maximum operating efficiency is obtained.

The "line of load" efficiency varies from about 40 to 75 per cent depending upon the size and design of motors, machines and roping. For instance a worm-gear machine with a low gear tooth pitch and with babbitt bearings may not show a greater efficiency than 50 per cent, while a high-speed geared elevator with a high gear tooth pitch, roller bearings throughout

and no idler sheaves, may show an efficiency close to 75 per cent.

Cable Compensation. As a rule the compensating of hoisting cables in buildings of ten stories or less is not an item. Above ten stories however, it is usually desirable to use some form of compensation to prevent the inequality of load on the motor due to the position of the car. The simplest form of compensation consists of wire cables of the same number and size as the hoisting cables connected to the bottoms of the car and the counterweight and passing over idling sheaves in the pit. Chains are often used in place of cables for cable compensation.

Conclusions

The desirable features are safe, smooth and quiet operation, ability to lift the required loads, no heating above Underwriters requirements, continuity of service, low maintenance costs and low power consumption. To obtain the lowest possible maintenance cost and power consumption, the first cost must necessarily be relatively high, so it is important to consider the frequency of duty demand in order to determine which to sacrifice in making an installation.

III.—THE ELEVATOR MOTOR

Power Required

In the application of the electric motor to elevator service, it is first necessary to determine what power is required to drive the elevator. This depends upon the net load to be lifted, the car speed and the various friction losses.

The static friction is unavoidably great, it being necessary in some cases to apply two and one-half times full-load running torque in order to start hoisting the fully loaded car.

The following formula will give the horse power required at full speed with full load on the car. The motor losses are included in this formula. Therefore h. p. = the horse power input to the motor. To get the horse power motor rating multiply h. p. by the motor efficiency.

$$\text{h. p.} = \frac{L \times S}{33{,}000 \times E}$$

where L = Net load in pounds.
S = Full speed of elevator in ft. per min.
E = Overall efficiency.

The line to load, or overall running efficiency of an elevator varies from about 40 to about 75 per cent, depending upon the type, design and construction of the motor, controller, machine, guides, etc. (See "Counterweighting" above).

If the efficiency is known, the above formula may be depended upon to accurately give the horse power rating of the motor for operating the car at full speed with full load. On direct current where, within reason, the available starting torque is a function of the inrush current the size of motor derived from the formula can be depended upon to start the load from rest.

On the other hand, the available starting torque of alternating-current motors is a question of inherent design, and all motor builders do not build their a-c. motors for the same percentage of full-load torque for starting, so it is desirable that these motors be checked on a torque as well as on a horse power basis.

The difference in treating this matter of torque and horse power by different manufacturers of motors has proved confusing. It is therefore of interest to know that the Electric Power Club has taken the subject in hand and is now working out standard ratings which it is hoped all motor manufacturers will adopt.

If a specific installation has an overall running efficiency of 50 per cent and it requires two and a half times full-load running torque of the motor in order to start the maximum rated load in the hoisting direction, the starting efficiency will be only 20 per cent.

After any gear-driven machine starts there is usually a decided increase in efficiency of the gearing owing to the oil film which rotation effects between the gears. Also on all types of elevator machines the efficiency increases after starting due to the oil film which rotation automatically places between the bearings. Therefore, immediately after starting there is an excess of torque which becomes available for acceleration. The amount of this torque depends first, upon the excess motor torque that is provided over and above that actually required to start the machine in motion, and second, upon the excess in elevator starting efficiency over and above the assumed 20 per cent.

In the following formula for the determination of torque required to start an elevator, the starting efficiency has been assumed at 20 per cent as outlined above. If this efficiency in any case is lower, the elevator will not start with the torque as derived by the formula. If the efficiency is greater and allowance is not made in the formula, the derived torque may be so great that the start will be abrupt unless some control arrangement, external to the motor, is included to reduce the initial torque.

$$T = \frac{5252 \times L \times S \times 2\tfrac{1}{2}}{33{,}000 \times 0.5 \times \text{r. p. m.}}$$

$$T = \frac{0.8 \times L \times S}{\text{r. p. m.}}$$

where T = Torque in pounds at one foot radius on the motor shaft.
L = Net load in pounds.
S = Full speed of elevator in ft. per min.
r. p. m. = Full-load speed of motor selected.

Really, instead of using the formula it would be better to actually test the pounds of torque required. Obviously this is not often possible.

General Motor Characteristics

Elevator motors should have the following characteristics:

1. Good speed regulation under varying load conditions.
2. High starting torque.
3. Relatively low inertia.
4. Quiet operation.
5. Adequate thermal capacity.

An elevator load varies from full positive or even 10 to 25 per cent positive overload to a negative or overhauling load. Good speed regulation is therefore an important consideration. A good many elevators are sold on the basis that they will develop a certain speed with a given load but that they will be capable of lifting a heavier load at a somewhat reduced speed. It is very important that the speed should not increase materially over rated speed in lowering a heavy load. If an elevator is operating at 600 ft. per min. under normal load conditions and it should lower the maximum load at full speed much in excess of this, it might trip the car safety guide grips.

The necessity for a high starting torque has already been outlined.

Because of frequent starts and stops and the necessity for a quick "get away" and rapid slow-down at landings, the inertia of the revolving armature or rotor should not be excessive. This means a relatively small diameter armature with not too much weight in its makeup, and revolving at reasonable speed. For passenger service about 900 rev. per min. is the usual maximum, although no definite limitation can be made, as there are successful elevator installations where the motors run as high as 1800 rev. per min. These however are usually the smaller, low-speed elevators.

While increased flywheel capacity of the revolving armature or rotor undoubtedly increases the power consumption, and therefore is objectionable, on the other hand, it is of advantage in preventing sudden variations in speed of the elevator car. A large flywheel capacity in the rotor of an elevator motor makes it difficult to obtain a rapid variation in acceleration or retardation and therefore makes for greater comfort to the passengers. It is best to strike a happy medium between comfort, speed of acceleration and operating efficiency.

Quiet motor operation is essential on practically all passenger installations and on many freight jobs also.

Because of the extreme differences in service and the great variety of load conditions encountered in electric elevators, it is impossible to establish any standard duty cycles for this service. It has been found that motors designed for a 15- or 30-minute intermittent rating will take care of most installations. A 15- or 30-minute rating means that the motor will carry its specified load for the specified period of time, starting cold, without exceeding the guaranteed temperature rise.

Direct-Current Motors

Most direct-current motors, whether shunt or compound wound have suitable commutating pole windings so as to insure sparkless commutation in both directions of rotation. The commutation should be such that with heavy momentary overloads at starting and during dynamic braking, the commutator will remain in satisfactory operating condition without need for frequent attention.

Direct-current motors are of two general types, single-speed and adjustable-speed, the latter having speed control by shunt field variation. For low-speed, heavy-duty service the motor is usually compound wound to produce sufficient starting torque. The compound winding should represent from 10 to 25 per cent of the total ampere turns on the main poles of the motor, *i. e.*, disregarding the commutating pole windings. The compound winding should be cut out of circuit after starting so as to insure more constant speed characteristics. To reduce the speed to insure accurate stopping, it is necessary to insert resistors both in series and in parallel with the armature. This means inefficient starting and stopping and increases the power consumption materially, as the number of stops per car mile increases. The parallel resistor is also used to secure dynamic braking in the off position.

The adjustable-speed, shunt-wound motor, usually having a speed range of two-to-one or more by shunt field control, provides ample starting torque without a compound winding. For high-speed installations, if this type of motor is used, the elevator can be run at full field speed practically as efficiently as at high speed. In transferring from high to full field speed the motor acts as a generator and returns current to the line. The amount of this returned current has been found from actual test of a three-to-one motor to equal 10 per cent of the total power consumption on an elevator making 150 stops per car mile. For slowing down from full-field to "drag" speed, series-parallel resistor connections are used, but the horse power is only a fraction of that at high speed, so that a saving of power at drag speed is realized over power used in slowing down a single-speed motor. Should anything happen to the armature shunt contactor or to the armature shunt resistor circuit the operator can always slow down to full field speed and make a safe stop without dynamic braking. One thing against the two-speed motor is that for the same horse power and speed it must be somewhat larger and more expensive than a single-speed motor. It is highly important that the two-speed motor be designed

to provide stable speed conditions when running with a weakened field.

Alternating-Current Motors

These are of two general types of a-c. motors, the high-torque squirrel-cage induction motor and the slip-ring, wound-rotor induction motor. The squirrel cage motor is used extensively up to about 20 h. p. because of its simplicity and because it only requires a relatively simple form of controller as it is generally thrown across the line with no starting resistor. When the installation is such as to require a smooth start, a resistor or reactance is placed in the motor primary circuit and gradually cut out after starting.

The last method of starting has been applied to motors as large as 50 h. p. with success. However, it has one disadvantage in that its speed regulation is poorer than that of a wound-rotor motor. While this is of little moment for the lower-speed elevators, it may not be satisfactory on the higher-speed cars. It is of interest to note that this regulation is not as bad as that of a hydraulic or a steam elevator. In actual service the power consumption of the squirrel-cage motor is slightly higher than that of the slip-ring machine, but due to the lack of slip-rings and fewer controller parts it is somewhat more reliable. The slip-ring motor for the same rating is more expensive and has a somewhat lower power factor than the squirrel cage motor.

The slip-ring wound-rotor motor is a standard product and has been used practically as long as electric elevators have had alternating-current drive. It has a higher full-speed running efficiency because the resistor in the rotor circuit is cut out by the controller after the motor starts. Its disadvantages have already been outlined.

Single-speed alternating-current motors cannot ordinarily be applied to elevators running faster than 200 ft. per min. because no slow-down can be obtained under the varying load conditions met with in elevator service, and no dynamic braking is available to assist the mechanical brake in bringing the elevator to rest. This means therefore, that the mechanical brake must be depended upon satisfactorily to stop the car from the full running speed. This is a difficult problem. The energy stored in the moving mass is proportional to the square of the velocity. The mechanical brake is capable of absorbing this energy only in direct proportion to the velocity, while a dynamic brake will dissipate this energy in proportion to the square of the velocity. The dynamic brake, unavailable with alternating current, is an important adjunct in assisting the mechanical brake for quick, smooth stopping of the elevator. While the development of the two-speed alternating current elevator motor is still in its infancy the demand is so great that rapid perfection of this type of motor for passenger elevator needs is to be reasonably expected. Alternating-current motors are very reliable, and alternating current is daily coming into wider commercial use, so it is quite essential that drastic efforts be exerted along these lines.

The available two-speed alternating-current motors today generally have two primary windings, although some motors are manufactured with but one primary winding which is re-connected to give a range in speed control.

In the two-winding type of motor the connections are usually so arranged that the speed of the motor can be changed without disconnecting the motor from the supply circuit, so that the motor is at all times operating under a positive torque and there is therefore no danger of losing control of the load.

Two-speed a-c. motors are built in both the squirrel-cage and wound-rotor types. The wound-rotor, two-speed motors have two secondary windings. Most of them have five slip rings so as to get the advantage of independent accelerating adjustments for the two windings. There seems to be a tendency toward the straight two-primary winding, squirrel-cage motor which is simpler and which has been found to give even smoother and quieter operation than the other type. Most two-speed motors have three-to-one speed range. Advantage is taken of the fact that in changing connections from the high- to the low-speed windings, with the car running at full speed, the low-speed winding acts as an induction generator, giving a very powerful slow-down action. This change is somewhat difficult to control smoothly under varying load conditions.

Some manufacturers, in order to get positive speed control with alternating current are using two motors of different rated speeds, both of which are direct connected to the elevator machine. This scheme permits the use of a squirrel cage motor for the low-speed member and a slip-ring motor for the high-speed member. With this arrangement it is possible to obtain the advantages of lower slip and higher operating efficiency which are characteristic of the slip-ring motor. Another point in favor of the two-motor arrangement is that the windings are in the usual form with which all repairmen are familiar and therefore the chances are that quicker repairs can be made. Also equipments have been built consisting of two distinct motors, both in one motor frame.

The two-speed alternating-current motor is being successfully used with car speeds as high as 350 ft. per min. Further development will undoubtedly increase this maximum.

IV—ELEVATOR CONTROLLERS

The elevator controller is one of the most important and at the same time perhaps the most complicated part of the equipment as it provides many of the safety features. The smooth operation of the

elevator car is largely dependent upon its functioning, and the design affects the power consumption to a marked degree. Considerable economy can be obtained by selecting the best type for each particular application.

Characteristics

Among the more important characteristics of the control are safety and reliability, although the motor selected should have characteristics that render it inherently safe for elevator operation. The connections to the controller must permit stopping the car at any time under any conditions of load; it should automatically stop upon the release of the car switch handle by the operator. The elevator car must be stopped automatically at each limit of travel to prevent it from traveling into the pit at the bottom or sheave beams at the top of the hoistway. The question of safety is associated with that of reliability. Even if the scheme of control is essentially safe, its proper functioning depends upon the apparatus being reliable.

Controllers must be designed and built to withstand frequent severe operation; one half a million operations a year, partly at least with inexperienced operators who do a great deal of "inching" for landings, not being unusual. Frequent plugging is common, with resultant high currents to be commutated. Also the location of elevator machinery is not conducive to regular inspection, and frequently maintenance is left to the janitor of a building who ordinarily knows little about electrical apparatus and its care.

Elevators are installed in buildings for the purpose of carrying passengers between the ground floor and the upper floors. Many buildings are so tall that it would be a distinct hardship and often an impossibility for the tenants to walk up and down stairs. It is, therefore, necessary to have the elevators in operating condition at all times. In the event of fire or accident it is important that they should function properly to remove the tenants from the upper floors of the building.

Frequently the elevator equipment is located above the hoistway or adjacent to it, so that it is essential to have the controller quiet; otherwise it may disturb the persons who occupy the upper floors.

All unnecessary complications should be eliminated from the controller and all essential adjustments should be readily understood and easily made. After being adjusted the parts should remain fixed under normal operating conditions.

The controller should be neat in appearance and all working parts readily accessible for inspection and repairs. It should be so located as to provide ample working space around it, and sufficient illumination should be provided to facilitate inspecting and repairing this apparatus.

Functions

The elevator controller performs a number of different functions, among the most important of which are the following:

To start the motor and accelerate it to full speed in either the up or the down direction, and to stop it at the will of the operator.

The starting and the stopping of the motor is performed by switches which must make and break the electric circuit. These switches are subject to considerable burning and should be of such design as to withstand this action with infrequent repairs and renewal of parts. The smooth acceleration and retardation of the motor are most important, and usually present the greatest difficulties in the design of the controller. Under different conditions of loading, the motor may act either as a motor or as a generator; therefore the usual methods of accelerating and retarding with a positive load may not give smooth operation when the load is negative. For example; when resistance is inserted in the armature circuit of a d-c. motor under a positive load, the speed of the motor decreases in proportion to the resistance which is inserted. If, on the other hand the motor has a negative load and is operating as a generator, the more resistance inserted in the armature circuit, the faster will be the motor speed. It can be readily seen, therefore, that the ordinary methods of control are not suitable for elevator service. The same remarks apply to a slip-ring induction motor with resistors in the secondary circuit.

To control the speed of the motor at the will of the operator.

The various methods of speed control will be discussed under a separate heading. It is necessary for the control to provide for one or more reduced operating speeds in order to make a satisfactory landing, particularly where the car speed is high. These low speeds should be positive so that they are available when the motor is operating as a generator as well as under positive load.

To stop the elevator at each limit of travel.

The elevator car travels in a hoistway which is limited at the bottom by a pit and at the top by the beams which support the sheaves and often the winding machinery.

Low-speed elevators can be readily stopped at the top and bottom landings without a preliminary slow-down device, but the higher-speed passenger elevators must be slowed down before the terminal landings are reached in order to make a successful stop. This can be better understood if we consider that the car may be approaching the bottom landing in one case with no-load and in the other case with the maximum load. If the car operates at a speed of 400 or 500 ft. per min. the loaded car will drift considerably farther than the empty car when the controller disconnects the motor

from the line and applies the brake. The terminal stops must be so adjusted that the car will reach the bottom landing with a light load. It will, therefore, drift considerably beyond this landing with the maximum load. If the controller provides means for reducing the speed of the car to 50 or 100 ft. per min. before the final stop is made the difference in drift between no-load and full-load will be very small and a satisfactory stop can be made.

To provide additional means for disconnecting the motor from the line and applying the brake in case of overtravel.

The car is stopped at either limit of travel by the regular slow-down and stopping device, but should this device become inoperative, additional means are provided for positively disconnecting the motor from the line and applying the brake in case the car travels beyond its ordinary limits. This latter means usually consists of hoistway limit switches so arranged that the car will open them and stop if it travels beyond its usual limits.

To provide a brake which will positively stop the car and hold it securely at the landing.

Two forms of brakes are used. One is a mechanical brake which is applied by a spring and released by a magnet. This brake is set when the magnet coil is disconnected; it is used for making the final stop and holding the load. The other is the dynamic brake which is used on direct-current machines to assist the magnet brake in stopping the machine. This is obtained by connecting the terminals of a d-c. motor to a resistor, the moving load driving the motor as a generator. By changing the resistance in the armature circuit the retarding torque can be adjusted to suit existing conditions. The satisfactory stopping of the car depends upon the proper adjustment of these two methods of braking.

The controller should govern the motor in an economical manner. The degree of economy will differ for each type of equipment. The current which passes through the resistor units represents a direct loss of energy; therefore the longer this resistance is in circuit, and the more current that passes through it, the less the efficiency of the elevator.

Methods of Operation

A controller may be operated in several ways:

Hand Rope and Lever Control. This consists of a rope which runs the full length of the hoistway in the form of a loop. (Fig. 7 shows the electrical equipment). One half of this loop passes through the elevator car. While the car is in operation this rope is stationary. In order to start, the operator pulls on the rope. This moves the controller and connects the motor to the line for the proper direction of rotation. When the desired landing is reached the operator takes hold of the rope so that the movement of the car pulls the rope in the opposite direction and brings the car to rest. This method of operating elevators is used for low-speed freight machines. A lever or hand-wheel may be used for manipulating this rope instead of having the operator pull on the rope directly. Attachments of this kind enable the operator to govern the controller at higher car speeds, but they are rather cumbersome and not as desirable as full electric control.

Car Switch Control. This method consists of locating a master switch in the car. (Figs. 8 and 9 show typical control panels.) The movement of the master switch handle to either side causes the car to travel in the direction desired. The connections are usually made so that the movement of the handle toward the door or front of the car causes a downward motion and a

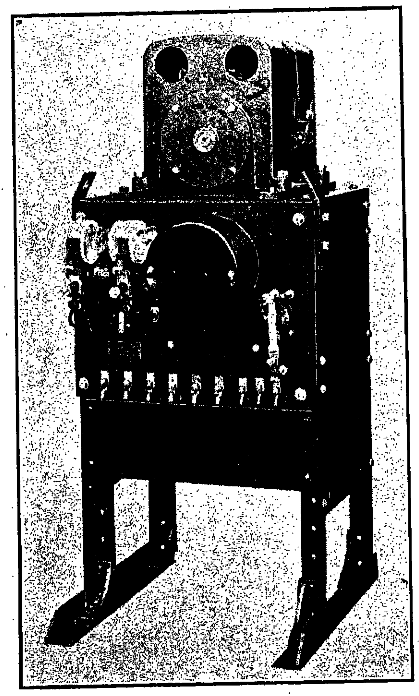

Fig. 7—Self-Contained A-C. Semi-Magnet Elevator Controller

With phase failure, phase reversal and low-voltage protection.

movement in the reverse direction an upward motion. The switch is arranged with a spring for centering the handle in case the operator releases it, thus bringing the car to rest. The handle is provided with a latch for holding it firmly in the "off" position to prevent accidental starting of the car.

This master switch is connected by wires with contactors on the control panel and operates the elevator by energizing the magnets of these contactors. The acceleration of the car is automatic so that the car switch is used only to determine the direction of travel and to select the proper operating speed.

Push Button Control. This method of controlling the car provides for automatically stopping it at the

desired landing. (Fig. 10 shows a typical control panel.) It has a particular field of application in apartment houses, small hotels, stores, clubs, etc. where the service does not warrant the expense of a regular operator. The control itself is inherently more complicated than other types and therefore is not quite

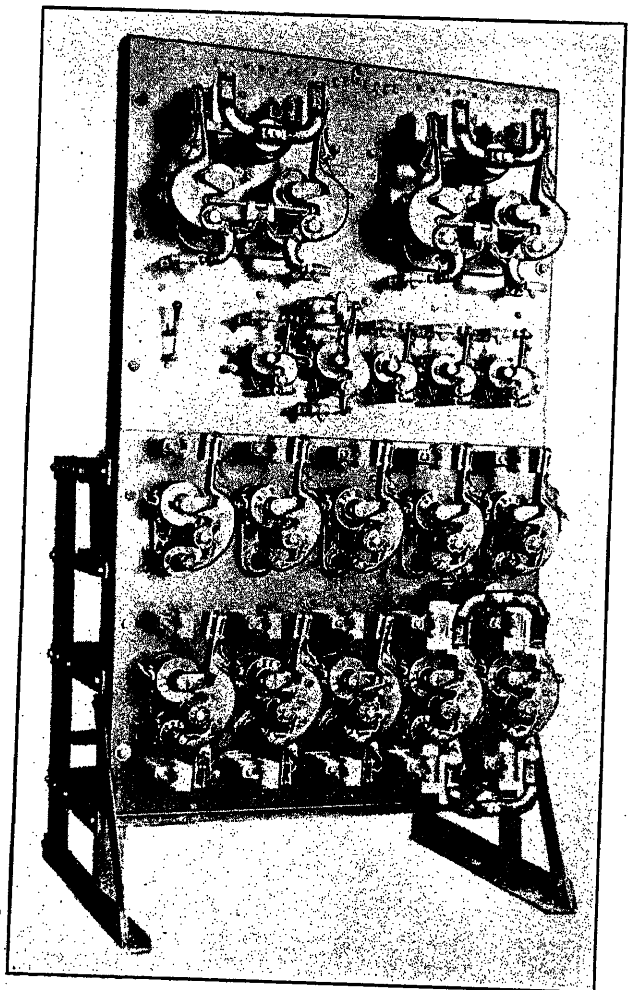

Fig. 8—Full-Magnet D-C. Elevator Controller

as reliable. It is a time and power waster because so many trips are made with light loads and without regard to floor demands.

A push button is located near each landing door. When a button is depressed momentarily, the proper connections are set up in the controller to move the car to that particular landing and to automatically stop it when it reaches the landing. Inside the car is located a series of buttons, one button corresponding to each landing. When the passenger enters the car and closes the landing door and car gate he momentarily presses the button corresponding to the desired landing. The car then travels to that landing and automatically stops. The control for elevators of this kind is substantially the same as for an elevator using a car switch, with the addition that a selector switch is provided which is driven either by the machine or by the elevator car and makes the connections that automatically stop the car at the desired landing. One form of selector is shown in Fig. 11.

Dual Control. Dual, or combination, car switch and push button control fills a demand where the service justifies the employment of an operator for only part of the time that the elevator must be in service. This demand comes in larger apartment houses, industrial office buildings, clubs, etc. Its first cost is higher than that of any other type, but due to the two different forms of control is somewhat more reliable than the straight push button control. Push buttons are provided at each landing for calling the car to that landing. A set of push buttons and a master switch is placed inside the car. Means are provided to render the push buttons within the car inoperative when the car switch is being used. At the same time the connections to

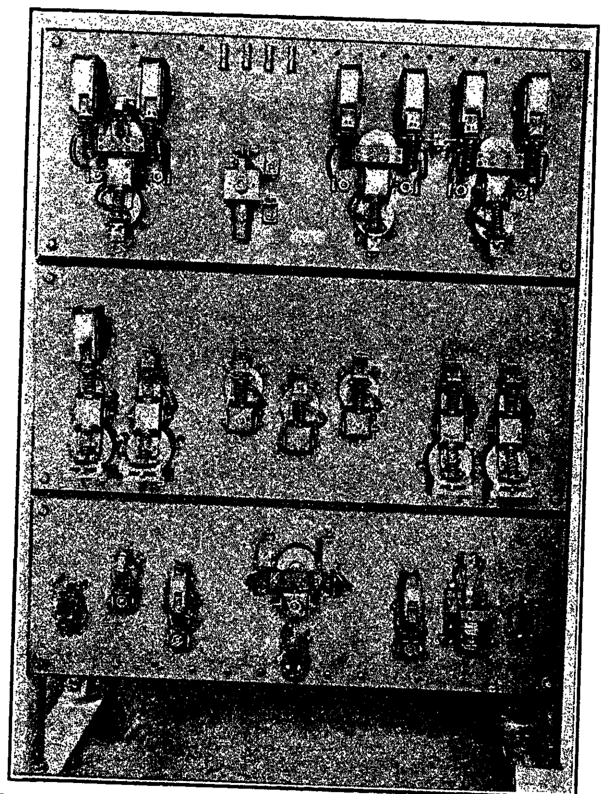

Fig. 9—D-C. Gearless Traction Elevator Controller

the landing push buttons are transferred to the annunciator operation.

Method of Acceleration

The elevator motor is automatically accelerated from rest to the operating speed. There are several methods for obtaining this automatic acceleration. Among the more common methods are the following:

Time Element Acceleration. This is based on the principle that time is required to accelerate the motor. Usually the device provides a definite time for acceleration independent of the load of the car. One of the

most common devices of this type is a dash-pot, either air or oil.

The advantage of this method of acceleration is the smooth start which it provides under all conditions of loading. Sufficient resistance can be provided to start the car smoothly with a light load. With a heavy load the timing device short-circuits sections of resistance until the motor develops sufficient torque to accelerate the load. Well designed accelerators of this type are not materially affected by variations in line voltage.

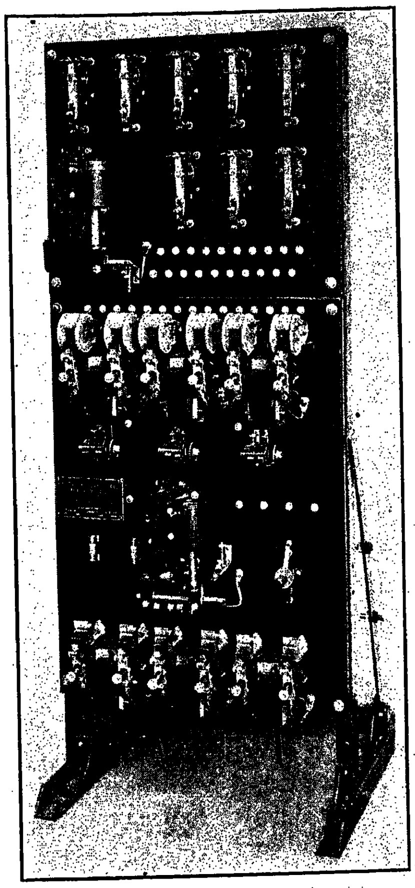

FIG. 10—A-C. FULL-MAGNET ELEVATOR CONTROLLER
With floor selector relays for push-button operation.

Counter E. M. F. Acceleration. This method makes use of the principle that the voltage across the terminals of the elevator motor increases with the speed of the motor so that magnet contactors connected across these terminals have their magnetism increased with the speed of the motor and can be adjusted to short-circuit sections of the starting resistance corresponding to different motor speeds. These magnetic contactors when properly designed are not affected seriously by atmospheric conditions, dust, or dirt, and therefore should remain in adjustment. This method of acceleration is sensitive to a variation in line voltage, but elevators are usually connected to the same service lines that furnish the lighting for the building and the voltage regulation is generally very good. Where poor regulation exists, special devices can be used to compensate for voltage fluctuation. The starting resistor should permit the motor to develop sufficient torque to start the maximum load.

Current-Limit Acceleration. This method of acceleration is dependent upon the current taken by the motor during acceleration. The motor must draw sufficient inrush current from the line to develop the torque necessary to start hoisting the maximum load. After this load has been started from rest the friction decreases as the running friction is less than the static friction; therefore, a larger part of the motor torque is available to accelerate the load, and the motor increases in speed until the torque developed is just sufficient to balance the load. At this value of current a relay closes the contacts to the next accelerating switch which in turn accelerates the motor to a higher balance speed. This process is repeated until all of the starting resistance has been short-circuited. With this method of control the motor is accelerated at a constant torque value, and therefore it reaches full speed quicker with a light load than with a heavy load as more torque is available for acceleration.

All magnetic contactors require an appreciable time to close so that any control system using contactors will have some time element. By modifying the design of these contactors the time element can be increased. This small time element is useful when the counter e. m. f. or current-limit method of acceleration is used to assist in giving a smooth start.

Another element which contributes towards smooth operation is the induction in the motor circuit. This inductive action checks the rush of current at the time a contactor short-circuits a section of armature resistance. The inductive effect may be increased by adding an impedance coil to the circuit or by a special design of the elevator motor itself. The time constant of the motor may be increased by several well known methods, thus smoothing out the transition between the steps in the controller.

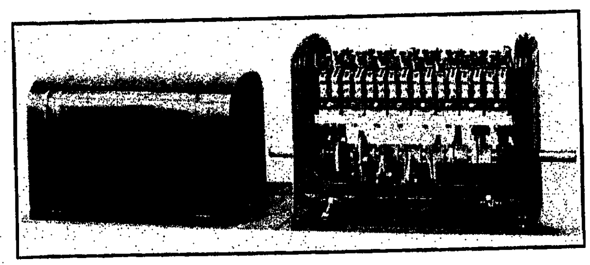

FIG. 11—ELEVATOR FLOOR SELECTOR

An elevator motor may be accelerated by a combination of two or more of these methods. As pointed out above, there is always some time element in every

contactor, which may be increased by special design, this giving a combination of *time element* acceleration with either *counter e. m. f.* or *current-limit* acceleration.

V. Methods of Speed Control. The speed control of the elevator motor is very closely associated with the method of acceleration and may assist materially in smoothing out this acceleration. The method of speed control depends upon the type and design of motor. Some of the methods are as follows:

By Adjusting the Field Strength of the D-C. Motor. Most direct-current motors can be operated at different speeds by simply changing the strength of their fields. The range of speed obtained depends upon the design of the motor. If a considerable change in speed is required by this method, a larger and more expensive motor is required than for the ordinary constant-speed design. If the motor is massive and responds slowly to a change in field strength, very little difficulty is introduced by this method of speed control. If, however, the motor responds quickly, relays or other devices are used to limit the current during the change in speed. This method of speed control is very popular, particularly for the higher-speed, geared elevators. This is a very economical method of speed control.

By Connecting Resistors in Series and in Shunt with a D-C. Motor Armature. The shunt resistor has a stabilizing influence and limits the speed variation under different conditions of loading. This method of control is very commonly used to obtain the low speed from which a landing is made. With the same amount of resistance the speed will vary considerably, depending upon whether the motor has a positive or negative load, but for making a landing this speed range is not too great to obtain practical results. It is the least economical method of speed control of a d-c. motor and is therefore, generally used only for obtaining the landing speeds.

By Applying a Variable Voltage to D-C. Motor Terminals. The best known system of this kind is where a separate generator is used for each motor, the generator field being changed to obtain the different motor speeds. Where the generator is properly designed the elevator motor can be operated from rest to full speed in either direction by changing the strength and the direction of the generator field. A good arrangement for the motor-generator set is to use a single motor driving two generators in order that the elevators may be shut down in pairs to eliminate the standby losses.

By Applying Several Different Voltages to the Terminals of a D-C. Motor. These different voltages are usually obtained from a motor-generator set having several different generators, each generator providing a different voltage. The transition between voltages is obtained by inserting resistance in the armature circuit. With this method of control it is necessary to reverse the armature connection to reverse its direction of rotation. One motor generator set usually supplies several elevators.

Where a storage battery is available the intermediate values of voltage may be obtained by taps taken from this battery.

The last two methods of control have been used to a limited extent. These increase the first cost of the installation but may reduce the cost of power by eliminating most of the rheostatic loss during acceleration and slowdown. This is of particular advantage in cases where the elevator motor has little speed regulation by shunt field control.

By Changing the Number of Poles of an A-C. Motor. These motors are of the induction type and may have either squirrel-cage or wound secondaries. They are usually provided for two different pole combinations; one, a large number of poles giving a low speed from which the landing is made and the other a smaller number of poles providing the regular running speed. The primary may have either two sets of windings, one for each set of poles, or a single set of windings arranged for two sets of connections. The introduction of the two-speed a-c. motor has enabled the operating speeds of a-c. elevators to be materially increased. One of the most popular combinations is a 3 to 1 ratio, although motors are now built with a 6 to 1 ratio.

By Changing the Frequency of Power Supply to an A-C. Motor. This method of control has been very little used up to the present. The most convenient method of obtaining the reduced frequency is to provide a small frequency changer which can be connected to the primary of the elevator motor when a low speed is desired for making a landing.

DETAILS

The elevator controller is made up of a number of unit parts, each of which performs a function in controlling the elevator. The parts usually found in a controller together with their functions are as follows:

1. A line switch for disconnecting one side of the motor from the line. This switch may be operated every time the car is moved or it may remain normally closed and be opened by a safety device or by failure of line voltage.

2. Reversing switches which change the direction of rotation of the motor and are normally used for opening and closing the motor circuit. Some of these switches operate each time the car is moved. For magnet control either two double-pole or four single-pole switches are used.

3. The accelerating device which automatically short-circuits the starting resistance when the motor is being brought from rest to the operating speed. A similar device may be used to limit the armature current when the field strength is changing.

4. A dynamic brake for slowing down the d-c. motor when the elevator is brought to rest. This brake consists of an electric connection between the motor terminals and a set of resistors. The switches for making these connections may form part of the reversing switches or may be separate units, the number depending upon the car speed and the type of motor.

5. A mechanical brake for making the final stop and holding the car securely at the landing. This brake is usually applied by a spring and released by a magnet.

6. Terminal stops for bringing the car gradually to rest at either limit of travel independently of the operator. Usually two different devices are used for this purpose, one of which operates normally and the other an emergency device as previously explained. The second set is generally known as *overtravel limit switches*.

7. Some means in the elevator car which will enable the operator to control the elevator. This may consist of a rope or a lever, a car switch or a set of push buttons depending upon the method of control.

8. A safety switch in the car for stopping in case of failure of the regular operating means.

9. A slack cable device for stopping the motor in case the car or counterweight is obstructed in its travel. A device of this kind is required only for drum machines.

10. High-speed elevators usually have a switch operated by the speed governor which automatically reduces the motor speed if it exceeds a predetermined limit.

11. Gate or door switches to prevent operating the elevator until all doors or gates are closed.

12. Every controller should provide overload protection. This may consist of fuses, but is usually a circuit breaker, or an overload relay operating in conjunction with the main line contactors.

13. Where the operating device in the car is not self-centering, low-voltage protection should be provided, to prevent the accidental starting of the elevator after failure of power until the operating mechanism has been returned to the "off" position. For a-c. elevators this device usually protects against the failure of power in any phase of the supply circuit.

14. Alternating current motors should have protection against an accidental reversal of phase which would cause them to operate in the wrong direction.

15. The higher-speed elevator controllers provide for a low-speed for making a landing. Sometimes the control provides for several operating speeds less than the maximum running speed.

16. A floor leveling device is sometimes included as part of the control. This consists of automatic means for bringing the car platform level with the landing and maintaining it in this position.

Each type of elevator requires its own special form of control. The lower-speed machines require a less complicated control than when the elevator is operated at a higher speed. Often freight elevators have different requirements from passenger machines. Considerable skill and experience is required in the designing of control equipment and selecting the necessary features. Each control should contain all of the features necessary for a successful operation, but any additional features add to the complication and may be undesirable.

V—BRAKES AND OTHER SAFETY ACCESSORIES

Brakes and other safety accessories have little to do with power application to electric elevators but they are so vitally a part of the elevator equipment that a good idea of the complete elevator plant cannot be obtained without a complete understanding of these features.

BRAKES

While the brake is a small part of an elevator machine it is an exceedingly important part. Because of the frequency of starts and stops it is highly essential that the car be brought to rest quickly and without shock or jar to the passengers. Also once brought to rest it is just as important that the car be maintained in its position in the hoistway while passengers are leaving and entering it. The functions of bringing the car to rest and maintaining it in a stationary position are obtained by the brakes. Elevator brakes are divided into three classes,—mechanical, dynamic and magnetic.

Mechanical Brakes. The straight mechanical brake is little used. To some extent it is still being installed on hand rope controlled freight elevators and sidewalk lifts. Most states prohibit its use on any passenger elevators because of its lack of protection to the car and occupants. As the name implies, it is simply lined brake shoes bearing against a pulley on the motor shaft. It is applied manually with the hand rope within the car, and automatically at the terminal landings by the traveling nut mechanism on the machine which has the double duty of returning the reversing switch to neutral, interrupting the motor circuit; and applying the mechanical brake. If, during operation, the voltage fails, the brake will not be automatically applied.

The mechanical brakes gives smooth results in stopping because a gradual application may easily be made by properly manipulating the control rope.

Dynamic Brakes. In the app ication of dynamic braking, advantage is taken of the ease with which a direct-current motor may be converted into a direct-current generator. The shunt field either partially or fully energized is connected to the line, and the revolving armature is shunted with a resistor. Thus

the motor operates as a generator and "pumps" current through the dynamic braking resistor thereby converting the mechanical energy of rotation into electrical heat. While this type of brake alone will not bring an elevator to rest, particularly if the load is overhauling, it will materially reduce the speed so that from that

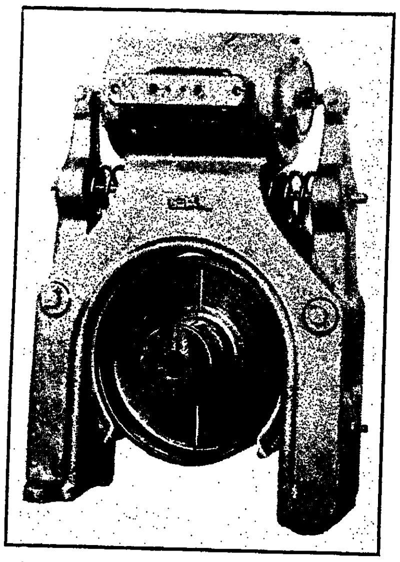

Fig. 12—D-C. Magnet-Operated Elevator Brake

speed the magnetically operated brake may easily be depended upon to bring the car to a safe and smooth stop. On the higher-speed d-c. elevators a graduated dynamic braking is furnished, which provides a braking more nearly proportional to load and speed conditions.

With alternating current, a braking effect similar to direct-current dynamic braking is sometimes furnished when a two-speed motor is used. In this case the low-speed winding is connected to the supply lines while the armature is rotating above the synchronous speed of this winding. Thus the motor acts as a self-excited induction generator and a powerful "dynamic" braking is obtained to bring the motor down to the synchronous speed of the low-speed winding. In this case energy is restored to the line during the braking period.

Direct-current dynamic braking is wasteful of electrical energy because the energy of rotation is lost in heat. The same applies to the mechanical brake where the energy is absorbed in the brake shoes. No effective method, economical of electrical energy, has been devised for quickly slowing down and stopping an elevator, although a direct-current motor with a wide speed range by shunt field control is economical in slowing down, as is also the two-speed alternating-current motor referred to in the preceding paragraph. (See Part III.)

Magnet Brakes. The importance of the magnet brake particularly on alternating current cannot be over emphasized. See Figs. 12 and 13. The reasons for its great importance have been outlined in Part III under the subject of "The Elevator Motor."

The magnet brake consists of brake shoes, similar to those used with the mechanical brake, operated by an electromagnet. This type of brake should always be used in addition to any other, except for low-speed freight sevice, for the purpose of positively holding the car stationary at the will of the operator.

On direct current, the magnet brake has been a small problem, but on alternating current it becomes a difficult one because of difficulties in satisfactory magnet design. Various types of magnets are being used, such as single-phase long-stroke, polyphase long-stroke, polyphase short-stroke and constant-stroke. The constant-stroke magnet is no more than a small motor designed to remain across the line with the rotor stalled. This magnet is sometimes called a *torque motor*. This type of magnet does not seal. It is difficult to keep quiet an alternating-current magnet that does seal. It is liable to slam in closure, and unless the laminated parts are perfectly surfaced and perfectly aligned it will hum after closure. A dash-pot is sometimes used for long-stroke magnets to reduce the slap in closing, and sometimes the entire magnet is immersed in oil to deaden the noise. One type of constant-air gap magnet, which is very quiet, absorbs the energy of rotation in a small auxiliary mechanical brake.

It is realized that if a mechanical brake action could

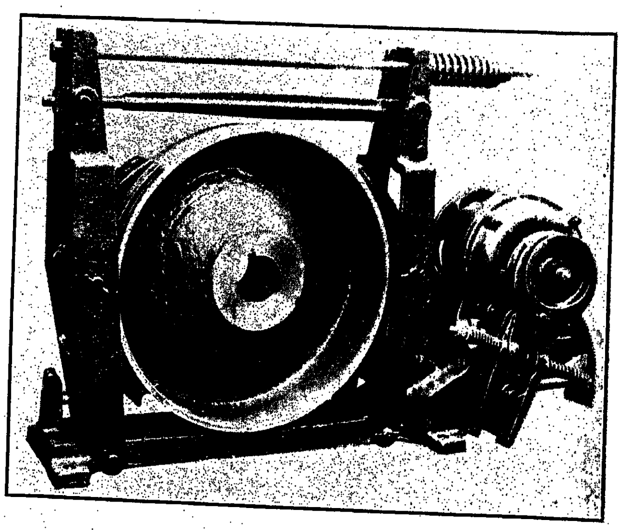

Fig. 13—A-C. Elevator Brake with Constant Air-Gap Magnet

be accomplished automatically in a magnet brake, smoother stopping results on alternating current could be obtained. Three manufacturers have tried the following schemes: A single magnet with the main brake spring partially counteracted by a weaker spring is used, and a dashpot is so arranged that the brake shoes are applied with partial pressure which quickly in-

creases to maximum. The main objections to this are the use of a dashpot and the fact that the operator does not have any control over the weak and strong settings. Another scheme is the use of two independent magnets or complete brakes, in which case the operator has control over the weak and strong settings, giving good stopping results. The objection to this is the use of two magnets. The third method consists in the use of a single short-stroke polyphase magnet with a variable reactance in the magnet circuit proportioned

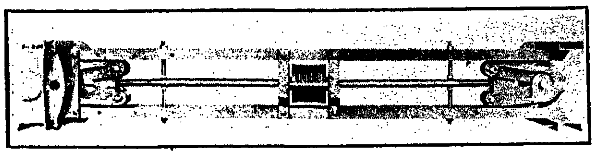

Fig. 14—Elevator Safety Guide Grips

to break the seal of the magnet but still maintain sufficient current in the brake coils to partially counteract the brake spring tension. As the car control switch is moved towards the "off" position, this reactance is decreased so the action of a mechanical brake is practically reproduced. This has worked out sufficiently well so that it is being used on elevators driven by single-speed motors and running 300 ft. per min. An objection to this method is the noise which is always

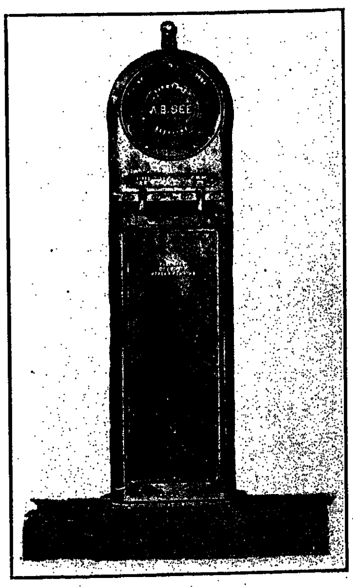

Fig. 15—Elevator Car Operating Switch

present to some extent when the reactance is cut into circuit.

The last two types must be so wired that there will be no way for the operator to hold the weak brake condition when the car is close to the terminal landings.

As a safety measure all magnetically operated brakes are so designed that the brake is released by the magnet and applied by springs or weights, so that a failure of power will always stop the elevator.

Safety Devices

These may be classified as electrical and mechanical. The mechanical are so closely allied to the electrical that they will be briefly described. The principal safety devices are, guide grips and overspeed governor with governor switch, car-operating switch, car safety switch, terminal-limit switches, overtravel-limit switches slack-cable switch, door switches, compensating-cable-sheave switch, buffers and air cushions.

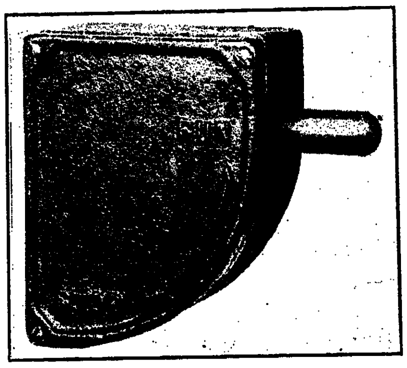

Fig. 16—Car Safety Switch

Guide Grips and Overspeed Governor. Guide grips have been made in a number of different types such as eccentric, dog, roller, and wedge, the wedge type now being almost universally adopted. See Fig. 14. The mechanism, is mounted below the car with a small winding drum which is connected to the overspeed governor by a steel cable. The holding of this cable at excessive car speeds rotates the drum so that the wedges force the grips against the guide rails and stop the car.

Usually a fly-ball type of governor is used in connection with the guide grips so arranged that the cable referred to rotates the governor shaft. The governor

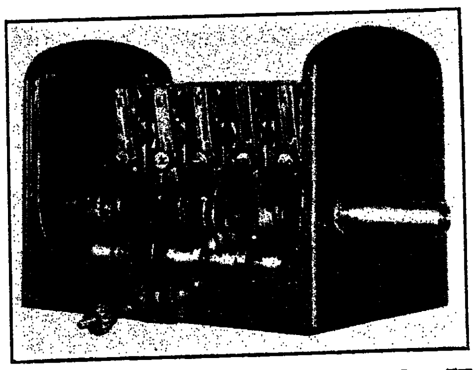

Fig. 17—Machine Limit Switch for Drum-Type Elevator

is arranged with a grip so that if the normal speed of the elevator is exceeded by a fixed amount it holds the governor cable and effects the setting of the guide grips.

It is accepted practise to install a control switch on the governor, so adjusted that the switch will trip to open the control circuit and disconnect power from

the motor at a speed lower than the speed at which the guide grips act. This switch prevents the guide grips from setting in case of a slight overspeeding. The switch is arranged so that it cannot be reset unless the guide grips are in the running position.

Car-Operating Switch. The car-operating switch usually has the automatic return or self centering feature so that if the operator's hand is removed from the lever it will return to the off position. See Fig. 15. It also is ordinarily provided with a center latch so arranged that any accidental leaning against the switch will not move the lever to the running position.

Car Safety Switch. The car safety switch is for the purpose of stopping the car in emergency in case

Fig. 18—Installation of Elevator Hoistway Limit Switch

of the failure of the car operating switch. Fig. 16. It is wired in a separate cable of opposite polarity to the car-switch cable, so that in case of grounds, etc., in the car-switch cable, the car safety switch will not be thrown out of commission.

Terminal Limit Switches. These act each time the car approaches the terminal landings, and function to bring the car to rest at these landings in case the operator is careless. See Figs. 17 and 18. They may be mounted on the car and operated by cams in the hoistway or vice versa for a traction-type elevator. These may also be used on a drum-type elevator although frequently limit switches geared to the elevator machine are used instead.

Overtravel-Limit Switches. Overtravel hoistway limit switches, Fig. 18, are always mounted in the hoistway and are operated by cams on the elevator car. They are placed beyond the normal range of car travel, and function to stop the car in case of the failure of the

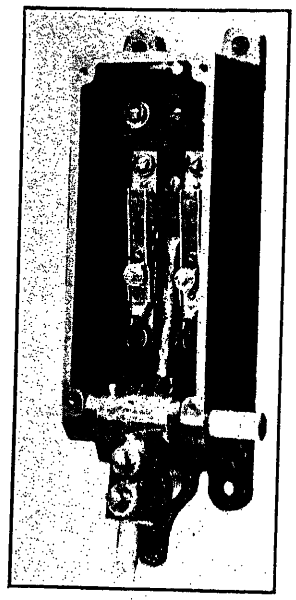

Fig. 19—Slack-Cable Switch

regular terminal stop limits. It is very desirable and the usual practise to arrange the connections to these limits so that the car cannot be backed out of them by manipulating the car switch. This gives an added safety feature as it requires the operator to call the

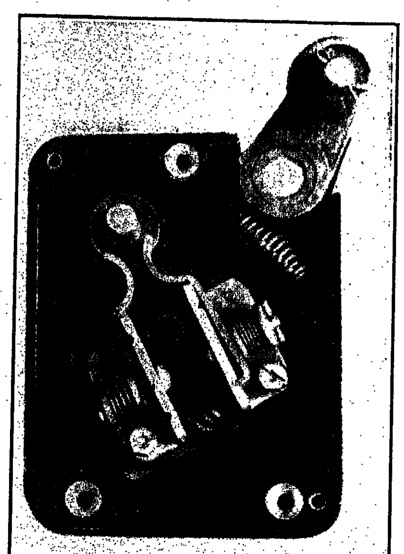

Fig. 20—Elevator Door Safety Switch

attention of an electrician or someone connected with the maintenance department to the fact that the car ran into the overtravel limits, and have the cause of this overrunning corrected.

Slack-Cable Switch. Ordinarily this is used on a

drum-type elevator to open the control circuit in case of slack cable caused by the car or counter-weight being caught in the guides. It is operated automatically when the cables slacken. See Fig. 19. It is sometimes mounted on top of an elevat orcar of high travel traction elevators where the cable weight is so great that the machine may not entirely lose traction in case of the bottoming of the car.

Door Safety Switches. These, Fig. 20, in combination with door locks, prevent the car from operating

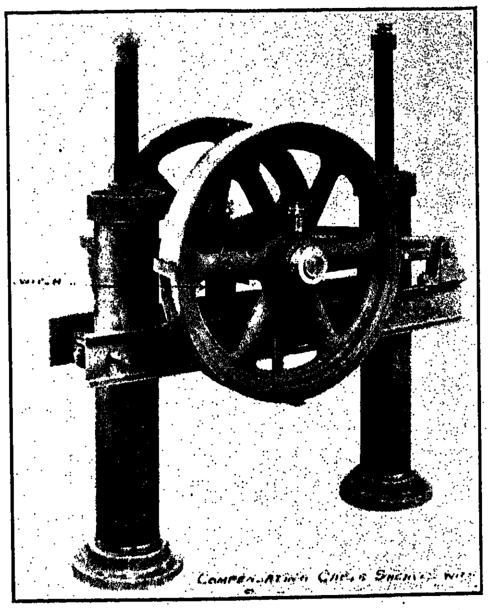

Fig. 21—Elevator Compensating Cable Sheaves with Switch

unless all doors are closed and locked. The design requirements of these devices are in many cases regulated by safety codes. There are numerous types manufactured and many have little value, so that door locks and switches should be investigated before installing. Some combinations lock the car-operating switch in neutral while the door is open. Others interrupt the car-control circuit when the door is open. Because the large majority of elevator accidents are due to not using suitable door interlocks, it is advisable to use them even though it decreases the service of the elevator to some extent. (See Part I.)

Compensating Cable Switch. This is connected so that it is opened by the lowering or raising of the compensating cable sheaves in the pit. See Fig. 21. The switch interrupts the control circuit and stops the car should the sheaves lower to any appreciable extent due to cable stretch. Also, in case of the car or its counterweight being caught in the guides, the compensating cable sheave will raise and operate the switch to cut off power.

Buffers and Air Cushions. A buffer is always required under the car. For lower speeds a spring alone is used, but for higher speeds a combination of oil dash-pot and spring is used, Fig. 22. These must provide a retarding effect so that maximum retardation will not exceed 64.4 feet per second per second.

At one time an air cushion was required for certain service in certain localities. This consists of a hoistway practically air tight at the lower end for a certain percentage of the total height. This involved very expensive enclosure construction and while effective in retarding the motion of a falling car it is understood the air cushion has been practically abandoned as unnecessary to safety. Another disadvantage of this scheme is the additional power required to move the car due to air friction.

Protective Devices

Besides the various forms of brakes and safety devices above described most elevators are protected against abuse by the following apparatus:

Main Line Service Switch and Fuses. These are mounted in an accessible location in the elevator machine room and are usually enclosed in a metal cabinet, preferably with an externally operated knife switch, and with a mechanical interlock making it necessary to open the knife switch before the cover can be opened to inspect or replace fuses.

Circuit Breakers and Overload Relays. Circuit-breaker protection of individual elevator motors is

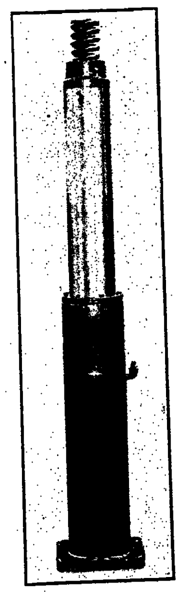

Fig. 22—Elevator Oil Buffer

not very often used inasmuch as the National Electrical Code requires fuse protection of elevator motors even when circuit breakers are used.

Frequently, however, in addition to the service fuses, overload relays are used in order to secure protection against overloading of the elevator itself. The overload relays are set below the fuse rating so as to prevent the blowing of fuses. The overload relays

are sometimes made to reset automatically with the return of the operating switch handle to neutral, so that after an overload it is unnecessary to go to the elevator machine room to again place the elevator in operating condition.

Overspeed Slow-down Relay. Some builders include in their electrical equipment a voltage relay so connected that an overspeeding of the elevator in either direction will cause the relay to act and thus automatically retard the speed. This relay is set to act at a speed below that at which the overspeed governor is set.

Phase-Failure Protective Relay. All alternating-current elevator installations on which the elevator motor may be continuously connected to the lines, such as hand-rope and push-button controlled elevators, include some form of phase-failure protection. Otherwise, upon the failure of a phase, the motor may be stalled on the single-phase condition, and burn out. The protective relay is usually a polyphase, shunt-wound relay with a control-circuit contact to maintain the control circuit of the elevator controller so long as the phases are all alive. The failure of any phase causes the relay to open the controller circuit and thus disconnect the motor from the supply lines.

Phase-Reversal Protective Relay. Many State electrical codes now require a phase-reversal protective relay on all polyphase a-c. installations. Frequently the phase-failure and phase-reversal relays are combined in one device. The reversal of phases immediately opens the controller circuit and prevents the elevator motor being connected to the lines until the relation of the phases is corrected.

VI—POWER CONSUMPTION

Anyone connected with building or industrial plant operation is interested in the power consumed by electric elevators. The architect and engineer are interested. The building owner is interested. From a conservation standpoint, everyone interested in the country's welfare is anxious to see the most economical use of electric power for all purposes.

Determining Factors

There are so many factors entering into this problem that it is impossible to give any accurate power consumption figures for any one type of elevator with a given capacity and running at a given speed, with a specified load on the car and with a specified number of stops per mile of car travel.

The operator himself is one of the variables. Some elevator operators run their cars to good advantage from a power economy standpoint, but many others are most careless in the way they operate.

Besides the operator's effect on economy other variables are inertia (including the weights of the car, counterweights, lifting ropes, balancing ropes, or chains, all moving parts of the machine etc.), rate of acceleration, and design and construction of all parts entering into the complete elevator. To show the importance of these factors, one company may design an elevator for a capacity of five tons that will have in its make-up approximately one half the material that another company may deem advisable for the same capacity and speed. When it comes to power consumption the lighter weight apparatus will naturally win out, even though it may not last long, due to its light construction. Therefore tests showing power consumption are naturally subject to all the variations that are inherent in elevator manufacture which is still somewhat lacking in standardization.

Regardless of all these variables it is of course possible to quote actual test figures for various types of elevators so that a general idea of the power consumed may be obtained.

The power consumption of electric elevators ranges from two to three kw-hr. per car-mile up to ten or more depending upon the variables mentioned above, but depending mostly upon loads, speeds, rate of acceleration, and number of stops per car-mile. Elevators make as many as 25 miles of travel per day so that even in a day's time the total energy consumption in a large office building is considerable and should be kept down to a minimum.

Results of Tests

Geared, Drum-Type Elevators. An average of several drum-type, geared elevators, with capacities between 2000 and 2500 pounds, at 350 to 400 ft. per min. regular service indicates the following results:

Capacity	Speed	Total miles per day	Kw-hr. per car-mile
2000	350	11.25	3.98
2500	400	10.90	4.35
2000	400	15.20	3.58
Average		12.45	3.97

Gearless Full Wrap Traction, 1 to 1 Roping. The following results were obtained from actual test of an elevator rated at 2500 lb., 500 ft. per min. with 800 lb. over-counterweight. Values are averaged for up and

Stops per car-mile	Kw. hours per car-mile	
	Balanced	Full load
0	1.20	1.82
50	2.22	3.39
75	2.90	4.07
100	3.50	4.80
125	4.10	5.46
150	4.28	5.93
200	5.12	7.10
250	5.81	9.07
300	6.50	9.20
400	7.90	11.50

down operation. The results are plotted in Fig. 23. The curves clearly show the variation in power consumption with load changes and with variation in the number of stops per car mile.

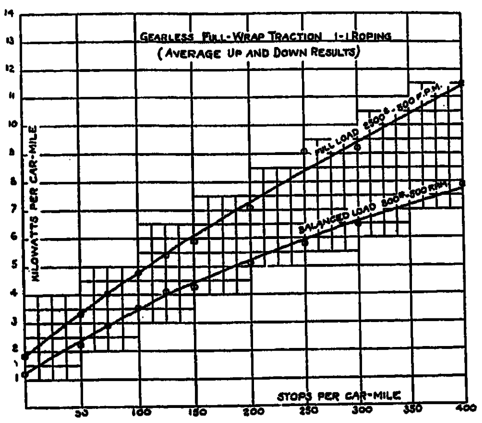

FIG. 23—RESULTS OF TEST OF GEARLESS FULL-WRAP TRACTION ELEVATOR, 1-1 ROPING

Values averaged for up and down operation.

Another set of tests on a gearless 1 to 1 machine rated at 2500 lb., 500 ft. per min., in a ten-story office building gave the following results. These are up and down averages. The car weighed 3900 lb. and there was 1060 lb. over-counterweight.

52 Stops per car-mile							
Load in lb.	Operator	666	1060	1360	2010	2360	2660
Kw-hr. per car-mile	2.35	2.08	1.95	1.87	2.15	2.50	3.22
104 Stops per car-mile							
Load in lb.	Operator	666	1060	..	2010	..	2660
Kw-hr. per car-mile	3.09	2.86	2.52	..	2.92	..	3.86
208 Stops per car-mile							
Load in lb.	Operator	666	1060	..	2010	..	..
Kw-hr. per car-mile	4.91	4.19	3.98	..	4.25	..	..
416 Stops per car-mile							
Load in lb.	Operator	666	1060	..	2010	..	..
Kw-hr. per car-mile	7.29	6.75	6.7	..	7.43	..	..

A test was made in a fifteen story building. The elevator was rated at 2750 lb. at 500 ft. per min. The regular service test with approximately 100 stops per car mile gave an energy consumption of between 3.32 and 4.73 kw-hr. per car-mile.

The effect of increased number of stops is shown in the following results obtained from a test in a 22-story office building:

Empty	—Stopping at every floor	6.4 kw-hr. per car-mile
Full Load	—Stopping at every floor	10.4 " " " "
2/3 Load	—Stopping at top and bottom only	2.4 " " " "
2/3 Load	—Stopping at every floor	8.8 " " " "

A 22-floor 600 ft. per min. elevator with express service to the tenth floor and local service from the tenth to the twenty-second floor, traveling an average of 22 miles a day consumed 3.5 kw-hr. per car-mile. Local elevators in the same building operating at 400 ft. per min. traveled nine miles per day and consumed an average of 4 kw-hr. per car-mile each.

Gearless Full-Wrap Traction Elevator 2 to 1 Roping. The only tests available for publication are shown in the following table. The elevator was rated at 3000 lb., 500 ft. per min., 1175 lb. over-counter-weight was used. Average up and down results are given:

Stops per car-mile	Kw-hr. per car-mile Balanced	Kw-hr. per car-mile Full Load
0	2.00	3.80
50	2.90	4.60
75	3.40	5.40
100	3.90	6.00
125	4.33	6.95
150	4.81	7.80
200	5.80	8.71
250	6.78	10.40
300	7.68	11.10
400	9.06	15.20

Geared Half-Wrap Traction Elevator. A test was made on several elevators rated at 2500 lb., 600 ft. per min., with the following average up and down results:

Stops per car-mile	Load in lb.	Kw-hr. per car-mile
16	1100	2.06
80	"	4.20
96	"	4.70
16	2500	2.40
80	"	4.80
96	"	5.20

An elevator running 400 ft. per min. serving an 18-story building and traveling an average of 21.8 miles per day showed a regular service consumption of 3.28 kw-hr. per car-mile.

Another at the same speed in a 13-story building and traveling 19 miles a day consumed 3.88 kw-hr. per car-mile.

The average of a lot of 400 ft. per min. elevators was 3.8 kw-hr. per car-mile.

The following test results were obtained with an elevator having a capacity of 2250 lb. at 500 ft. per min. The over-counterweight was 580 lb. In this case the motor had a 3 to 1 speed variation by shunt field control. Had there been less or no control by shunt field variation the power consumption values would have been considerably higher. (See Part III.)

Stops per car-mile	Kw-hr. per car-mile Balanced	Kw-hr. per car-mile Full Load
0	1.50	2.05
50	2.10	3.00
75	2.50	3.43
100	2.92	3.90
125	3.30	4.46
150	3.57	4.90
200	4.23	5.91
250	5.30	6.70
300	5.90	7.55
400	6.95	8.50

Lack of proper maintenance will also increase the power consumed. It is evident that all moving parts such as the machine itself, sheaves, guides, etc. must be properly lubricated at regular intervals in order to insure the most economical results. Also if the brakes are not properly adjusted the operators will find difficulty in making accurate stops without inching and the resultant loss in power.

Conclusion

While the above test figures are of interest they actually are of little comparative value on account of the many variables indicated under "Determining Factors." Some years ago the Cincinnati Gas & Electric Company made some operating cost tests on a great many elevators in its district. The averages of all these tests are given as follows:

Freight	Cost per elevator	$8.00 per month
"	" " h. p.	1.09 per month
Passenger	" " elevator	14.64 per month
"	" " h. p.	1.26 per month

These are, of course, costs for power only, and would not apply with present-day power costs.

Attention is called to the fact that the big determining factor in the cost of elevator operation lies in the number of starts and stops and not in the load carried by the car.

Ways in which Operation and Maintenance Affect Power Consumption

It has already been mentioned that the operator himself is one of the important factors determining the power consumption of electric elevators. It is interesting to note how this factor affects the results.

If an operator is so expert that he slows down the car as nearly as possible to the landing at which he is to stop and if he stops the car accurately with the landing without "inching" he reduces the current used in slowing down or running at low speed and reduces the number of starts and stops by eliminating the inching operation so frequently used by unskilled operators. Besides this he improves the service of the elevator which point is of vital consideration.

Evidently from the manner in which many elevators are run little attention is paid to this important factor in elevator economy. If building owners would realize the importance of this point it would be possible by careful instruction and competition between operators to materially cut down the power consumption on many installations.

Towards this end a watt-hour meter might be installed on each elevator. Also car-mile recorders and counters for registering the number of stops could be added. In this way accurate data on the performance of each elevator could be obtained. If an operator is assigned to a particular machine a bonus might be paid to the operator who showed unusual saving in power consumption due to skilful operation. In a large building this would set up a rivalry between operators and might be very beneficial from the standpoint of the power consumed.

Discussion

H. D. James: The selection of the proper size elevator car and the proper speed of operation is very essential for the success of any installation. The tendency is to use car speeds of 500 to 600 ft. per min. on the larger installations and even higher speeds have been tried out in practise. The tendency in New York City towards very high buildings of the tower construction may lead to elevator speeds of 1000 ft. per min. or even more.

In selecting an elevator speed, consideration should be given to the distance between stops. In an ordinary office building an elevator operating at 600 ft. per min. will have to travel at least two floors to obtain full speed for even a very short part of that travel. The power consumed during acceleration is an important part of the total power consumption so that the cost of operating at 600 ft. per min. in a low rise building may be out of proportion to the benefits ordinarily obtained, unless an improved method of control is adopted.

The more rapid the rate of acceleration, the greater the advantage obtained from high-speed elevators. If the acceleration curve is the correct shape a very rapid rate of acceleration is just as comfortable as a slow rate. The human being feels the rate of change of acceleration more than the actual rate of acceleration. The correct curve can be obtained by using the second derivative of the speed-time curve. The use of the direct 1/1 traction elevator machine which eliminates all gearing is an important factor in obtaining a rapid rate of acceleration without discomfort to the passengers.

In accelerating a motor using a rheostatic controller the resistance in circuit with the armature is changed in definite steps which tends to cause abrupt changes in motor torque. One way to reduce this effect is to provide inductance in the circuit. Every electric circuit including a motor, has some inductance but this is small and a large number of controller

steps are required to avoid a disagreeable acceleration. A large number of controller switches in themselves decrease the rate of acceleration as time is required for manipulating these switches. It is true that improved operation can be obtained by slowing down the operation of certain switches, but there is a corresponding necessity for speeding up the contactors in other parts of the control. A better way to obtain the desired result is to introduce additional inductance in the armature circuit. If this inductance has the correct value few contactors are required in the control circuit and the acceleration curve can be adjusted to conform very closely to the theoretically perfect curve. An important advantage in using the correct inductance is that when once adjusted the smooth operation of the car is not interfered with by minor changes in the time element of the individual contactors caused by the accumulation of dirt, change in friction, atmospheric conditions, etc.

Recent improvements in elevators have been obtained by the use of a variable voltage system of control. The older and more common control known as the rheostatic, is operated from a constant voltage system, the voltage across the motor armature being varied by changing the resistance in circuit. The variable voltage system directly changes the voltage of the generator supplying the elevator motor and no rheostatic control is required in the armature circuit. Briefly, the system consists of an individual generator for each elevator motor. The armature of the motor is connected directly to the armature of the generator and this circuit is not opened for normal operation. The direction and speed of the elevator motor is obtained by changing the direction and strength of the generator field. The only rheostatic losses are those of the field rheostat in the generator circuit.

This variable voltage system of control is inherently smooth in operation, as the field strength of the generator does not change abruptly giving the effect of an infinite number of control steps. By properly proportioning the field winding of the generator, a very high rate of acceleration may be obtained following the theoretically correct curve for acceleration and deceleration. This system of control will permit an acceleration from rest to 600 ft. per min. in very close to two seconds. It permits elevators to be operated by a-c. or d-c. power circuits as the motor-generator set can be driven by either a d-c. motor or a polyphase or single-phase a-c. motor. The a-c. driving motor may be a synchronous motor adapted for power factor correction where conditions require such an arrangement.

The power required when starting and operating at low speeds with the variable voltage system of control is less than with the rheostatic in the proportion that the generator voltage bears to the line voltage. For instance, if the generator voltage is 25 per cent of the line voltage, the elevator motor can draw approximately four times its full-load current without exceeding the full-load demands from the line. This is particularly valuable where the source of power is alternating current. Alternating-current motors during acceleration take a current equivalent to two or more times the full speed value. With the variable voltage system of control, the power demand during acceleration may be less than full load.

Where 500 or 600 ft. elevator speeds are used with the variable voltage system of control, the cars may be operated at reduced speeds with very little loss in efficiency, whereas with the rheostatic control, the power taken from the line is not reduced when the elevator speed is cut down.

In making a landing with a rheostatic controller the car speed may vary over a range of 3/1 or 4/1, depending upon the loading in the car, as the low speeds with this system of control are obtained by the use of armature series and armature shunt resistors, the voltage across the motor armature changing with the load. The variable voltage system of control can be designed to give close speed regulation at all speeds independent of the load so that the operator in approaching a landing can rely upon a definite car speed. This enables him to make his landings with greater accuracy and materially reduce the time consumed at landings. The accuracy with which low speed control can be obtained independent of the load with this system permits stops at either limit of travel to be accurately set, insuring greater safety of operation.

The magnet released friction brake used on elevator machines ordinarily functions to hold the car at the landings, the slowing down being accomplished by dynamic braking. If the friction brake is set abruptly, it causes a rough stop. In order to insure a smooth stop the tendency has been to ease up on the brake shoe so that the retarding effort of the shoe may not be much in excess of that required to actually hold the car at the landing. This is a dangerous tendency as the brake is intended as one means for emergency stopping. For that reason the brake is released by a magnet and applied by springs. If the brake is to be considered one of the safety means for stopping the car as well as holding it at the landings, the torque of this brake should be sufficient to stop within reasonable limits a fully loaded car travelling down at full speed, or an empty car travelling up at full speed. This introduces difficulties in the design of the brake as the torque required to bring the loaded car to rest within a reasonable distance may be sufficient to cause a rough stop under normal operating conditions. It is, therefore, necessary to proportion the windings of the brake so that the shoes are gradually, though quickly, applied. The best way to accomplish this is by means of magnetic induction, as a mechanical dash pot of any kind may stick fast and thereby introduce a hazard.

I would like to say a word about the high-speed geared elevator in comparison with the direct traction machine. It is well known that the efficiency of a low speed d-c. motor is inherently less than a high speed motor of the same rating, and this argument has been advanced as a reason for using a geared machine. Unquestionably there is a lower limit to the car speed which can be obtained with a direct connected 1/1 traction machine and, therefore, it is necessary to use a gearing for low speed elevators. The gearing may consist of a 2/1 rope hitch on the car giving half normal speed, or it may consist of some form of worm or spur gearing. The 2/1 rope hitch introduces additional friction losses and increases the wear on the rope. It, however, does not involve maintenance of the gearing and is an advantage from that standpoint.

All mechanical gearing has some clearance between the teeth. The high speed gearing for the steam turbine drive of ships reduces this clearance to a minimum by various mechanical expediences which, so far as the writer knows, have not been applied in the elevator field. The objection to clearances in the gearing for elevators is the lost motion when the torque is reversed. If the gearing is accurately cut and carefully adjusted, this lost motion may not be objectionable when the machine is first installed but the tendency of all gearing is to wear and wear increases the back-lash. Worm gearing requires thrust bearings to take the end thrust on the worm. The clearance required for this end thrust and for the teeth of the gearing introduces a difficult problem with high car speeds. Low speed elevators may be accelerated and decelerated at a relatively slow rate but high speed elevators require rapid acceleration in order to obtain the full advantages of high car speeds; this rapid acceleration and deceleration increases the difficulty of maintaining a geared machine in satisfactory operation.

If we assume that the overall efficiency of the high speed geared elevator can be made equivalent to the gearless machine we still have the advantage of eliminating all mechanical gearing which at best is a potential source of trouble. Where geared elevators have been installed in office buildings to operate at high car speeds, it would be interesting to know their rate of acceleration and deceleration; also how much the clearance in the gearing has increased after five or six years of service.

H. P. Reed: Mr. James suggests that the use of a gearless elevator machine is an important factor in obtaining a rapid

rate of acceleration without discomfort to the passengers. It would be interesting to have Mr. James explain this, for it is not understood why the gearless elevator can have any advantage over the geared machine in this respect.

The discussion included a statement that a large number of contactors decreases the rate of acceleration. This all depends upon the inherent characteristics of the contactors. They can be designed to give quick, smooth operation without the necessity of making some contactors slower than others. With correct design of contactors the time element will not vary, but will remain constant indefinitely regardless of atmospheric conditions.

Mr. James says that with rheostatic control, the slow car speed will vary over a range of 3-1 or 4-1, depending upon the loads. This is probably true of rheostatic control of a single-speed motor, but is not true of one having a wide speed variation by shunt field control.

Undoubtedly Mr. James' remarks on the variable voltage system of control will be received by engineers with much interest. The two possible objections to this system are, first, the difficulty of "teasing" or "inching" for an accurate landing, and second, that the all-day power consumption may be higher than with other methods.

Mr. James points to the lost motion between worms and gears as an objection to the geared elevator. If the elevator machine is properly built, this lost motion does not exist and high speed geared elevators have been in regular service for many years without this lost motion developing. The probable life from a satisfactory service standpoint of the elevator worm and gear, is in the neighborhood of 15 to 20 years. The maintenance of the worm and gear is not a serious item. It has been proven by actual comparative tests that the d-c. geared elevator with a 3-1 motor shows power economy over the gearless elevator on any installation requiring not less than 50 stops per car mile.

David Lindquist: In the large expensive buildings being erected today, the whole venture may prove a success or a failure depending on whether you have adequate or inadequate elevator service. It is therefore of utmost importance to be able to predetermine the service conditions and the service requirements, because only by doing that properly can a satisfactory and adequate elevator equipment be installed.

In other words, the first, and most important thing is to provide adequate elevator service in a building. Second, you have got to provide reliable service. In other words, maintain such service under the most exacting and most severe operating conditions. Third, you must provide elevator service that is reasonably economical. Fourth, you have to have the quality of service. In other words, smoothness of operation, easy access to the car and egress of passengers, ease of handling, etc.

Mr. Reed's excellent paper calls attention to the necessity of taking the operating requirements or the service requirements of the building into account. Unfortunately, however, I feel that he hasn't sufficiently warned you against taking average figures, average data, and applying those to specific conditions. While the human beings are considered, and have been called "unit packages of freight," they are by no means unit packages or standardized as far as their size and shape is concerned, and when you come to the mental attitude and the psychology, then you will find even greater differences than the physical differences of size and shape.

The psychology of it is more important than anything else, because you will find that in certain buildings handling a certain crowd your average constants we will say for loading and unloading the car don't hold good at all. In other words, the average constants may give entirely too long a time. In other cases it is entirely too short. Take the hired help part of a modern office building today and you will find that you can handle them faster and more efficiently than most any crowd. On the other hand, in hotels and department stores, you have an entirely different situation. The majority of the patrons will not be of the rushing kind, and therefore you have got to allow entirely other time constants for handling passengers of that kind. Some of the figures mentioned in Mr. Reed's paper are averages, and no doubt good averages, but I warn you against applying those specific figures for special cases.

In connection with speeds and capacities, Mr. Reed mentioned 700 feet as very nearly the maximum speed. Mr. James pointed out that at the present time the tendency, particularly in New York and for high buildings, is toward much higher speeds. As a matter of fact, a thousand feet speed mentioned will probably not be the limit in the near future.

Now regarding passenger service in office buildings, Mr. Reed has given a table, giving the relation between rise in feet and suitable car speeds. Those figures are good averages, but may, under specific conditions, and in many cases, be considerably modified in order to suit the requirements.

Mr. Reed further mentions that for automatic push button service 300 ft. per min. is considered at the present time the speed limit. That is true with the method of push button control that has been used in the past, where one passenger has absolute control of the car to the exclusion of all the rest that may want elevator service.

Now push button controlled elevators have quite recently been very materially modified, particularly in reference to the method of control and the operating conditions. The method of controlling is substantially the same as with the car switch operated elevator, except that no car switch is required, and that the car stops in the direction in which it has been initiated at the desire of the passengers. In other words, there is no signal system except indicating that the car is going to stop at the landing, but no signals to the operator, and no operator in the car in many cases.

At the present time there is being installed in New York City an elevator installation utilizing full automatic push button control for 700 ft. per min., in a high class office building. The reason for that is not to slow down the service and get less service, but to increase the rapidity of service or the volume of service as well as the quality of service with a certain number of elevators over what could be obtained with car switch control at the same maximum speed of 700 ft. There will be a man on the car, merely a guard. His functions is principally pressing the buttons as floors are called out by the passengers in the car. In any sequence, depending upon how they call the numbers of the floors, in other words, they may call 17 first, 13 next, and 19 next, but in any sequence at all, the elevator will stop in proper sequence.

At the same time, assuming, for example, that the elevator is ascending, in case a passenger on any floor wishes to go in the up direction, the car will automatically stop for him in the up direction, without the operator or the guard in the car even knowing about the fact that the signal has been set or the stop has been set for the elevator.

Now that condition is somewhat modified by the control arrangement. An elevator may be in the up motion at the third or fourth floor. This elevator may be signaled to stop at the 19th floor for a passenger. In such a case that elevator is considered too far away from the 19th floor, so, therefore, the first elevator that reaches the 19th floor will stop there, although it hasn't been dispatched by the guard in the car to stop there.

On the other hand, if an elevator has been dispatched by the guard to stop at a certain floor and that particular car is waiting say four or five floors from that particular floor, then this mentioned elevator would stop at that floor, not only to let out passengers, but also to take on passengers, and all the other elevators that may be active will not get the signal to stop there. By that method the number of stops required for

a certain service is materially reduced. You no doubt have noticed that frequently a car comes up, stops at the floor to let out passengers, and another car stops on signal at that floor to take on passengers for the same direction. That situation, of course, would be entirely eliminated.

For apartment houses the control is somewhat modified. The elevator runs on a round trip schedule. In other words, of course the complete run up and down takes on passengers and lets off passengers, as the case may be, and no operator or guard is required.

In department stores, for example, particularly where they are stopping at every floor, the guard's only function is to press the closing button for his door and gate and the closing of the door and gate will initiate motion of the car and it goes to the next floor, gets up to the top floor and reverses.

Mr. Reed mentioned that for department stores particularly, 250 feet speed is the accepted and correct limit. I don't quite agree with him. I believe that elevators can be operated satisfactorily and from an economical point advantageously at considerably higher speed. As a matter of fact, even 400 feet speed is probably not the economic limit.

Mr. Reed points out that the average number of stops in office buildings will be from 125 to 175. While that is true, it deserves further consideration. No attention has been paid, to the size of the car. That is a very important consideration, because if you have a large car, carrying a large number of passengers, the number of floor stops naturally will be increased, and if the car is very large, you stop at every floor, or practically so.

I would like to make some statement about the 75 lb. per sq. ft. loading as the accepted standard. While that is an accepted standard for the purpose of rating of elevators' capacities, a baseball crowd, at, for example, 181st Street subway station, pays no attention to the standardized loading of 75 lb. per sq. ft. The average is often over 100 lb. per sq. ft. and, as a matter of fact, we have records of as high as 115 lb. per sq. ft.

This, again, brings out the point that in order to put in adequate elevator equipment, you must know the service conditions.

Suggestion is made to decrease the speed of an elevator for the purpose of economy. Now that economy, in the example, is a false economy. It only deals with economy of power consumption, and not with economy from a broad point of view. Mr. Reed figures out that the interval of time, by using the higher speeds, is only decreased from 17.58 to 16.65 seconds, in other words, less than one second.

Looking into it a little more carefully, you will find that second is quite an important length of time. That difference in interval of time means in approximately twenty elevators you can save one. Now Mr. Reed has figured out that the power saved per year for ten elevators amounts to $288.00, for twenty elevators therefore it would amount to twice that, call it $600 per year. How much do you think that you save per year if you reduce the number of elevators from 20 to 19? Why, you save several times that amount in a building, because the space alone is worth considerably more than the power saved.

The statement is made about the half wrap traction machine that the principal objection is that the traction between the ropes and the driving sheave varies with wear of the driving sheave. That is true with the ordinary V groove sheave, but with a modified construction of sheaved grooving is not true at all. The traction remains with that construction just the same as it does on the U groove.

Now with the wear of the V groove naturally your pressure angle changes, and your traction is decreased. Now, on the other hand, if you want to make a single wrap machine, or half wrap, as Mr. Reed prefers to call it, out of this machine, all you have to do is to undercut your groove and as wear takes place your pressure angle doesn't change, and your traction remains practically constant. Mention is made that it is still an open question whether the full wrap or half wrap machine is the better. It is true, under certain conditions, the double wrap is better than the single wrap or the full wrap is better than the half wrap.

The statement is made that cable life is generally a little longer on the half wrap machine.

There again is one of those general statements that while true, are quite misleading. If you consider the total number of machines in service then it is true but on the other hand the great majority of machines with half wrap consist of geared machines, in which the sheave diameter is considerably larger, for various reasons, than employed with the double wrap, which has principally been used on the gearless traction machines.

One thing, however, is true about the half-wrap, and that is that you have got to be careful in selecting your sheave diameter and the number of ropes and the load per rope, and also the quality of the rope, because the surface pressure between the rope and the sheave is very much higher, and for the same traction effort is more than twice as high as it is with the U groove.

Certain trouble has been experienced due to the fact that this particular situation was overlooked, and in quite a few cases excessive wear of the driving sheaves has been found.

Another statement regarding the slower speed motor for the gearless traction machine. "That inherently means a very large machine." That is true. "and therefore, to keep the size down only a small range of speed is obtained by a change in shunt field." That statement is also true, but I think it is somewhat incomplete. I believe that it might be well to add there that due to the large time constant of a field of a large motor, for the sake of rapidity of acceleration, it it unsuitable to use a large field variation, even if cost was not considered.

In reference to duplex or tandem gear machines, I believe that his statement is somewhat misleading. I refer to this statement: "The field of the tandem-gear elevator is heavy duty continuous service since it minimizes gear pressure by using three points of gear contact." Well, that is true, it has three points of gear contacts but only two of those are in contact with the worm. I made the general statement here that as far as I have been able to find, from my experience with geared machines, there is no advantage at the present time with a tandem-geared machine. As a matter of fact, a single-gear machine with properly designed thrust bearings, is superior to the tandem-geared machine. There may be cases where you, on account of space conditions, require a machine that is built on the style of a Los Angeles bungalow. There, of course, a tandem-gear machine has certain advantages. The tandem-gear really had its days when proper ball bearing thrusts couldn't be obtained.

I don't think that anyone would seriously consider it a cinch automatically to level a 600 ft. elevator by shunt field control or by frequency changing in an a-c. elevator and level that elevator automatically within an eighth of an inch, or say even a quarter of an inch of the landing sill. Still, by reading the author's statement I got that impression.

In regard to counter-weights, attention hasn't been paid to the fact that frequently it is necessary to modify the counterweight on account of lack of traction. Then there is a statement about the benefit of the flywheel effect for smooth operation. Now there again I don't think that anyone would seriously consider adding flywheel effect to an elevator motor for the purpose of obtaining smooth operation. Now I want to call your attention to the fact that the gearless machine, with the best operation, has the least possible flywheel effect. While it is true that flywheel effect may aid a poorly operating controller, I don't think that anyone would put in flywheel effect for that purpose.

I am just going to conclude with reference to rating of elevator motors. The statement that the 15 or 30 minute rating with full load is sufficient to determine whether that elevator motor would not overheat in service. Well, such a test has

absolutely no significance, particularly when it comes to two speed a-c. motors.

H. P. Reed: We will grant, as has been stated in the paper, that the service calculation given, comes far short of covering all cases as it was not the intention of this paper to present details which could only be of interest to those directly connected with the elevator business. A complete treatment of this subject would in itself require a full text book.

The high-speed push-button elevator described by Mr. Lindquist, is very interesting and theoretically ideal, but as those experienced in the art will grant, the more complicated the device is made the more trouble is to be expected. In other words the advantages Mr. Lindquist claims is to increase the elevator service so as to reduce the number of elevators and save building space. However, in the scheme described it is feared that complications have been added which will increase maintenance to such an extent that it will require additional elevators to take care of shut-downs.

In the discussion Mr. Lindquist stated that the paper held 250 ft. per min. as the maximum speed for department store elevators. The average speed, which applies to about 12-ft. floor heights, was given as 250 ft. per min. in the paper, but it will be noted that the paper mentions a speed of 350 ft. per min. as a possible good maximum. This speed would be all right in a building having 15-ft. floor heights.

Mr. Lindquist said he felt the paper could not possibly mean what it evidently conveys, that floor leveling can be accomplished with a shunt field control motor, but as there are many in operation giving accurate results with this arrangement, there is no objection to interpreting the paper in this manner.

Mr. Lindquist touched briefly on heat specifications for elevator motors. This is a very good point and it is hoped that someone in the near future will come forward with a paper giving suggestions of specifications for actual installation heat tests for elevator motors.

J. J. Matson: There are two main points which I wish to discuss in Mr. Reed's paper. The first is the advantages and disadvantages of a high rotor moment of inertia; second, the application of alternating current motors to passenger elevators.

A high rotor moment of inertia increases the power consumption during starting. It also tends to increase the size of brake required. It has often been pointed out that service and smoothness of operation are two of the main features of an elevator installation. This is particuarly true when dealing with passenger installations. Provided a large moment of inertia is used, the smoothness of retardation and acceleration is improved. This is evident on account of the larger amount of stored energy in moving parts. The larger this energy compared to the power being required for moving the elevator the smoother is the starting and stopping.

Mr. Reed has stated that he believes the limit of a-c. motors on passenger elevators to be at approximately 350 ft. per min. I would take exception to this statement, inasmuch as there are several very satisfactory installations at the present time using a car speed of 425 ft. per min. Other installations have been recommended when using a-c. motors to run at 500 ft. per min. This I do not believe is too high a cage speed when using a-c. 2-speed motors.

The higher-speed equipments when using d-c. power supply uses a gearless drive. This consists of a low-speed motor, direct connected, to the driving sheave. A low-speed d-c. motor is a good electrical proposition. When you go, however, to alternating current, there are many inherent difficulties in reducing the synchronous speed so as to use a direct-connected motor. This can be readily understood when it is pointed out that in order to obtain a synchronous speed of 72 rev. per min. it would be necessary to furnish a 100-pole induction motor. Then when you consider that, in order to get slowdown for accurate stops, it would be necessary to cut this speed at least in a third, it is evident that a 300-pole low-speed motor would be desired. For the size of motor involved, this is at the present time practically an impossibility.

We, therefore, can consider that the a-c. installations must be of the geared type, and not only must the motor characteristics be considered, but also the gear characteristics must be considered. At the present time, I believe I am correct in saying that there are few elevator gears in operation at speeds exceeding 500 ft. per min. Undoubtedly, the elevator manufacturers can design and satisfactorily build higher speed gears and still obtain a very satisfactory device. It, therefore, appears that there are two limiting features: first, the gears, which is entirely the elevator manufacturer's problem; second, the motor, which is an electrical problem.

Relative to the electrical design of the motor, it would be possible to install a variable frequency and use this frequency instead of a difference in number of poles, in order to obtain slow downs. This same set could also be used in acceleration with the inherent degrees of power consumption. I believe that the use of a multi-frequency should be considered and investigated, as it certainly appears to be one of the several ways that will enable us to increase elevator speeds when using a-c. equipments.

H. P. Reed: Mr. Matson mentions that the paper gives the limiting speed of a-c. elevators as 350 ft. per min. At the time the paper was under preparation, this was essentially so, but since that time, at least one installation has been made of four elevators traveling regularly at 540 ft. per min. This speed was obtained by the use of motors having a 4-1 speed range.

Mr. Matson's further comments on a-c. motor design limitations will be welcomed by everyone interested in electric elevators.

A statement was made in Mr. Matson's discussion which pointed to the gearless machine as the only type used for the higher car speeds. Exception should be taken to this statement, as there are many geared elevators used on high car speeds.

E. B. Thurston: Reference is made to the downward tendency of elevators speeds. I don't believe it was the intention of the committee or the intention of Mr. Reed to give the impression that seems to be given. Therefore it is advisable to add to that a suggestion that it only applies to a high number of floor stops, because we all know there are installations of 600 ft. per min. where the elevator is stopping at practically every floor, and the higher speed is a very uneconomical installation.

In reference to that statement by Mr. James regarding the rate of acceleration, from our experience on the elevator side we fail to agree with him that the acceleration should be anything but constant. You cannot, it seems to us, change the rate of acceleration without its being objectionable to the passengers riding. There are many installations where this is quite evident. There are probably very few of you in the crowd who have not ridden on elevators which always start out too fast and objectionable.

A standard is mentioned in the paper of 5 ft. per sec. per sec. as quite satisfactory. If you exceed that very much it is objectionable to many people.

Mr. James also made mention of gears getting back lash in operation and stated that he didn't know of any installations where how certain principles had been applied to elevator gears. I would like to state that such principles as he mentioned have already been applied to elevator gears, and are working out very practically. He also questioned the possible rate of acceleration of geared machines. I would like to give him a test made on a geared machine operating at about 630 ft. per min. in regular service. Its rate of acceleration, with 1830 pounds unbalanced load on the car, was just 2¾ sec. It is possible with a geared machine to get and obtain any rate of acceleration, irrespective of the load and it stays put. It is interesting to note, because generally I have been an advocate

of some shunt field control, the results that have been accomplished. With the gearless type of elevator it is not yet possible to build a motor with any appreciable amount of shunt field control. While the gearless machine is a simple mechanical machine, it seems to have sacrificed desirable electrical characteristics, all day operating efficiency, positive speed control, cost of maintenance and constant rate of acceleration, irrespective of direction or load. The results of the last two years of development to get a method of controlling the gearless machine have brought out many new and interesting features. It is interesting to note the use of the multi-voltage, the variable voltage control system, etc., but even with all these added it is still a big question as to whether it is equal to the economic running and cost of maintenance of the straight shunt field control.

H. P. Reed: Mr. Thurston no doubt refers to the statements appearing on page 328, column 1 in the third from the last paragraph. Mr. Thurston's comments are appreciated, as it is agreed that the statement could be much improved upon by adding the facts brought out in the discussion regarding the power economy with higher car speeds under certain service conditions.

It is felt that the statement in the paper is true for elevator service requiring an average of a stop for each elevator at every other floor.

W. S. Atkinson: Many of the larger cities and some states have elevator codes which prescribe with considerable definiteness the provisions that must be made for safety, and these frequently involve major features of design in the installation. For example, while 75 lb. per sq. ft. of floor area is generally accepted standard for determining rated capacity of passenger elevators, as stated in this paper, some codes prescribe 60 lb. for elevators in hospitals. There are also limitations in regard to the application of hand rope and hand wheel control, types of governors and "safeties," etc.

Hence, elevator manufacturers are not always entirely free in selecting equipment but must consult such local authority when it exists.

In the example worked out on pages 327 and 328 to determine the number of elevators required to serve a hypothetical New York Office Building, it is noted that the elapsed time from the departure of the car at main lower landings to its next departure therefrom, is designated as "time of round trip." In such calculations the writer prefers to apply this term to the actual time the car is away from the main terminal landing,—the elapsed time from departure of car to its return, which is actually a round trip. The distinction is of practical importance as affording a measure in comparison, excluding as it does the arbitrary allowance for lay-over or waiting time at main landing. The writer used the term in the sense here used in a paper some two years ago outlining this method of developing car schedules, but has abandoned it for the reason stated.

Also the wisdom of serving the sixteen story office building entirely by local elevators, as is here shown as an example, instead of dividing the 10 elevators into the express and local, will be questioned.

The majority of elevator installations going in today outside of the field of the high-speed gearless machine, are alternating current, and the importance of developments in motors and controllers for this application is to be emphasized. The advent of the two-speed squirrel cage motor and a realization that blocks of resistance in the primary could be used as a means of control have marked two important steps in recent successful extensions of the field of a-c. installation, the three-to-one speed ratio being the favorite. A very recent development is the six-to-one speed ratio squirrel cage motor where the low speed winding is made use of in approaching a landing.

H. P. Reed: From Mr. Atkinson's discussion, it is assumed that perhaps the paper includes some statements that are too definite. It was thought that some fairly definite statements should be made in order to bring out discussion. From the number of written discussions received, it appears that the paper has served its purpose in this respect.

Mr. Atkinson takes exception to the method of calculating the number of elevators required for an office building as given on page 327, column 2, in that all variable time factors are not introduced individually. It is felt that these factors carried through as one variable will give just as good results.

It is admitted that the question of whether all local or local with some express service elevators shall be used to serve a 16-story office building is open for discussion.

The same factors as given can be used directly by dividing the elevators up into express and local. In a building of this height however, it is felt that either method may be used with good success. With express and local service for the calculation given in the paper, the frequency of service cannot be less than 24 to 30 seconds, but it is possible to empty the building in a somewhat shorter period than with all cars running local. This condition means that the best elevator service can be obtained by express and local for the outgoing rush hour to empty the building quickly and at all other times all the elevators may be run local and still maintain a floor frequency service of 16 to 20 seconds.

Mr. Atkinson's remarks on the application of a-c. motors to high-speed elevators are most timely. The demand for such equipment is increasing by leaps and bounds, and it is only a question of time when more and more a-c. elevator installations will be made in the down-town districts of our large cities.

Theo. Schou: Gearless traction motors are being built with a speed of 50 rev. per min. with a full field. By weakening the shunt field, this type of motor may be operated at a speed as high as 85 rev. per min. with good commutation. It is believed that by a further study into this type of motor, a special design could be created whereby shunt field speed could be brought down to probably 35 rev. per min., giving a shunt field control from 35 to 100 rev. per min. Though this type of motor has a high running efficiency, the actual operating efficiency is probably lower than the geared machine, due to a rather less amount of shunt field control, necessitating considerable control by armature resistance. If this type of motor, therefore, could be designed with a lower shunt field speed, it would have a higher operating efficiency.

The name plate ratings of elevator motors should indicate starting torque and pull out torque, as well as horse power rating. This would give the elevator builders more definite information in regard to the motor from which to design their installations.

Direct-current motors in most cases have sufficient starting torque when provided with shunt field only; a 10 to 25 per cent compound winding for starting is only necessary for low speed heavy duty service. This compound winding is short-circuited after starting, and it is very difficult to completely short this winding under operating conditions, and therefore, difficult to obtain good speed regulation under varying load conditions.

Direct-current shunt-wound adjustable-speed elevator motors can be built with a speed range of one-to-four and still obtain, by special design, stable speed condition when running at high speed with a weakened field.

Both the single a-c. squirrel cage motors with stator windings for two or three speeds, with speed ratio one to three, or even one to six, and also slip ring squirrel cage elevator sets with a speed range of one to three are being built, and it is believed both these types of a-c. elevator motors have their place and will continue to hold their respective places in the future.

The slip ring squirrel cage motor is built as two motors, and assembled as a 2-bearing set, the low-speed squirrel cage motor being used for dynamic braking when run over speed.

It is true as stated in the paper that the future points to more developments and the supremacy of a-c. elevator motors in comparison with d-c. motors. In the past, there has been a great deal of objection raised to the noise of a-c. apparatus, including the motor, controller and magnetic brake. This

trouble has been eradicated by furnishing motor driven control in place of the noisy magnetic control, and this has inspired motor builders to do all possible to remove the noise from their motors so that the a-c. equipment of modern type can now be procured for very quiet operation, and is controlled much better today than in the past.

H. P. Reed: Mr. Schou suggests a wider range of speed control by shunt field regulation for d-c. gearless traction elevator motors. This is a good suggestion, as a design of this nature will give the advantage of greater power economy, as well as more positive low speeds under different loading conditions. However, it is believed that Mr. Schou's suggestion of a maximum speed of 100 rev. per min. or even 85 rev. per min. is not practicable for a gearless machine with one-to-one roping as this would mean car speeds greater than allowed by law at the present time as it is considered that the approximate minimum diameter of driving sheave is 30 inches.

Arthur Liebenberg: The most significant statements in the paper seem to the writer to be

(1) That elevators of the worm gear type are now produced, giving perfect service at any speed up to 600 ft. per min.

(2) That the safety and economy of these types now seems to be superior to the gearless.

(3) That excessively high car speed is expensive and does not necessarily accelerate the traffic.

The writer would like to give a few added details of how and why this is true.

The tardiness of the worm geared elevators in claiming a place in the highest class of service has been due to the failure to perfect its details rather than any inherent fault of the type. The reverse is true of the type, for it was evident to the first inventor that the shunt motor had all the safety and other features needed but that some gearing was necessary to combine a commercially possible motor of 800 revolutions with a practically possible car speed requiring a 60 revolution drum. Nothing seemed more obvious than a worm gear and therefore it was the first used, and has been used for the lower speeds ever since. Only recently, however, designs and machinery have been perfected for producing commercially a satisfactory worm and gear. Today they can be produced, hobbed if you please, so they will run perfectly without any grinding in. The surfaces in contact are sufficient to give proper oil flotation so wear will not show in years of service.

The second factor that made the worm geared elevator for high speeds not only possible but most logical was the development of the interpole shunt motor.

The interpoles fix the point of commutation so that definite speeds can be obtained with variable loads by means of shunt field regulation.

The speed range for elevators having variable, positive and negative loads may be as much as 3½ to one.

All these speeds can be fixed within 3 per cent regardless of the load. Sparking or flashing on the commutator is avoided and heating need not be considered.

The motors are wound plain shunt except for the series turns on the interpoles. Some current is maintained in the field to give fast acceleration. For elevator work such a motor is ideal where direct current is available. For alternating-current, two-speed motors have now been developed having similar characteristics to the d-c. shunt motor. These also require gearing to keep the motor within commercial limits.

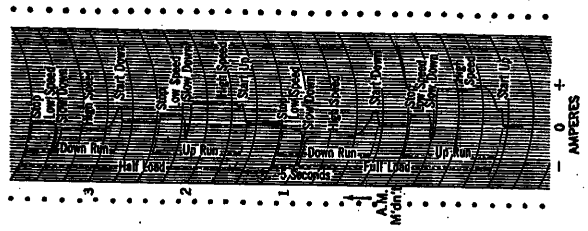
The interpole motor is desirable for elevator use because,

(1) In its economical speed range it is inherently safe from runaways for a wide range of loads.

(2) It has so much excess capacity at low speed that it can be given as fast acceleration as may be desired.

(3) The fixed low speed permits most accurate floor stops to be made. These stops are so definite that they can be made automatic if desired.

(4) The control is simple consisting of line and reverse switches and resistors in armature and field. The supply power eliminates all questions of safety, leaving the problem of acceleration simple. With automatic and uniform timing of control steps the car accelerates in equal times regardless of the load.



220 volts. Each division 10 amperes. Read right to left.

FIG. 1—GRAPHIC AMMETER RECORD OF TEST

Elevator capacity 3000 lbs. at 400 ft. per min.

Motor..........................220 volts, 120 amperes
Full load starting current.................... 60 amperes
Full load accelerating current...............130 amperes
Full load running current.....................120 amperes
Full load running efficiency..........................70 %

Power consumption between 2½ and 3 kw-hr. per cm. mils for office building service.

It is economical because armature resistance, which is used only in accelerating up to the slow speed is all cut out when the car has traveled 12 inches. The field regulation used in accelerating above the low speed entails practically no loss. Dynamic braking regenerates the energy of starting and restores it to the line as useful current. See graphic ammeter curves in Fig. 1. The running efficiency is so near that of the gearless that these savings make its average efficiency much greater in any service where the loads are variable and the stops frequent.

Variations in speed in a standard shunt motor without interpoles amount to 15 per cent either from balanced load to positive or negative full load. Hence in a gearless equipment even with multiple voltage control the low speed for stopping will probably vary that much with differences of load. Hence while these expensive luxuries will improve the efficiency they leave the problem of making accurate stops to the second extravagance, the levelling device.

With the fixed low speed of the interpole worm gear elevator the power can be cut off at a point within about 8 in. of the floor and an accurate landing assured. The stop is attained with a combination of dynamic and two shoe brakes, one on the worm and the other on the drum itself. The drum brake prevents the slap from back lash that would occur when the direction of pull is reversed on the worm.

This brake has long been applied to the tandem worm gear but only recently to the single gear type.

Worm gearing is much more efficient than usually thought, not less than 95 per cent in the average passenger elevator units having 9 to 18 revolutions of the worm to one of the drum.

It is dependable and durable, showing little wear in 20 years of hard service. Ball or roller bearings are used to take the annular and thrust loads of the worm. The other bearings are provided with bushings of babbitt metal that are interchangeable.

Drum type traction, which the author did not describe, consists of a single chased drum on which the six ⅝ in. cables used are laid together, giving each one and one-half wraps of contact. When the elevator moves these cables travel together, along the face of the drum, a distance of a single groove for each revolution. This amounts to about 10 in. for 150-ft. run of the car. The standard idler traction described in the paper gets 2 half wraps so that slipping is usually imminent and the cables cannot be lubricated as they should. Further than this the idler triples the number of bends in the cables and the friction of the drum shaft and its idler. With the drum type of traction there is no

slipping, and creepage due to differences of the average load is limited by a switch in the drum.

Readjustments of the cables is accomplished quite easily by running the car or weight on the buffers, relieving the traction.

Seven years of experience assured us that this system of traction is entirely safe and satisfactory.

Timing and the control of resistors with small motors through cams, one for the armature resistor and one for the shunt, has prove very satisfactory. It is very quiet in operation and lends itself to the proper adjustment of the acceleration to get the fastest comfortable rate.

Control is a prime requisite for good elevator service and the confidence born of smooth acceleration and accurate stops greatly accelerates the movements of the passengers entering and leaving the car.

The Warner Elevator Company has contributed largely to the development of the single worm gear elevator, which it has built exclusively since 1895. In 1915 it developed the ideal type described herein, which it has produced in large numbers ever since. It has given such good and economical service in high buildings that the makers of the gearless types have had to resort to multiple voltage control for groups of elevators and variable-voltage Ward-Leonard control for single units to meet this competition. There seems to be no warrant for the gearless equipment in buildings of less than 20 stories and not in them for local service.

W. H. Patterson: The variable voltage control system is an old principle and one thing that hasn't been spoken of very much here this morning was the noise and burning of contacts, on the control boards, which means cost of upkeep. That is one of the principal advantages in this system of control. We don't open any heavy armature currents, such as 150 or 200 amperes, but are merely handling field currents of three to five amperes.

Mr. James gave you a brief description of this system, so I will not repeat. But I would like to point out to you the current consumption that we recently got in tests which were made, on some elevators traveling 12 floors, with 2000 lb. load, at 500 ft. per min. With the balanced load and 75 stops per car mile, we got 1¾ kw.; with 150 stops we got 2¼ kw.; with 300 stops, 3 kw. With full load in the car and 75 stops per car mile we got 2¾ kw.; with 150 stops, 3½ kw., and with 300 stops, 4.7 kw. These tests show a remarkably low kilowatt consumption per car mile. They were made by our engineers and were recently checked by Mr. Bassett Jones of New York. He got practically the same results to the third decimal point. I therefore believe that this system of control warrants the attention of all elevator engineers and manufacturers. It offers the advantage, first, of smooth acceleration and deceleration; second, of low-current consumption; and third, low maintenance. The maintenance cost on your control board is going to be practically negligible because of the small current you are handling. Fourth, it solves the problem with a-c. current for high speed elevators. While great progress has been made in the last few years with two-speed motors, I think there is considerable developmental work yet to be done along that line to have it as satisfactory for high-speed passenger elevators as is the system of control such as this.

H. P. Reed: Mr. Patterson's discussion on the variable voltage elevator control is very interesting. It is felt however, that the power consumption tests do not tell the whole story on power economy. Test runs may easily be made with this system of control and show a considerable economy. However, it would be interesting to know just what the all day test will show, for instance, for an office building where there are not many stops per car mile, where the elevators are in service at least running not over 30 or 35 per cent of the time and where the standby losses of the generating equipment constitute quite an item in the power bill.

Bassett Jones: For the reason that not even an approach has been made toward a solution of the service problem in freight elevator engineering, I shall confine this discussion of Mr. Reed's paper to passenger elevator engineering. The passenger problem is relatively simple because, as has been said, "the passenger is a standard automotive package that stacks itself in one tier." However, this is only approximately true since the package in question has ideas of its own. But, being human, he does, in general, as all other passengers of his own class do, and so permits himself to be averaged as a member of a package group. Therefore there is some reasonable basis for treating the passenger as such a standard package.

As Mr. Reed says, service requirements form the premises from which the character, arrangement and size of the elevator equipment should be deduced. This point should be heavily accented. The determination of service requirements is the only logical basis for the solution of any elevator problem, freight or passenger. Given the service requirements, a determination of the most suitable size, duty, number, and arrangement of cars follows by mere arithmetic. But no amount of arithmetic will give the right answer unless the premises are sound. An error in determining the probable elevator service requirements in a building leads to a wrong determination of equipment no matter if the subsequent calculations be most precise.

Unfortunately the determination of service requirements must remain largely a matter of judgment based upon experience, and upon statistics gathered by painstaking observations. At best the answer is an intelligent guess, and so we have recourse to the best possible method of guessing—probabilities and frequency graphs.

Such studies in elevator services show that there are several important service factors, or rather coefficients, the probable value of each of which must be determined in each case before the probable service requirements as a whole can be properly established.

It is not merely a question as to how many people must be handled in a given time, but also what kind of people they are. Their working habits and group psychology must be determined. How promptly do they come to work, or leave, or go to lunch? How long can they be expected to wait in the corridors for a car without complaining?

All these and many others have to do with geographical location, vicinity to transit terminals, class and business methods of tenacity, etc. In these respects a bank building in Boston is not the same as a bank building in New York. Nor is an office building in down town New York the same as an office building in up town New York. Then, in office buildings alone, are the tenants, bankers and brokers with the attendant stream of messengers; are they professional; are they in insurance or in the textile trade? Are the tenants permitted to do small manufacturing such as clothing; will they in general occupy large areas with employees on the time clock, or will they occupy small areas and have few casual employees? These are a few of the questions that must be answered.

The renting management must also be considered. To-day, many buildings are inadequately elevatored, but had they been rented differently, would have ample elevator facilities. A single large tenant occupying separated floors may entirely upset the assumed desirable schedule. In general, the larger the individual tenants the worse the conditions will be.

In addition the tendency of real estate development must be studied, also in a few years the building may prove to be hopelessly under elevatored, or, on the other hand, it may be stranded with a costly equipment on its owner's hands. The space of ten years has seen radical changes in the character of certain districts in our larger cities.

Having come to this point in our study, the next question relates to the probable total population that must be handled, either initially or ultimately. This will vary widely with the

factors noted above. Depending upon these the population density may be anywhere from 40 sq. ft. rentable area per person to 200 sq. ft. rentable area per person.

The next step is to establish the probable rate of traffic flow, separately for the arrival period, for the departure period, lunch period, inter-floor traffic, and transient traffic. These, too, will depend on the locality, class, and working factors above enumerated. The arrival traffic may be anywhere between 20 per cent of the population in 15 minutes and 50 per cent of the population in the same time. The arrival traffic may be denser than the departure traffic or vice versa, and the departure traffic is more difficult to handle because of the absence of starters where it originates. Or, again, the combined inter-floor and transient traffic may be the determining factor in establishing service requirements. The location of toilets, restaurants, clubs, locker rooms—all must be considered as elements in the problem, and sometimes very important elements.

Thus, for example, measurements have shown that on the average, every woman in an office building visits the toilet, or woman's rest room, once an hour. Since 15 per cent of the population may be women, this means that 15 per cent of the population uses the elevators twice an hour, or 7.5 per cent in 15 minutes. Obviously the location of women's toilets has considerable bearing on our problem. Suppose the combined arrival and departure transient traffic is 8 per cent of the population in 15 minutes while the simultaneous business interflow traffic is 10 per cent of the population influx during 15 minutes. The net result including the female traffic is that over 20 per cent of the population use the elevators in 15 minutes, and this, due to the greater number of stops required, may be a heavier demand on the elevators than $33^1/_3$ per cent of the population arriving in 15 minutes during the morning arrival period. The 15 minute interval is frequently used as a convenient standard time measure. It is quite arbitary however.

Next we must know something of the probable distribution of the traffic flow during the worst period. What is its peak value and for how long does it last? Suppose that the average maximum arrival traffic during the 15 minutes is 25 per cent of population in this time. That is, during the worst 15 minutes 25 per cent of the population arrive at the building. During five minutes in this 15 minute period, the average rate may be 25 per cent greater than the 15 minute average, and allowance for this must be made unless crowding and delayed service is to result. Commonly, variations in traffic flow are observed by counting passengers entering the cars every five minutes. Graphs of such observations continued all day usually furnish a curious, and sometimes amusing commentary on the habits of the tenants. The character of the traffic frequency distribution will depend on the tenancy character factors previously mentioned.

I have devoted so much time to this sketch of service factors, because, after all, they constitute the basic data for our calculations. Without such a determination of traffic flow any method of determining the physical character of the elevator equipment results, as it begins, in a pure guess.

Questions as to corridor dimensions and arrangements as well as the size and types of door ways giving access to the corridors have not been mentioned above. As affecting the flow of traffic to and from the cars, such matters are of importance and should be studied.

Having covered these preliminary subjects, we are now in a position to discuss briefly the logical sequence of steps in the subsequent calculations.

We have established the probable traffic flow at the cars for arrival and departure periods, as well as the inter-floor and transient traffic and have selected one of these as determing the maximum service conditions. This selection may not be quite so obvious. In which case the computation will be made for the arrival traffic and then, as a matter of comparison, for the inter-floor and transient traffic.

Generally the computation will be started by assuming a desirable interval between cars. This, for the reason that the satisfactoriness of the service is determined by the interval or, what is the same thing, the maximum time a passenger has to wait for a car. On the average the car stands the full interval at the ground floor. This will vary with conditions of traffic. On the average a car travelling in each direction of motion passes each landing every interval. A car leaves the top landing every interval. Note that the interval taken is an average—it may be longer or shorter. If the interval, as an average, be taken too long in the beginning the maximum interval during the worst conditions may be out of all reason. Cases are on record where bad car design and restricted openings have increased the interval during a crowded period of inter-floor traffic to 4.5 minutes in a 16-story building. During the inter-floor period the traffic is equal in both directions, passengers both get on and off the cars at the same stop, and a crowded car, may and generally will, cause a considerable increase in the round trip time, lowering the interval. Frequently it is necessary to accept an inter-floor interval longer than the arrival interval.

Waiting for a car to arrive, or standing in a car that is not in motion, is the feature of the service that makes it seem either sluggish and slow. or snappy. Under these conditions 30 seconds seems 30 minutes to the impatient business man. It is entirely a question of passenger psychology, but it indirectly affects the rental value of a building.

In the highest grade office buildings in the New York financial district arrival intervals as short as 20 seconds have been used, but due to increasing population this is rarely maintained. A 24-second interval is considered good service; a 30-second interval is only fair service; a 40-second interval is slow service. The desirable intervals vary in different cities. In Boston, for instance, a 30-second interval is quite satisfactory.

Assuming a given interval as a starting place, from it must be deducted the time required to open and close car gates and landing doors at the ground floor to find the time available for handling passengers. For power operated gates and doors this deduction may be taken as 3.0 seconds. For hand operated gates and doors without car-landing door interlocks the deduction may be taken as 5.0 seconds, and with such interlocks 6.0 seconds or 7.0 seconds. The remaining time is available for unloading and loading passengers.

At the ground floor, where a starter is in charge, passengers can unload and load in 1.0 second each. At other floors the time per passenger will average 1.25 seconds with wide car openings, uncrowded cars and a reasonably effective means for announcing the arrival of the car at the landings. With crowded cars or restricted openings the time will increase. It is also increased in deep narrow cars. In crowded deep narrow cars the time may rise to an average of 2.0 seconds per passenger, and seriously affect the service.

Let us now assume a case. Assume arrival traffic amounting to 1000 persons in 15 minutes, and a 5-minute maximum of 416 persons. Assume a 30-second interval as desirable; hand operated gates and doors. Then the maximum number of passengers that can be loaded in the remaining 25 seconds is about 25. To prevent crowding a 30 passenger car should be used. But this is a very large car, and in office building service will run lightly loaded most of the day with marked unbalance and therefore at high average power consumption. Our traffic studies for this building show that the average load for the day will be 4 passengers, which, with the operator added, is a load of 750 pounds, and should be as nearly equal to the difference in weight between car and counterweight as it is reasonably possible to make it.

Let us then assume a 20-passenger car and either instruct the starter that only in emergency is he to admit more than 16 passengers, say during the 5-minute peak, or, cut down the interval to 25 seconds, which, as a matter of fact, is the best alternate, for then only 20 passengers can enter in the time available.

It is assumed that during the arrival period no passengers

will be unloading since none will be coming down from the upper floors.

Let us then correct the interval to 25 seconds. Then in 5 minutes 12 cars leave the first or ground floor each carrying 20 passengers—a total of 240 passengers. But in this time during the peak 416 passengers arrive. Obviously the remaining 176 passengers must be carried in another bank of cars.

This second bank could have smaller cars than the first bank, but, due to possible shifting of population density in the building, it will be wiser to make all cars of the same size. The area of the car platforms should be 42 sq. ft. arranged 7 ft. wide by 6 ft. deep. The maximum load rating will be 3150 lb.

These cars, two wide in a bay, will require a double hoistway, about 16 ft., 4 in. wide by 7 ft. 10 in. deep clear inside dimensions. Unless service conditions demand that the steel work be designed to permit this, generally hoistways of such dimensions can not be obtained. This is one of the unfortunate factors in elevator engineering. Architects rarely consider the real importance of installing cars of the right size, compelling the use of a larger number of smaller sized cars at a greater first cost and operating expense. In the above case, it may be necessary to use cars 6 ft. wide, then a depth greater than 5 ft. 6 in. is wasted. The platform area is 33 sq. ft., the rated load 2500 lb. The maximum passenger capacity is 16 persons. The interval becomes 21 seconds if delays and waiting at the ground floor are to be avoided. There are 14.3 departures in 5 minutes, giving 228.8 passengers maximum per bank. The service is almost the same as with the larger cars at a longer interval as it should be, but more cars, or more expensive elevators of higher speeds and acceleration will be required to maintain the shorter interval. Thus the building structure itself also effects the situation. Let us, however, suppose that the larger cars at a 25-second interval can be used. We have now established the size of the cars, their maximum duty load and the number of banks.

To determine the number of cars in each bank we must calculate the average round-trip time in each bank. This, divided by the interval gives the number of cars, required in each bank. The calculations are given in extenso to show how and where the different variables enter in and affect the result.

For purposes of calculation the *round-trip time* may be conveniently divided into *running time*, or the total time the car is in motion, the *standing time*, or the time the car is at rest during its round trip, and *lost time*, or the time consumed in false stops, limit stops, synchronizing, etc.

The running time is best determined from time-speed data for the various types of hoisting engines. The best type to use is the one that makes the running time a suitable proportion of the round-trip time. This establishes the desirable velocity—acceleration characteristic of the equipment.

The *standing time* is made up of time consumed in operating gates and doors and loading and unloading passengers, at all stops above the first floor. To this is to be added the interval, or the time the car is standing at the ground floor.

Let us start out by taking the first bank. Let the building be 20 stories. The proportion of the population to be handled by the two banks is as $176/240 = 0.73$, assuming equal population on all floors which may not be true. Then the first bank will feed $0.73 \times 20 = 15.6$, call it 16 floors. The hoist is 207.5 ft. on the average. The cars will stop at 0.8 of the landings "up," motion and none down motion. Therefore they stop at $0.8 \times 16 = 10.8$ landings, and the average "jump" or distance between start and stop is $207.5/10.8 = 19.2$ ft.

On the way down the car makes one jump of 207.5 ft.

On the way up the car starts with full load and ends with no load, so its average load is half full load. On the way down it is lightly loaded. Therefore, it will travel faster on the way up than on the way down when maximum unfavorable unbalance exists. These differences may amount to a material item in computing round trip time:

The standing time is made up as follows:

Gates and doors, 10.8 stops at 5 sec.......	=	54.0 sec.
Passengers, 20.0×1.25 sec..............	=	25.0 sec.
Interval..............................		25.0 sec.
Total..............................		104.0

The time lost is—

One limit slow down at top..............	=	3.0 sec.
25 per cent false stops at 2.0 sec. = 0.25 $\times 10.8 \times 2$..........................		5.4 sec.
Synchronizing..........................		5.0
Total..............................		13.4

The sum of the standing item and the lost time is 117.4 sec.

Let us try 8 cars in the bank, then if R be the running time, we have

$$E = \frac{R \times 117.4}{25}$$

or

$$R = 82.6 \text{ sec.}$$

Assume a car on resistance control running at 600 ft. per min. 5.0 second acceleration time rated at balanced load. The time-speed curves for such a 1:1 roping direct drive hoisting equipment show that running down light it will accelerate just to maximum velocity and at once retard to a stop in 9.5 seconds, and will cover 60 ft. in doing it. The remaining travel at maximum velocity is $207.5 - 60 = 147.5$ ft. which will be covered in 14.7 seconds.

This leaves $82.6 - 14.7 = 67.9$ seconds running time up motion or $67.9/10.8 = 6.3$ (nearly) seconds per jump of 19.2 feet with half load in the car. The time-speed data for this equipment show that the car will do this actually in just under 4 seconds. So there is a small amount of time to spare.

If power operation of gates and doors were used, $10.8 \times 2 = 21.6$ seconds would be saved. This, added to the spare running time of $2.3 \times 10.8 = 24.8$ seconds is practically two intervals, so two cars can be saved in this way, and the bank reduced to six cars. Without power operation of gates and doors, one car may be saved, making the bank seven cars. *Every time an interval is saved, a car is saved.* Obviously, the method outlined is subject to many variations. We might have started the calculation of the running time by assuming a velocity and speed and a type of hoisting engine, instead of assuming a number of cars. Then the running time would be calculated from the time-speed curves of the equipment assumed, next, the round trip time determined, and finally, the required number of cars obtained. The method is necessarily cut and try because there are inherently more variables than equations in the problem. It has the advantage over the method proposed by Mr. Reed that the variables are all put in one place where they are recognized as such, and can be given experimental values until the best solution is reached. Empirical formulas and methods are largely eliminated.

In one recent case I completed over 60 separate calculations before the best possible answer was found. But the resulting saving in first cost between the poorest and the best was in six figures, and the annual savings were in five figures. Of course, this was a very large installation in five banks of cars.

There are one or two other points in Mr. Reed's paper that I want to discuss very briefly.

The height of buildings are decidedly limited by the elevators—Mr. Reed says they are not so effected. If cost of space occupied by the elevators is considered, as well as building costs, it can be shown that in high grade office buildings on costly plots where taxes are high, it is not possible to economically elevator buildings above 26 stories in height in the usual manner unless the service to the upper floors be curtailed. When zoning laws affect the situation the 20th floor becomes the economic limit. The only recourse is to much higher velocity than the law now

permits and to extreme acceleration. In order to make it economically possible to build a building 36 stories high in New York under the zoning law, it was found necessary to use cars reaching a velocity of 800 to 900 feet a minute in 3.0 seconds, requiring automatic voltage control and push button initiation of starts and stops otherwise entirely automatic. The owner desired a taller building so as to get more space, but it proved entirely uneconomical.

Unless the entire character of real estate development alters, such buildings are the future type, and, in them, elevators must attain velocities now unheard of. New types of control and operating devices will be necessary, and are, in fact just beginning to come into use. The additional cost of the elevator unit is little if the number required to furnish service can be reduced sufficiently. Nor does the increased power consumption at these velocities amount to a serious factor, for the saving of a few feet of rentable area can easily offset it. In fact, it is the overall cost that counts, and the power costs are but a minute fraction of the whole. Relatively speaking, reduced elevator speeds may save a penny here and there, but to offset this they reduce the whole rental value of the building, besides requiring more cars and consuming more rentable area. As a matter of fact, multi-voltage control may save as much as 30 per cent of the kilowatt hours required to give the same service with resistance control, yet this saving may be but a few per cent of the total consumption by the building and at a very low rate. The main value of such controls is not in saving kilowatt hours, but in making it possible to attain rapid acceleration, just as the principle value of the auto-leveler in passenger service is to make stops possible at high velocities. In general, both of these devices are essential for economic elevatoring of buildings 20 floors high or more. Where the stops are frequent, they may be worth while in buildings not so tall.

Mr. Reed suggests that a downward revision in car velocity is of advantage to the owner due to the lower power consumption of the low speed car. In my opinion this is an entirely fallacious argument. The reasons for this opinion may be best set forth by a specific case.

A particular office building in New York has 28 floors. Up to and including the sixteenth floor a proper service can be obtained with cars traveling at 600 ft. per min., attained in 5 seconds—the maximum conditions giving good operation and reasonable freedom from false stops with resistance control and car switch operation. With voltage control the same smoothness of operation and percentage of false stops can be obtained at 700 ft. per min. attained in 3.0 sec. The resulting average increase in service capacity is figured from the time-speed curves at 12 per cent. Therefore, in the total of 17 cars, as computed on the 600-ft. 5-sec. basis, 2 cars are saved, resulting in a net first cost saving of nearly $20,000. The kilowatt-hours are cut 25 per cent amounting to $2400 a year. Two operators are saved amounting to $3000 a year. Interest and amortization are reduced by $2400 a year. Maintenance is reduced by 5 per cent or $500 a year. Grade B rentable area amounting to 2500 sq. ft. is saved, which at $3.00 rental value is $7500 a year. The total yearly saving is $15,300. Of course, all figures are approximately to 10 per cent variation.

Above the sixteenth floor, a bank of 8 cars rated at 600 ft. 5.0 sec. is required. Changing to rating to 800 feet—3.0 sec. voltage control, auto-levelers to make stops possible under these conditions, and incidentally eliminating all false stops, with power operation of doors and gates, push-button car operation and grouped landing signals, reduces the bank to 6 cars. The saving in first cost is not material but there is a saving of 1900 sq. ft. Grade A rentable area at $5.00 a sq. ft. or a yearly saving of $9500. In addition the kilowatt-hours are cut 30 per cent and two operators eliminated. But the principal factor is the saving of rentable area amounting to 5 per cent of that total which determines the economic possibility of the building above the 20th floor. Numerous other similar cases might be cited.

In all of this I wish to draw your attention ot the necessity of determining running time from time-speed curves obtained by accurate methods such as by the oscillograph, and to the fact that empirical methods of estimating elapsed time between start and stop may introduce serious errors in computing the round-trip time. The obvious errors in the methods of estimating time by the scheme of calculation given by Mr. Reed must be eliminated. A large amount of data both of running time and standing time must be accumulated and reduced to frequency tables by which the coefficients may be intelligently classified. It will then be found that the average deviation from the mean can be reduced to a determinable probable value.

There is no present reason why velocities as high as 1000 ft. per min. should not be used. The only limit is the physiological effect on the passenger, not due to acceleration or to retardation, but due to rate of change in air pressure. Discomfort due to rapid acceleration can be eliminated by voltage speed control of the motors. The disagreeable effect so common with resistance speed control even at velocities as low as 650 ft. per min. attained in 5.0 seconds, is entirely due to the rate of change of acceleration being a variable. There is no discomfort when traveling at a constant velocity of any amount except that due to change in air pressure. The discomfort appears only when the velocity changes, and then, only if its rate of change be irregular, or perhaps if the acceleration or retardation be so excessive that the equivalent variation of the gravitational field increases the weight of the body to a point approaching the elastic limit of the muscles.

One other matter—the a-c. elevator. This is a matter of vital importance to the public utilities companies in our bigger cities. At the present time the velocities attainable are limited due to the inherent character of the a-c. motor, and not inherently in the control, as Mr. Reed states. It is a high speed motor and must drive the drum or sheave of the hoisting engines through a mechanical gear. High velocities via a gear of any ordinary kind are doubtful, although the writer is responsible for one such installation operating satisfactorily and economically with a car velocity of 400 ft. per min. I think it could be jacked up to 500 ft. per min. The motor used is a double affair—a two-speed squirrel cage and a slip ring on one shaft, the two stators in one housing. But at the higher velocities, d-c. direct drive hoisting engines on proper voltage control can be operated from an a-c./d-c. motor generator set at less over-all power consumption than required by the d-c. hoisting engine on resistance control—in many cases this saving will be sufficient to pay for the added cost of the voltage control, particularly where the change to a-c. service brings about a reduction in rates.

H. P. Reed: Mr. Jones mentions that no solution is given of the service problem on freight elevators. The service problem on freight elevators is so varied that it requires a special solution in each case, depending on the use of the building and the method of handling material.

Mr. Jones goes into some details on the service problem which is felt are not of particular interest to the electrical engineer. We must take exception to his maximum population density of 40 sq. ft. per person. This means but approximately 6 x 6 feet of space per person, which is felt is almost impossible inasmuch as rentable areas is understood to include closets, safes, partitions and all lost space outside of corridors.

Mr. Jones takes exception to the method of calculating the number of elevators required for an office building and favors the introduction of each variable factor, whereas it is felt that these factors carried through as one variable will give just as good results.

In the discussion, a criticism was made of a statement that height of buildings are not limited by the elevators. In making this statement it was not intended to include commercially eco-

nomical construction of any particular building due to the size of the plat or the shape of the building. As far as the mechanical and electrical features of the elevator are concerned, they can be built for any height of building.

Mr. Jones' criticism of the suggested saving due to slower speeds was answered by Mr. E. B. Thurston's dis-ussion.

The discussion mentioned that a 30 per cent power saving can be realized by applying multi-voltage control in place of rheostatic control. This may be so for the elevator machine as a unit, but it is felt that the stand-by losses of the generating equipment producing the various voltages will off-set to a large extent any possible power saving.

Mr. Jones mentions the advantage of the auto-leveler in passenger service in order to make reasonable stops at high velocities. While this may be true in some types of motors and control, it is not true of some other types. The use of shunt-wound d-c. motors with a wide range in speed control by shunt field regulation and a constant time element acceleration control provides an equipment which will give accurate slow speeds and practically constant rate of acceleration, regardless of load conditions. Therefore, with equipment of this nature, accurate stops can be quickly made without the aid of the auto leveler.

According to Mr. Jones the paper mentions that the limitation of speed of elevators driven by a-c. motors is due to inherent control limitations. We fail to see where this statement appears. No such limitation exists as successful installations of passenger elevators driven by a-c. motors are now operating 540 ft. per min.

It is granted at high velocities with an *ordinary* gear, but as stated previously in the paper, it is being proved daily that if correctly designed and constructed a geared elevator is giving as smooth and satisfactory operation as any gearless type, and with greater economy. Moreover, as the multi-speed a-c. motor can be successfully applied to the higher elevator car speeds, there is no need for the transforming to direct current with the resultant stand-by losses.

H. L. Wallau: In all of our larger cities we have the d-c. system of distribution in what is generally known as the downtown or business area. This development came about very naturally, due to the fact that the Edison System was the first developed and the cities that are now the largest cities, were the largest then, and had the initial electric systems installed. However, there are a great many of the medium sized and smaller cities in which the Edison system is not in use, and a-c. current only is available, or in certain cases special 500-volt d-c. elevator circuits are run.

Now these smaller cities are gradually getting into the class of the larger cities, larger buildings are being erected, so that they are becoming metropolitan in character and high-speed elevator service is required. It is therefore very gratifying to note that an installation is being made in Toledo today in which three hydraulic elevators are being replaced by a-c. elevators with a speed I understand of 550 ft. per min. I have been told, although I haven't personally inspected the elevators, that their operation is very satisfactory, quiet, the acceleration is smooth and the development begins to have very hopeful possibilities.

Mr. Hellmund: It occurred to me in this discussion that there was too much reference made to the speed of the elevator when a-c. and d-c. service is compared. It is not so much the speed of the elevator that limits the application of the a-c. motors as it is the number of stops that are made. The two-speed squirrel-cage motor, which is now applied to some extent to elevators, will give excellent service if the number of stops is not too frequent. As is well-known, all the starting energy and the braking energy, from the high speeds to low speed, is dissipated in the motor, and therefore the number of starts and stops is of utmost importance with regard to the motor heating.

In this connection I should like to refer to one point in the paper where certain calculations are given about the loading of the motor. With a squirrel-cage motor, it is not only a question of what the load is, but it is also very important to consider how often it has to start. If one goes too far with the frequency of starting, overheating will result even with zero load. For this reason, I believe that the two-speed a-c. elevator motor, while undoubtedly having a large field of application, cannot be applied to everything. When it comes to frequent starts, something else has to be used.

One possibility for such cases is the two-speed motor with wound secondary, which is, however, not a very elegant solution of the problem on account of the many slip rings and the complicated control.

Another possibility, previously mentioned, is the Ward-Leonard system of control changing from a-c. to d-c. power. This certainly has a number of attractive features and, for the higher class of elevator with frequent starts, it looks like an excellent proposition.

Reference has also been made to the possibility of obtaining adjustable speeds for a-c. motors by means of frequency changers. The Westinghouse Electric and Manufacturing Company has an installation in operation where frequency changers have been applied with good success. Of course, this requires an extra piece of rotating apparatus, and if such is used, it is perhaps just as well to convert to direct current and have the additional advantage of being able to use the direct traction arrangement, which is almost impossible with a-c. motors.

Another point which has been briefly mentioned in the discussion is the question of noise. One of the speakers stated that a-c. motors can now be built so that they are not so noisy. That is somewhat optimistic. In connection with the noise problem, we must realize that it is largely a question of natural periods and resonance of various parts, and no engineer is able to calculate the natural periods of the various parts entering into an elevator installation. Motors may be quiet in one place or one position, and when they are put into the penthouse, they may vibrate on account of the resonance effect of the floor. Therefore, we cannot claim that the noise problem is fully solved. But there are certain predominant causes for noise, which are now more fully understood than in the past, and therefore the matter is not altogether hopeless. I think we shall be able to equip the large majority of a-c. elevators pretty soon so that they can be called practically noiseless or, at least, not any noisier than the d-c. installations.

H. P. Reed: The author hopes that the paper with discussions will be of value to architects, engineers and to everyone connected with the manufacture and use of electric elevators. Perhaps more real active engineering problems are occupying the attention of the elevator engineers today than at anytime in the history of the elevator business. Many of these problems are but briefly mentioned in the paper, but are deserving of further study. It is hoped that further elevator papers will soon be available, particularly on the following subjects.

(1) High-speed elevator travel using a-c. motors.
(2) Variable voltage control (Ward-Leonard system.)
(3) Automatic leveling devices.
(4) Multi-voltage control.
(5) Door interlocking equipment.
(6) High-speed push button and dual control.
(7) Actual comparative test results of power consumption for the many types of machines, motors and control.

The Improvement of the St. Lawrence from the Viewpoint of Private Capital

BY HUGH L. COOPER

Consulting Engineer, New York, N. Y.

THE subject of the reconstruction of the St. Lawrence River, and the results to be obtained therefrom, lead us into magnitudes that are very difficult of practical visualization. In order that you may be properly oriented I would like to refer you to the map, Fig. 1. In the course of my remarks I will call your attention to a general plan which I have worked out for a part of this reconstruction, and will give you a general description of my ideas as to what should be done with the remainder of the river. It is my present belief that the best public interest demands that the St. Lawrence River should be harnessed by the construction of five dams; the first one being located at Cat Island above Massena, the second at the foot of the Long Sault, the third at the foot of Cedar Rapids, the fourth at Cascades Point, and the fifth at Cote St. Paul.

Before we go further, I wish to tell you very plainly that I am not flattering myself that I have solved the St. Lawrence problem. Later, very necessary investigations may show that dams Nos. 1 and 2 should be combined. I believe that the judgment of no one engineer will ever be accepted for work of this magnitude, and that before any engineer's plans are adopted, they will have to pass successfully through the acid scrutiny of a high grade commission of engineers from Canada and America, the personnel of which, when examined, will show that the Commission is qualified to the fullest degree by previous experience, to write the verdict.

Divisions of the Subject

I desire to divide our St. Lawrence subject into the following divisions:

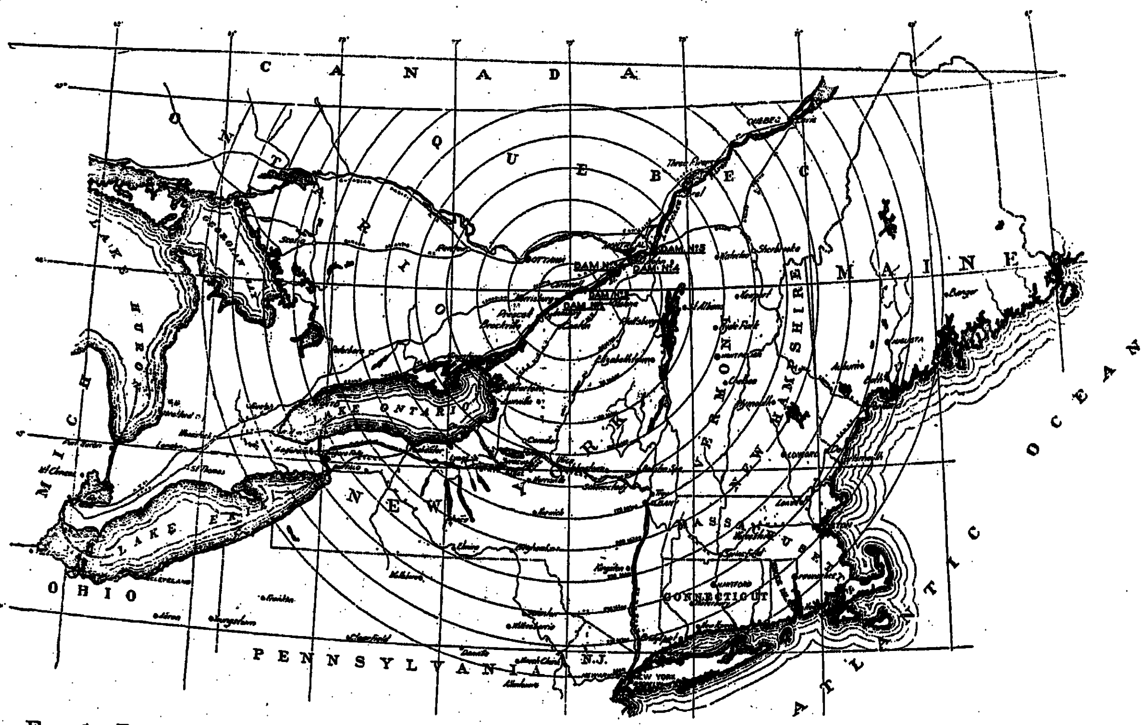


Fig. 1—Power Territory Available for St. Lawrence Power in Canada and the United States

Transmission line distances will average about 115 per cent of the distances shown by the circles that center at Dam No. 1. The territory within these circles and within circles that can be drawn using Dam No. 5 as a center can be served without invading any experimental field.

First, private capital personnel and proposal.

Second, the attitude of water power people toward navigation.

Third, with reference to the magnitude of the work as a physical structure.

Fourth, six new great values to the public from a reconstructed St. Lawrence River.

Fifth, how St. Lawrence benefits should be achieved.

Private Capital Personnel and Proposal

It has occurred to me that I should clear up the minds of this audience as to the honesty of a small amount of propaganda that still remains with us about

Address delivered at the Spring Convention of the A. I. E. E., Chicago, Ill., April 21, 1922.

the so-called water power trust. I assume that in the public mind, a proper definition of a trust would be an organization which could, because of its holdings either of rights, or property, or both, rob or hurt the people without hindrance of law. As I read a few of our newspapers, this definition seems to fit the case. The studies which I have been carrying out on the St. Lawrence for about three years have cost the interests that supplied the money, something over $250,000 for engineering research, and $500,000 more is ready to complete our investigations, as soon as governmental permits are granted. This money has been furnished by interests who own the Frontier Corporation of the State of New York. It is opportune to state here very plainly that the Frontier Corporation has never been engaged in any propaganda in the past, and will refrain from such methods in the future. We have not asked for, nor will we be seeking the support of any particular section of the press. When the St. Lawrence question is fully understood it will be regarded as a national problem in which the points of the compass must be omitted. As we are asked for our views by the press, by government officials, and by the general public, we will gladly give them the facts, and stop there. Our well defined expectations of success are based entirely upon the good sense and intelligence of our people to decide what is in the best public interest.

The members of the Corporation at this time are, the Du Pont Company, the General Electric Company, and the Aluminum Company of America. They have been brought together because of the belief that no lesser syndicate of successful men of industry could cope with the problem from a private capital standpoint. The carrying out of a project of the magnitudes here under consideration, will call for the very best intellects that America can produce, and the American people have a right to demand that when the St. Lawrence work is finished, by whomsoever it is constructed, the work shall represent a magnificent monument to American ability. Such a monument can never be expected to result from government ownership, or from the leadership, however earnest and honest, of merchants, railway men, lawyers, doctors, newspaper men, or others; it can be expected to come about only by the combined efforts of organizations which are familiar with the work to be undertaken, and whose records with great enterprises are successful.

The Aluminum Company of America, as you may know, has spent several millions of dollars in the purchase of lands along the Long Sault stretch of the River between its Massena intake and Cornwall. When the purchases of these lands were made, it was hoped at some future time to develop water power on this property for use in metallurgical chemistry. Over two years ago the Aluminum Company came to the definite conclusion that this great water power in the St. Lawrence was of far more value to the public if used for general distribution to little and big consumers, than it was of value to the same public through the consumption of aluminum, and some time after reaching this decision, the Aluminum Company passed the control of all its holdings to the Frontier Corporation.

At the time the Frontier Corporation was formed, over a year ago, and for some years before that time, all of our syndicate members were fully aware of, and in complete accord with the provisions of Federal and State Laws that require, individually and collectively, the most thorough supervision at the hands of public service commissions, state water power commissions, and the Federal Water Power Commission, of all of the energy that could be created from the St. Lawrence or any of our other navigable streams. Under the operation of these laws which I have just mentioned, the rates to be charged to consumers, the character of the service, the territory to be served, and the issuance of securities, are all in the hands of public service commissions, the servants of the consumers themselves.

The members of the syndicate have entered upon this endeavor with the full knowledge of all of the restrictions that I have just mentioned, and with which you are all so familiar, and to call such an association of men a "trust" or a "power ring" is plain dishonesty. No good person seeking the truth can ever accuse the Frontier Corporation, and the men behind it, of having anything but the highest aims in this whole matter. It is further proper to say at this time that the quantity of money required for the first unit of installation will be so great that the interests behind the Frontier Corporation, strong as they are, can never be anything but leaders and holders of a small minority of the total securities that will necessarily be sold. The majority of the securities will have to be taken by the public at large. This investing public will never subscribe to these securities if their attractiveness is clouded by propaganda of abuse and misrepresentation in any considerable amount. Before the Frontier Corporation, or any other corporation, can finance units of development on the St. Lawrence, it must prove to governmental authority, and its prospective investors, that its financial and engineering plans, after full official inquiry, have been found not only the best that can be devised in the public interest, but superior to all other plans considered.

The members of our syndicate have an abiding confidence in the ultimate fairness of American and Canadian people, and believe they will eventually accord us the approval we must have. We realize that much patience will be required on both sides, and we believe when the cards are all on the table, where they should be, neither the people nor we will have much to complain of.

Attitude of Water Power Toward Navigation

Over the St. Lawrence River there is now transported annually about 4,000,000 tons of freight, a few passenger steamers, and there is developed at present

from the St. Lawrence less than 200,000 horse power. For some time in the past, our friends of the opposition, in different places, have been trying to create a false impression regarding the attitude of the water power people toward navigation. This attempt was wrong because it was based upon falsehood. The opposition should have given us credit for more intelligence than to suppose that any group of men would, for a moment, consieer the mutilation of, or encroachment, in the slightest degree, on the great transportation facilities the Great Lakes and the St. Lawrence can offer to more than 40,000,000 existing people, to say nothing of the vast increase in this population future time will record. That navigation is paramount to power, every one concedes, and I know of no one who has ever disputed this view, whose opinion is worth noticing. The laws under which we are hoping to operate, specifically make navigation paramount to power, and require that all of the water levels in the pools shall be regulated in the interest of navigation, by government.

We have always known, advocated, and maintained that by the right of the people, by existing law, by common sense, and by every other avenue of good reasoning, power is secondary and incidental to navigation, now and always will be.

PHYSICAL MAGNITUDE OF THE PROPOSED PLANS

The stretch of the St. Lawrence River under consideration is 120 miles long from Ogdensburg on Lake Ontario, to Montreal, and drops, in this stretch, about 220 feet—approximately 200 feet of which is available for power purposes.

You are, of course, aware of the fact that the International Joint Commission, created by the Act of Congress, January 11, 1909, has recently made a report to the Governments of the United States and Canada, on the subject of the reconstruction of the St. Lawrence River, based upon the recommendations of their respective government engineers. Open criticisms were called for by the International Joint Commission of the Government Engineers' report, and I have filed with the International Joint Commission comments on the Government Engineers' report. I have found myself unable to agree in any sense with the recommendations of the Government Engineers, and believe the adoption of their plans would constitute a most extraordinary mutilation of a great international engineering possibility. This sweeping opinion is fully shared by every hydraulic engineer of experience I have consulted, and I have consulted several of them. I do fully agree, however, with the recommendations of the International Joint Commission to the effect that because the problem before the Commission was of such great magnitude, the whole subject should be referred to a new enlarged commission of engineers whose previous experience in work of this character would be acknowledged everywhere as of the highest acceptability.

I shall not take your time in an extended review of my differences with the Government Engineers' report, but will instead give you a very brief outline of what they have proposed, and what I have proposed, and will refer you to the comparative profiles shown in Fig. 2. The Government Engineers propose the installation of

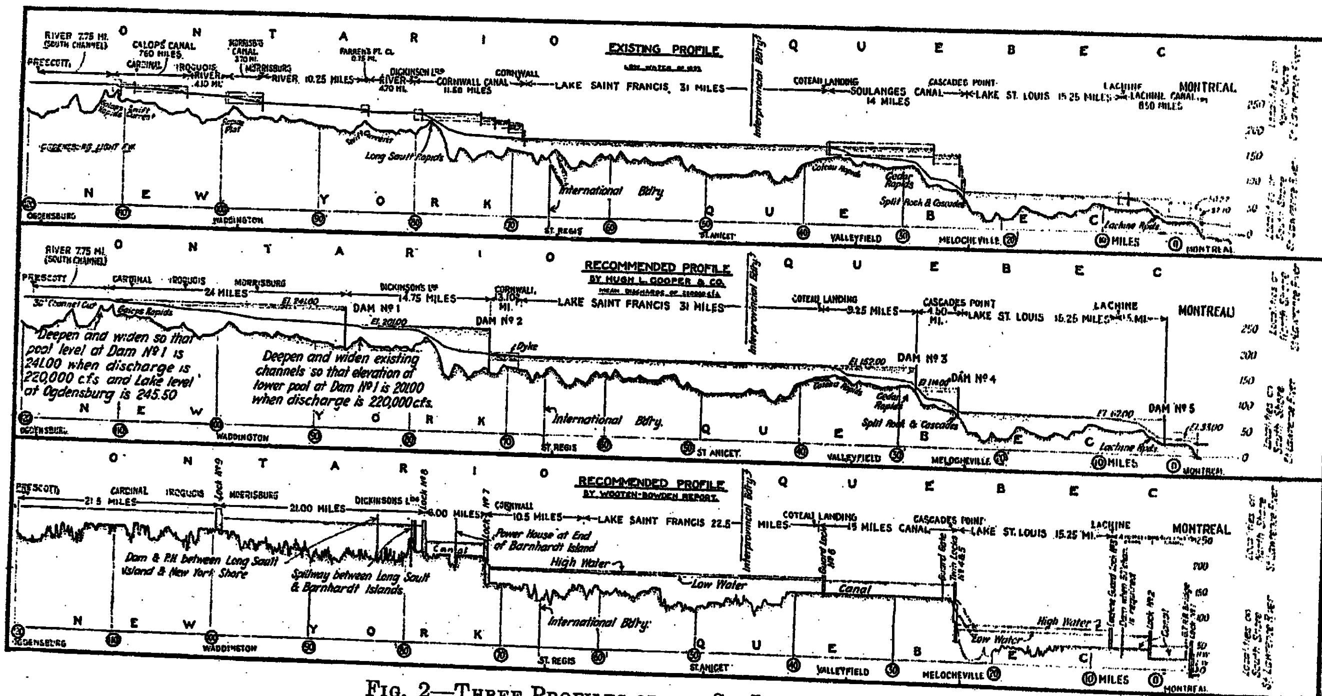

FIG. 2—THREE PROFILES OF THE ST. LAWRENCE RIVER

1. Existing profile.
2. Profile recommended by Hugh L. Cooper subject to such changes as final surveys require.
3. Profile recommended to the International Joint Commission for adoption by the Wooten-Bowden engineering report.

three dams in the St. Lawrence, nine locks, thirty-one miles of canals, and the installation of 4,545,000 horse power capacity, at a grand total cost of $506,000,000, without any interest during construction, or during the loading period for the power, and all of this for power houses that would, if operated to capacity, automatically shut down in times of ice attack. In my opinion, this $506,000,000 cost estimate is not only valueless because it excludes interest, which has to be paid as well as principal, but it is otherwise valueless because the estimate is on structures that sadly fail to produce the best efficiency either in navigation or power. My plans call for the installation of five dams in the St. Lawrence, six locks, six miles of canals, and 5,400,000 horse power capacity, at a total cost including all charges, from one billion, two hundred and fifty million, to one billion, four hundred million dollars, depending on results of final surveys.

I will now direct your attention to the Figs. 3 to 19 inclusive, which will illustrate better than words, the general power situation, as I see it.

Because of the greater ratio of pools to narrow canals, my navigation plans provide for 25 per cent greater speed, and much greater safety through the St. Lawrence than the Government Engineers' plans provide for. They have thirty-one miles of canals, and nine locks, where I have six miles of canals, and six locks. In all other navigation requirements, my plans are either equal or superior to the Government plans. In addition to producing far better navigation facilities than those proposed by the Government Engineers, my plans produce 855,000 more horse power capacity for general use, 550,000 horse power of which is in the international stretch of the river. The public in Canada and the United States will never consent to throwing away navigation facilities and power in the way the Government Engineers have recommended. Some day our St. Lawrence Tidewater Association friends will see and admit the inferiority of the Government engineering plans with respect to both navigation and power, and the superiority of our plans with reference to the same subjects.

Six New Great Values to the Public from a Reconstructed St. Lawrence River

The first value to the public from a new St. Lawrence, if Mr. Hoover, Mr. Barnes, and many other high authorities on this subject are correct, will be the creation of a permanent link in a navigation system capable of handling 200,000,000 tons of freight per navigation season. As soon as the Great Lakes district is completed to the same capacity as the St. Lawrence, there will thus be created the greatest inland navigation facility in the world, producing permanent distinct advantages to producers and consumers alike.

Second, the saving of coal and labor. As to the value of 5,400,000 horse power that can be commercially developed from the St. Lawrence River on a load factor varying from 70 per cent in the winter to 80 per cent in the summer, 1,200,000 of this horse power would belong to the United States by treaty right, and 4,200,000 to Canada by the same right. Inasmuch as Canada already has a superabundance of hydroelectric power in the vicinity of the St. Lawrence to supply her needs for decades to come, it is probable that at least a part of this power can be used in the United States until the Canadian markets require it.

The statistics of the United States Government show that 5,400,000 horse power will save more than 54,000,000 tons of coal per annum. It is difficult to visualize numerals of this magnitude. Using fifty-ton coal cars as a basis, 54,000,000 tons of coal would make a railway train 9000 miles long, a distance greater than the diameter of the earth, and over three times the distance between New York and San Francisco. At the ordinary rate of coal transportation, 54,000,000 tons of coal would make 1,080,000 carloads, 36,000 engine hauls of 150 miles each, and require the use of 5000 railway men, to say nothing of the labor of 70,000 men used to mine the coal, and 80,000 other employees who would automatically be released for other uses.

Third, the saving to railroad property of the United States and Canada. A careful study of reliable statistics shows that every new hydroelectric horse power installed automatically releases something over $100 worth of coal carrying railway property for other general uses. The substitution of 5,400,000 hydroelectric horse power for coal generated power will relieve for other more useful purposes, $540,000,000 of existing railway property in the United States and Canada, and thus relieve the investment field of the need of furnishing this great sum for new railway construction and equipment.

Every well-informed person knows that for many years in the past, the railways in the United States have been handicapped in carrying out needed extensions of all kinds because of lack of funds, and that when our business revives, as we all hope it will some day, the railroads will be behind in capacity to handle freight. Any proposal that will relieve the demand upon railroads (and we of course furnish most of the coal Canada uses) is, as a matter of fact, a blessing to our railroad systems as a physical machine, and therefore, a blessing to the people themselves who in the last analysis really own the railroads. Some people seem to think that the president and board of directors own the railroads. The stockholders own the railroads. When the late James J. Hill died, he owned only 3 per cent of the stock of the Great Northern Railroad, if the newspapers can be believed.

Fourth, the saving in power bills. The construction, and putting to work of 5,400,000 hydroelectric horse power will save power consumers in the United States and Canada at the rate of $35 per horse power per annum, or $189,000,000 per annum, figuring pre-war coal costs which, of course, we all know will never

again be available. This great annual saving in power cost will be a tremendous aid to industry in both countries, that can not be secured in any other possible way.

Fifth, the impetus to new industries by the placing of St. Lawrence power in Eastern Ontario and Western Quebec, New England, and New York, and also along the 354-mile length of the Erie Canal, will create demands for labor and material of great benefit to the public on both sides of the international boundary line.

Sixth, the reconstructed St. Lawrence plus the Niagara power potentialities present and future, will give to the territory extending from Detroit and Windsor on the west, to Quebec and Bangor, Maine, on the east, a continuous power zone in which more than 8,400,000 hydroelectric horse power will be available for industry at practically the same average price on both sides of the line. History does not record a single case in which one of the two bordering countries is continuously prosperous at the expense of the other. The best prosperity is founded always on a full consideration of the "live and let live" policy. The juxtaposition of cheap navigation and cheap power will produce industrial prosperity on both sides of the line which will never be forced to respect, for any great length of time, any international boundary. This prosperity will flow everywhere by the laws of good sense and good economics, as the people are educated up to where they can see the permanent value of genuine reciprocity.

The foregoing six great values are in reality economies with a vengeance, and we should use them before vengeance is upon us for their non-use at a time when economic conditions not only existing, but for decades to come, require our use of every possible economy, if our industries are to survive European and Asiatic competition.

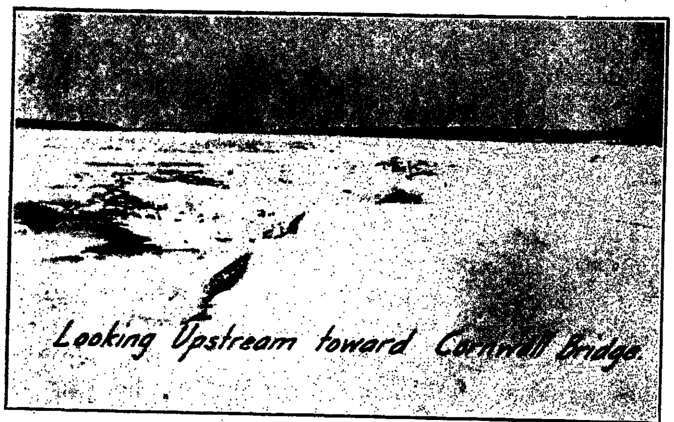

Fig. 3

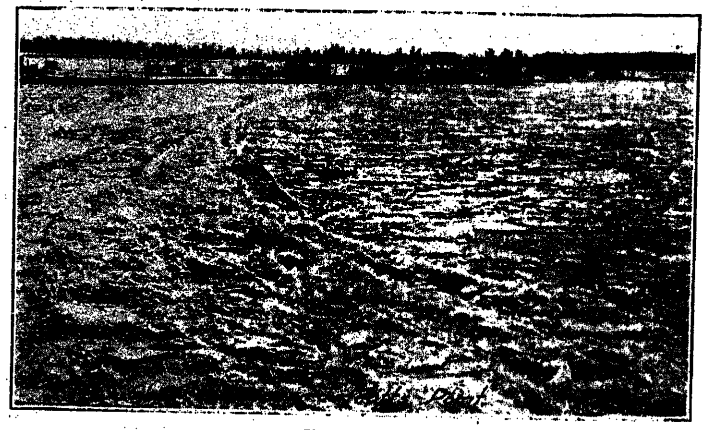

Fig. 4

Fig. 5

Fig. 6

Figs. 3, 4, 5 and 6 show average ice conditions in the St. Lawrence that navigation and power structures must successfully control. At times more than 675,000 tons of ice per hour will have to be automatically controlled if navigation structures are to continue safe and if power plants are to operate to capacity. The history of eleven power plants at Niagara Falls and on the St. Lawrence, covering approximately fifteen years, shows that in attempting to handle but a small portion of the total ice moving, all but one of these eleven plants, that of the Toronto Power Company, have suffered annually severe ice interruptions to a degree that would seriously interfere with satisfactory long-distance transmission. If power from the St. Lawrence is to be made available for the territory under consideration, the ice problem must be absolutely solved by using the engineering principles that have stood the test at the Toronto Power Company's plant on the Canadian side at Niagara Falls.

All of these six new great values (and more could be enumerated if time permitted) can be supplied to our people on both sides of the international boundary line without hurting any public or private investment or good purpose, and what is more phenomenal still in the accomplishment of these great results, navigation will not be called upon to sacrifice a fraction of an inch

of navigation depth to water power, and water power will not have to yield a fraction of a horse power to navigation. Surely any set of men who are seriously proposing this great work, and who, with all of the resources of leadership, men, and money at their command, will assume all the risks involved, and will bring about such a consummation in the public interest, deserve and will receive the full support of all of our good people.

How St. Lawrence Benefits Should be Achieved

The question is, how shall this need be supplied, and we are led at once into the age-old controversy of public versus private ownership. The advocates of both of these views are undoubtedly sincere. Twenty years ago before public service commissions had demonstrated their usefulness, too many corporations were guilty of the "public be damned" policy, and the public service commissions were, therefore, the normal result. Thanks to the good work accomplished by these public service commissions the controversy as between public and private ownership is, in my judgment, rapidly coming to a close. The war in a great way demonstrated to us the evils of government management in large affairs. Most of the intelligent people of the United States are now convinced that well regulated private corporations are the best for everybody, as opposed to the inevitable inefficiency that has always been found in government management of business. The history of the Hydro-Electric Commission of Ontario, as it is today being sadly written, is final and convincing proof of the inability of governments to successfully handle great public utilities.

In view of its influence on the whole St. Lawrence situation, I desire to call your attention very briefly to the unusual conditions which have developed in power production at Niagara Falls on the American side. You are aware that in the early nineties when Niagara power first began to take shape, progress in the art of turbine and generator design, together with the scarcity of a reachable market, compelled the use of only a fraction of the total head in the Niagara River. Plants using from 40 to 60 per cent of the total available head were accordingly installed. These fractional heads resulted in the proportionate inefficient use of the water, but it was a case then of inefficiency or nothing. The public everywhere properly acclaimed the courage of these early pioneers in going forth with these new enterprises at a time when so little was known as to what the ultimate destination would be. Hydroelectric engineering all over the world is greatly indebted to the early installations on both sides of the line at Niagara Falls for the experience thus made available in aid of the succeeding advances in hydroelectric engineering. Now, because of great increases in the demand for power, governmental authorities on both sides are requiring that the old diversions at fractional heads should be abandoned, and the water used at maximum efficiency. This requirement has called for the absorption by the new efficient plants of the great sums originally invested in the partial head plants. This union of costs will result in making the present and future cost of generation at the busbars on the American side, between \$17 and \$19 per horse power, according to the quantity and character of service rendered. On the Canadian side, when the Canadian power plants are compelled to abandon their existing fractional head plants, as they must eventually do in their own interest, their busbar costs will be in excess of \$20 per horse power, when all of the charges are in. Any proposals to develop power from the St. Lawrence must take into consideration power prices at Niagara Falls, as to be financed by private capital they must be able to show that St. Lawrence energy compares favorably with Niagara Falls costs, failing in which the project would not attract investment.

The power costs just mentioned bring us now to the all-important question of what percentage of the total cost of the reconstruction of the St. Lawrence River should be charged to power, and what percentage should be charged to navigation. My figures show that according to present day costs of material and labor, and overflowed lands, this ratio should be approximately 75 per cent charged to power, and 25 per cent charged to navigation. If more than 75 per cent is charged to power, the resulting costs will not enable us to compete with Niagara Falls, and thus finance the project. If less than 75 per cent is charged to power, the load on navigation would be more than the traffic can sensibly bear. If the 75-25 ratio is accomplished, it is my opinion that the final cost for energy at generating station busbars will be approximately \$17 per horse power exclusive of federal and state taxes. This price of \$17 will be guaranteed to the public in advance, and thus save the public from the punishment experienced in the past through overruns in construction costs.

At a juncture when America is in sore need of every economy human ingenuity can devise, is it not most remarkable that we find ourselves, because of many changes in an art not yet forty years old, brought face to face with these unexpected possibilities from the St. Lawrence River?

It is indeed notable that in a stretch of the St. Lawrence River, the average total drop of which is only a foot and seven-tenths to the mile, 5,400,000 horse power can be built which can compete on a par with the greatest water power on the American continent, if not in the world.

We have heard much in recent years about the savings which can be secured to the public by installing great superpower systems, at costs running into the hundreds of millions. These proposals read fairly well, and are attractive to the imagination, and will, I believe, some day be carried out but the raising of these hundreds of millions will be found extraordinarily

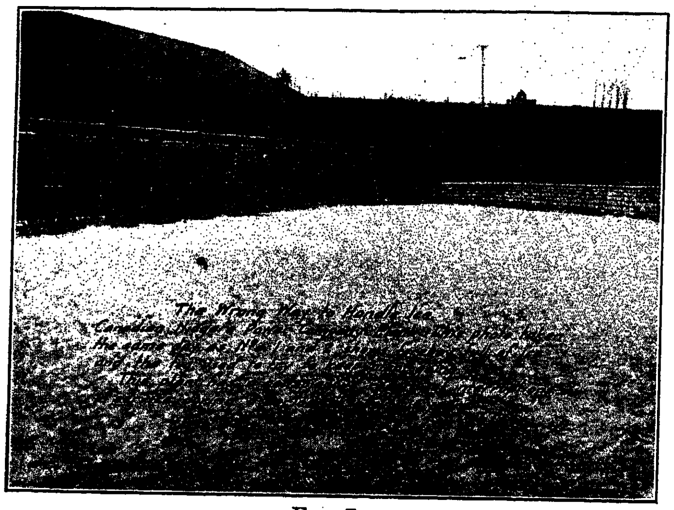

Fig. 7

Figs. 7, 8, 9 and 10 tell their own story. The Toronto Power Company plant is successful and the Canadian Niagara power plant is unsuccessful in handling ice because the Toronto Power Company plant takes its power waters at an angle of 90 degrees with the outside waters that carry the ice, and the attending fact that the average velocities toward the turbines are always less than the velocities carrying the ice. Ice always follows the higher velocity and can not be diverted from the tendency by booms set an appreciable angle from the natural general outside ice direction. Fig. 10 shows the parallel positions of the submerged arches with respect to the ice laden outside waters in the Toronto Power Company plant (called Electrical Development Company on this drawing), and shows the submerged arches of the Canadian Niagara Power Company and their angularity with respect to the ice laden outside water. When the ice is called upon to hit such a submerged boom, as is the case with the Canadian Power Company intake, a sufficient amount of ice passes under the boom to cause the showing in Fig. 7.

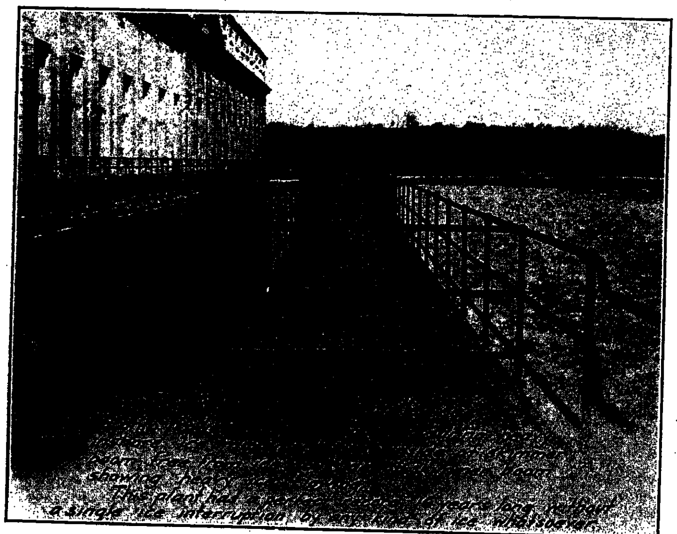

Fig. 8

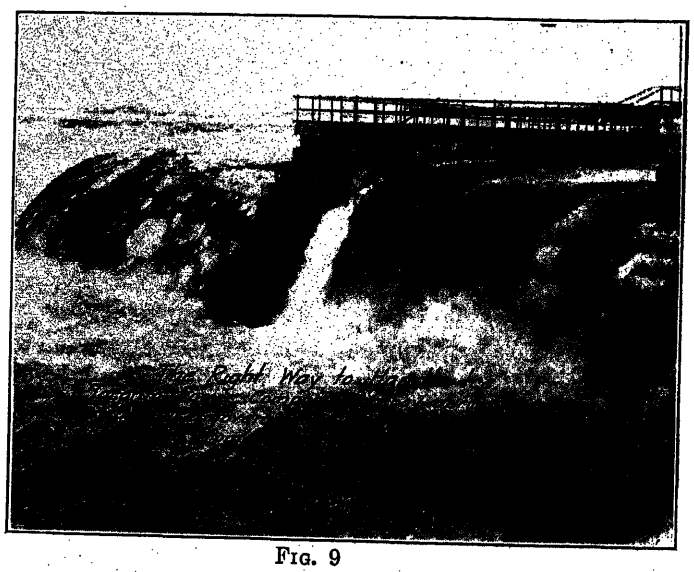

Fig. 9

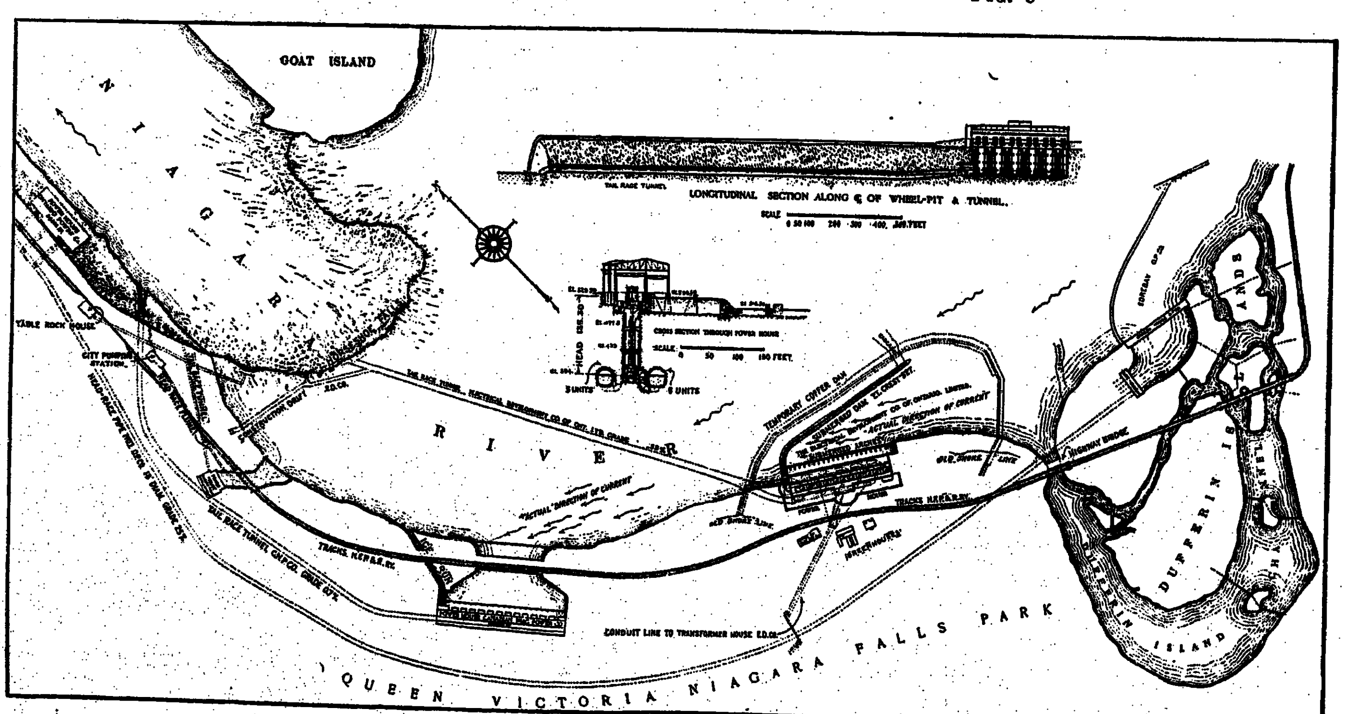

Fig. 10

difficult. The superpower plans will need every big talking point which can honestly be brought to bear upon the subject, and it is my opinion that no great aggregation of money can be secured for steam installations and busbar trunk lines in these new superpower zones until the greater part of the available water power is developed and available as the vertebrae for the superpower zones. Engineers and financiers are not going to assume the responsibilities incident to hundreds of millions in trunk transmission lines and great central stations until the water power competition and capacities are known and ready to become properly the foundation for the big project.

I should like now to give you some very distinct reasons why, in my opinion, the St. Lawrence River must eventually be reconstructed by private capital. My first reason is that governments cannot and private capital can purchase and direct the engineering and construction ability which will be required to reconstruct the St. Lawrence. The engineering and construction ability required for the St. Lawrence work is far greater than that required for any previous construction in the history of engineering. Cofferdams of unprecedented size must be constructed on river beds when more than 200,000 cu. ft. per sec. are flowing, and this quantity of water alone is about five times the maxi-

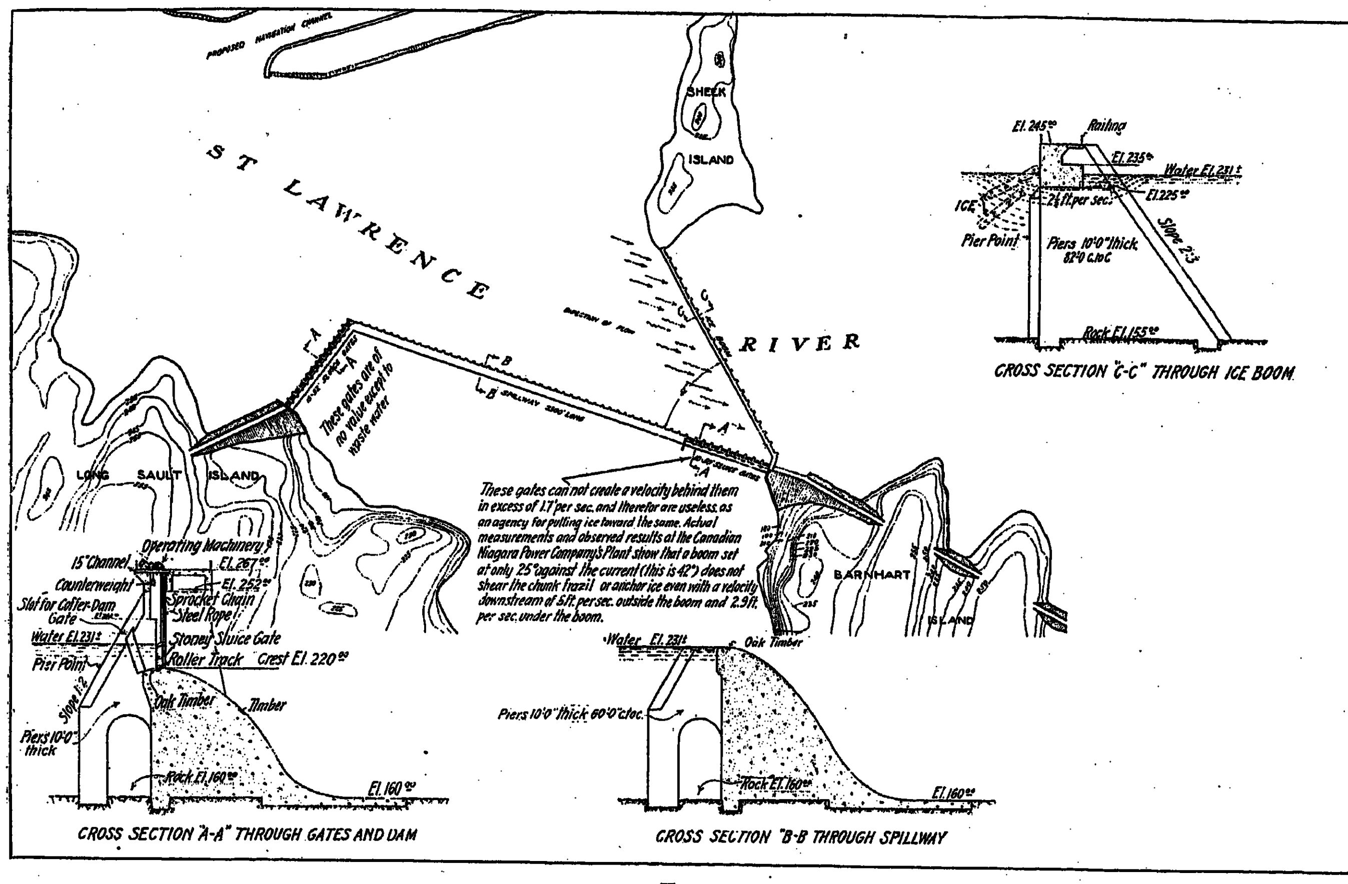

FIG. 11

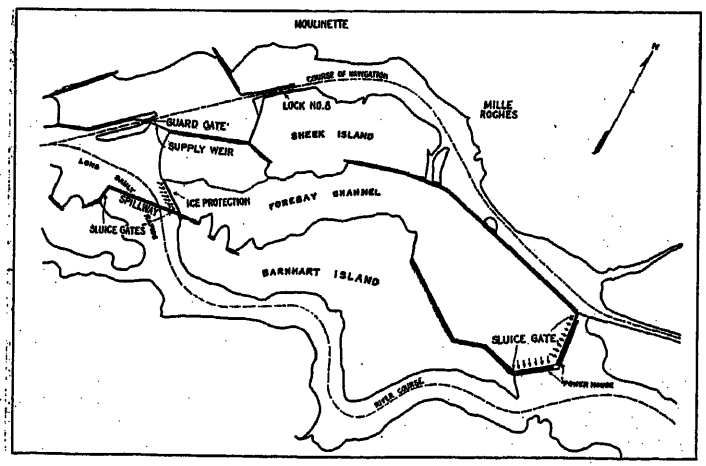

FIG. 12

Figs. 11 and 12 show the manner of handling 675,000 tons of ice per hour recommended by the Wooten-Bowden report. The reasons why this recommended plan would fail are set forth on these drawings. In times of ice movement over 60 per cent of the 1,768,000 horse power would have to be shut down until the ice movement was completed. This shut-down would vary from one day to fifteen days which would be fatal for general power distribution, but would not of course be so serious if the current were used locally for chemistry.

mum previously achieved. In all previous construction it has been possible to install cofferdams during low periods of flow, but no such low periods exist in the St. Lawrence. As you have seen, ice conditions of extraordinary severity must be overcome through at least four winter seasons for each unit of development. The loss of interest during construction and loading periods will call for unusual progress during the eight or nine months of construction weather. While the Panama Canal cost around $300,000,000 (about twice the official original estimate), this great cost was represented by work which was extraordinarily easy of construction; it was merely a matter of quantity. On the St. Lawrence we have engineering difficulties to which only the tubes under the East and North Rivers in New York are comparable. Speaking of engineering difficulties, it is my opinion, and the opinion of many engineers of my acquaintance, that the greatest engineering work ever accomplished, from the viewpoint of difficulties overcome, was the work of constructing the Pennsylvania Railroad tubes into Manhattan Island and Long Island, and yet I prophesy that when the history of the construction of the St. Lawrence work is written, the consensus of all engineering opinion will be that the St. Lawrence situation presented far more difficult problems than were encountered in the Pennsylvania tubes which I have just mentioned, but would anybody have the temerity to suggest that any government on earth could have carried out the tube construction as it was carried out by the late Alfred Noble and his assistants?

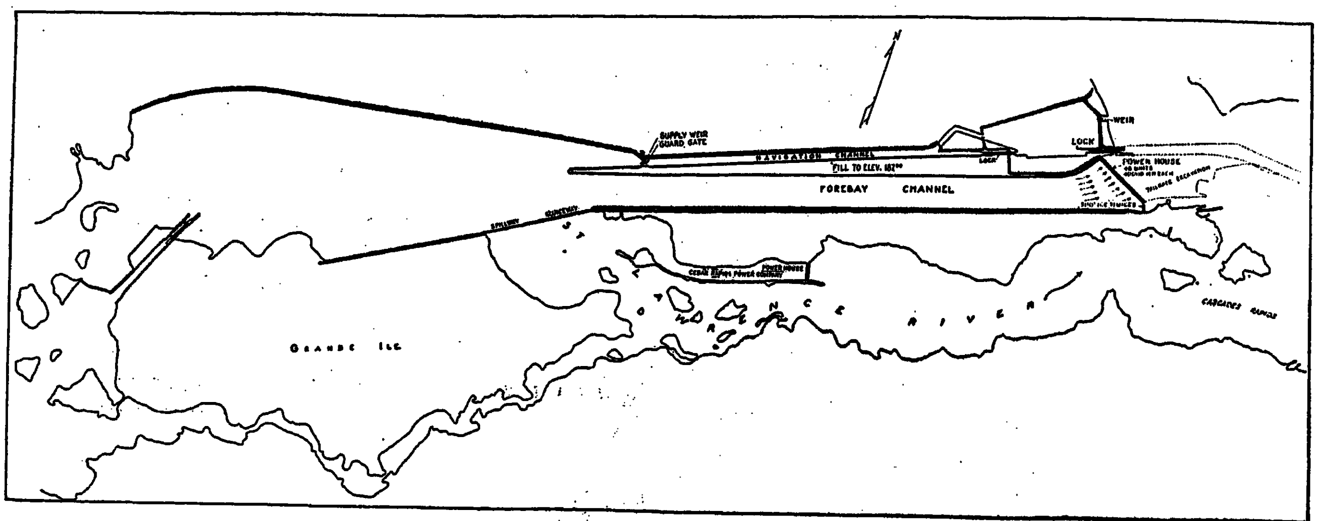

Fig. 13

This shows provisions in the Wooten-Bowden recommendations that are more objectionable even than those shown for the Long Sault plant, Fig. 11. The capacity here proposed for interruption (by even a greater percentage than the 60 per cent at the Long Sault) is 1,020,000 h. p.

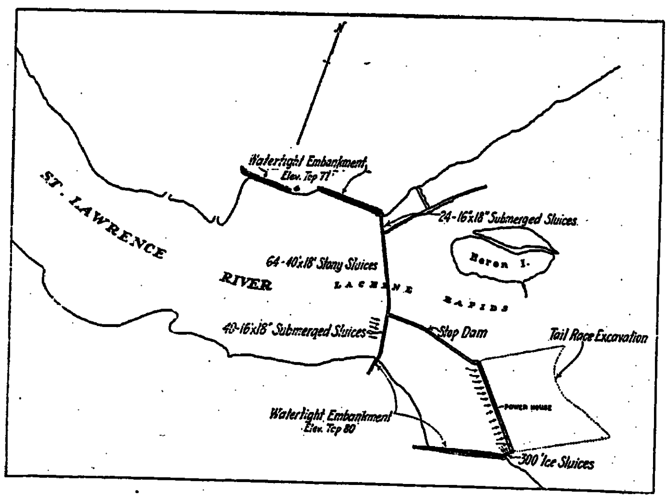

Fig. 14—Proposed Installation at Foot of Lachine Rapids Recommended by Wooten-Bowden Report

Capacity, 787,000 h. p.

Only a small percentage of this plant (not exceeding 15 per cent) could be operated when Lake Ontario and the St. Lawrence River ice is moving out.

The next reason why no government could ever carry out successfully the St. Lawrence work, is the fact that no human direction of day labor has ever been able to cope with governmental red tape, and make government employees really work. It may be claimed by government ownership advocates that the government could contract the St. Lawrence work to regular contractors. My answer to this suggestion is that there are no contractors whose experience would justify their undertaking work of this character and magnitude. The history of the Panama Canal proves this claim, where everyone knows that the contractors fell down. The Panama Canal was carried out by able American engineers from private walks of life, under the able management of General Goethals; but because the difficulties on the St. Lawrence are so much greater than at Panama, the Panama method of construction would fail on the St. Lawrence.

Another great reason why the power side of the St. Lawrence could not be handled by government agencies lies in the fact that coincident with the construction

of the generating stations on the St. Lawrence, there must be constructed vast distributing systems, by private capital, for the use of the energy when it is ready for delivery. The private capital for these distributing systems will not, in my judgment, be found willing to undertake the financing of distributing systems that are to receive their current at some unknown time when government agencies could complete the work, if they could complete it at all. If the St. Lawrence power development is made by private capital it will be entirely practical and feasible for distributing companies to make private contracts with generating stations, which contracts, being approved by the public service commissions, and enforcible by law, will therefore be proper foundation for distributing system financing. If governments should undertake the construction of the power work in the St. Lawrence, the only way distributing companies could operate would be to wait some indefinite time until the power plants were completed, and such a wait would entail, of course, vast losses of interest.

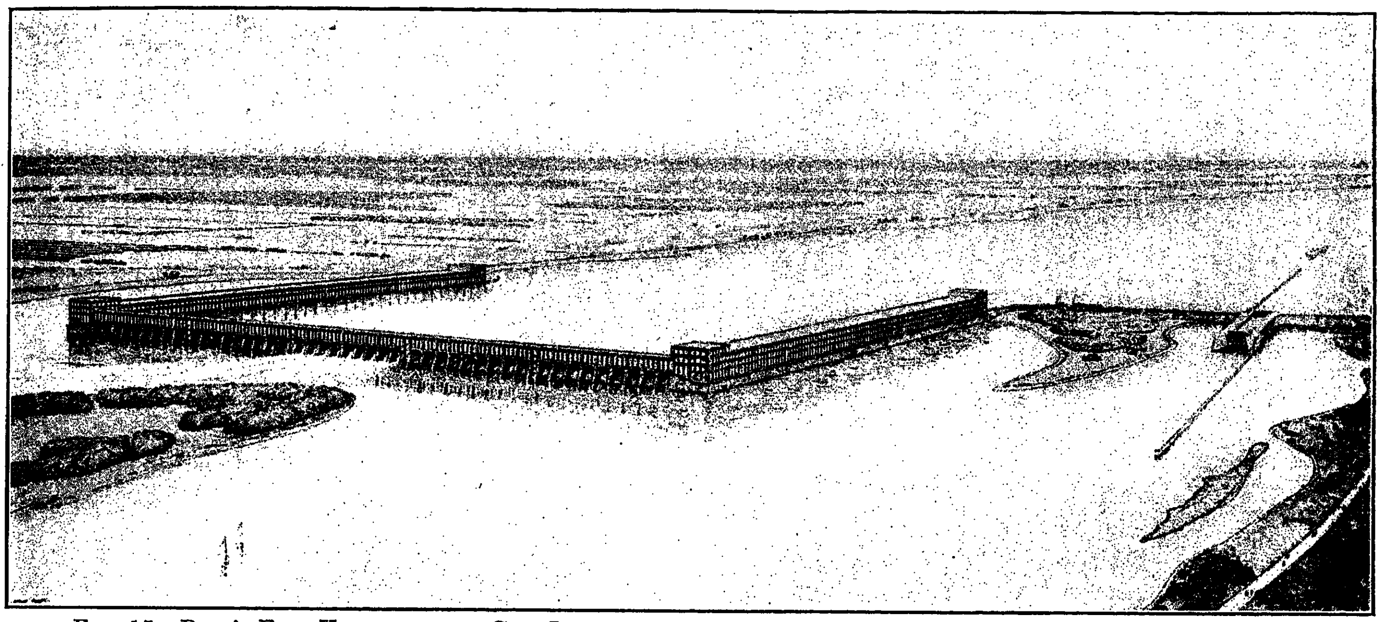

FIG. 15—BIRD'S-EYE VIEW OF THE CAT ISLAND PLANT FOR INSTALLED CAPACITY OF 1,200,000 HORSE POWER
This view is a true perspective from the Canadian shore made from a complete set of borings in the bed of the river, from a complete set of mechanical drawings and from a complete set of topographical maps costing altogether in excess of $200,000.

As to building the locks, this work will have to be in the hands of private management, because the very nature of the work would prohibit the use of two organizations trying to manipulate heavy construction at the same time and place. While the locks and their appurtenant works will have to be paid for and operated by the governments, their construction by the organization which builds the power works can be arranged for on terms advantageous to the governments.

I have briefly enumerated a few of the major benefits that will result from a reconstruction of the St. Lawrence River. We are all in accord as to the value to the public of this greatest of our undeveloped resources, and of the urgency of our need of these resources. The St. Lawrence River and its Great Lakes basin have been under active official study and survey for over one hundred years, with the result that no other region of our Continent is so fully covered by general engineering reports. Of course we could go on discussing and reporting on this subject for another hundred years. What we need now is to begin physical work as soon as the best plans can be adopted. The outstanding need in American industry today is relief from present excessive federal taxation. Until this relief is felt the

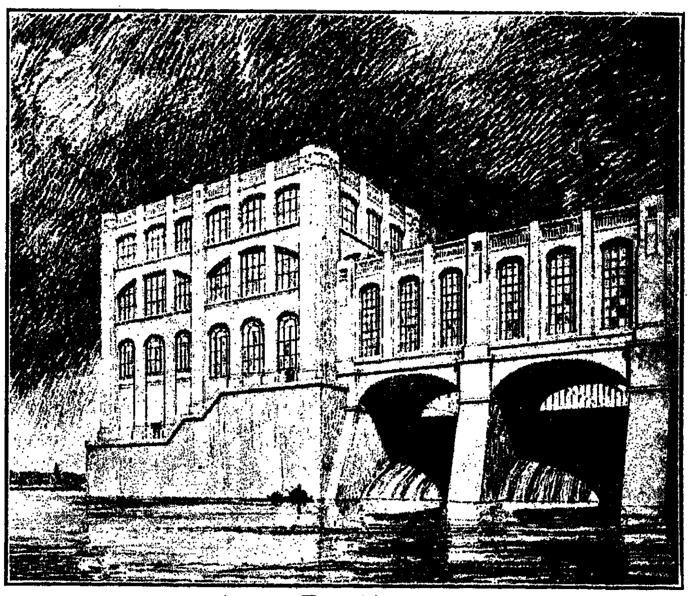

FIG. 16
Close-up perspective drawing showing two of the eighteen feet deep control gates, their gate-house superstructure and its connection to the downstream end of either the Canadian or the American power house.

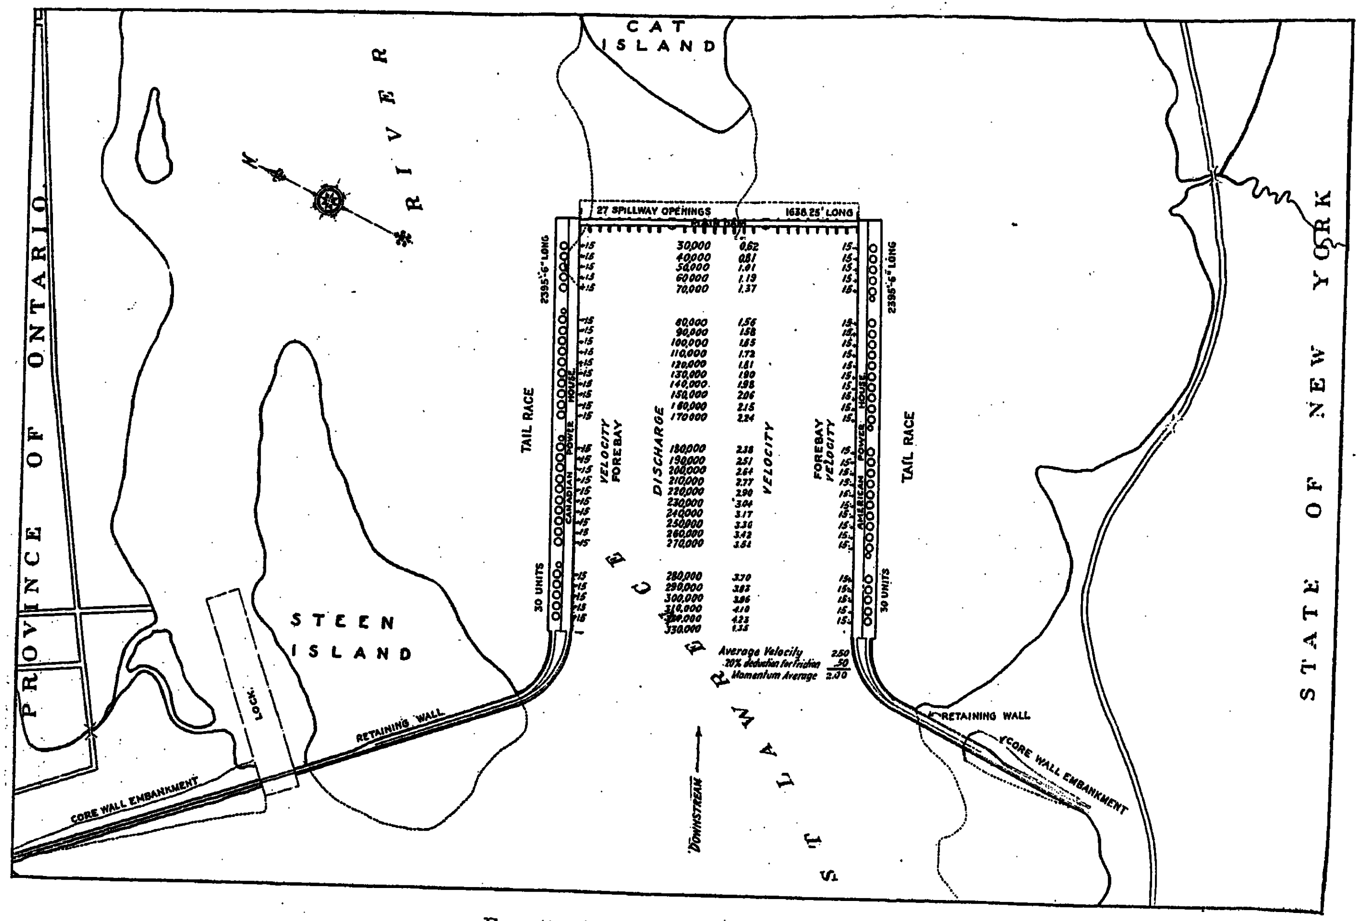

FIG. 17—DAM NO. 1 AT CAT ISLAND

No diversion of approaching ice from its natural direction for two miles above the control dam is required. It is disposed of through the main dam without the diversions previous experience shows conclusively must be avoided. The average velocity toward the dam is 33 1/3 per cent more than the velocity of the power waters to the wheels. This arrangement, as will be readily seen, calls for a great increase in the cost of the work because of a heavy increase in all cubitures of masonry, cofferdams and excavations. The project must stand these extra costs necessary for 100 per cent reliability or remain unconstructed. The incomplete but fairly satisfactory data in hand show that the general arrangement recommended by the Cooper plans for the Cat Island development can be installed with but little modification at Dams 2, 3, 4 and 5.

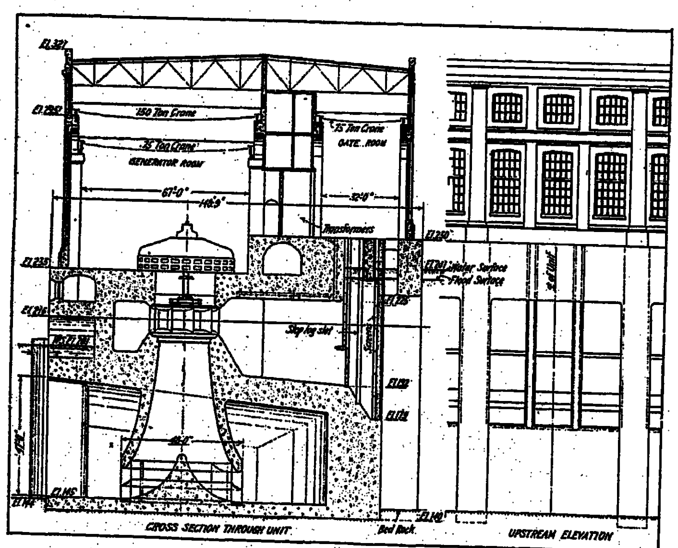

FIG. 18—CROSS-SECTION OF THE CAT ISLAND POWER HOUSE SHOWING A MAIN GENERATOR 20,000-H. P. UNIT

It will be observed that this work is standard except for the depth to foundations which is about 65 feet.

cost of living will be high, and labor and capital both must suffer. To hope that the Federal Treasury at Washington can supply for many years to come, the hundreds of millions needed for this enterprise as a governmental measure, even if its feasibility as such were unquestioned, is hoping for the unreasonable and impossible, and what of Canada and her half of the costs as a governmental measure? Canada has 9,000,000 splendid people who are today struggling with a per capita debt nearly twice our per capita debt, incurred through her wonderful loyalty to the mother country. Her casualties were 800 per cent per capita greater than ours. Canada is today struggling with an annual deficit of more than $60,000,000 in government owned and operated railroads. She must bear the burdens incident to an oversupply of hydro-electric power in Ontario, the cost of which is unnecessarily high by many millions and she has many other problems of a financial and social character, all of which she will solve in due time with great credit to herself. Because of all of the foregoing every sane, thoughtful Canadian knows that Canada cannot take on her share of the cost of the new St. Lawrence as a governmental venture for decades to come.

No, the government ownership program is not the way forward. The way forward is through encouraging private capital, properly regulated, to take up the rebuilding of the St. Lawrence along the lines the Federal Congress and the State of New York have laid out for private capital after more than ten years of continuous study of the navigation and power questions as applied to our navigable streams. I am of the opinion that the Federal and State Water Power laws provide the safest and most expeditious plan of procedure for the achievement of the new St. Lawrence. In these laws, the public interest is most fully protected. They give private initiative the fullest competitive opportunity, and thus provide maximum efficiency. If the Commissions, Federal and State, will issue the necessary St. Lawrence permits, and if Canada does her part, as I am sure she will, and finally and most important, if Canada and the United States will provide at once a high-grade permanent commission of engineers to approve the plans that are agreed upon under the operation of the permits, and to supervise construction when licenses are issued, then we will safely and speedily bid good-by to the "talk" zone, and go hopefully and confidently forward into the "work" zone of this great endeavor. No other plan, it seems to me, will ever get us anywhere for years and years to come, and if the plan I have recommended is safe and sane, why don't we get together, and pull together, and always pull in the same direction?

In conclusion I desire to thank you heartily for the close attention you have given this very brief address on what I know you will agree is a subject that will be in the minds of all of us for many years to come. I will have no pride of opinion on this subject as and when better views are advanced. The St. Lawrence enterprise is too important in its wide influence upon millions of our people to allow any mistake to be made. Its early consummation requires only the elimination of a small amount of public and private misinformation regarding it, and I predict this elimination will be accomplished much sooner than most people think.

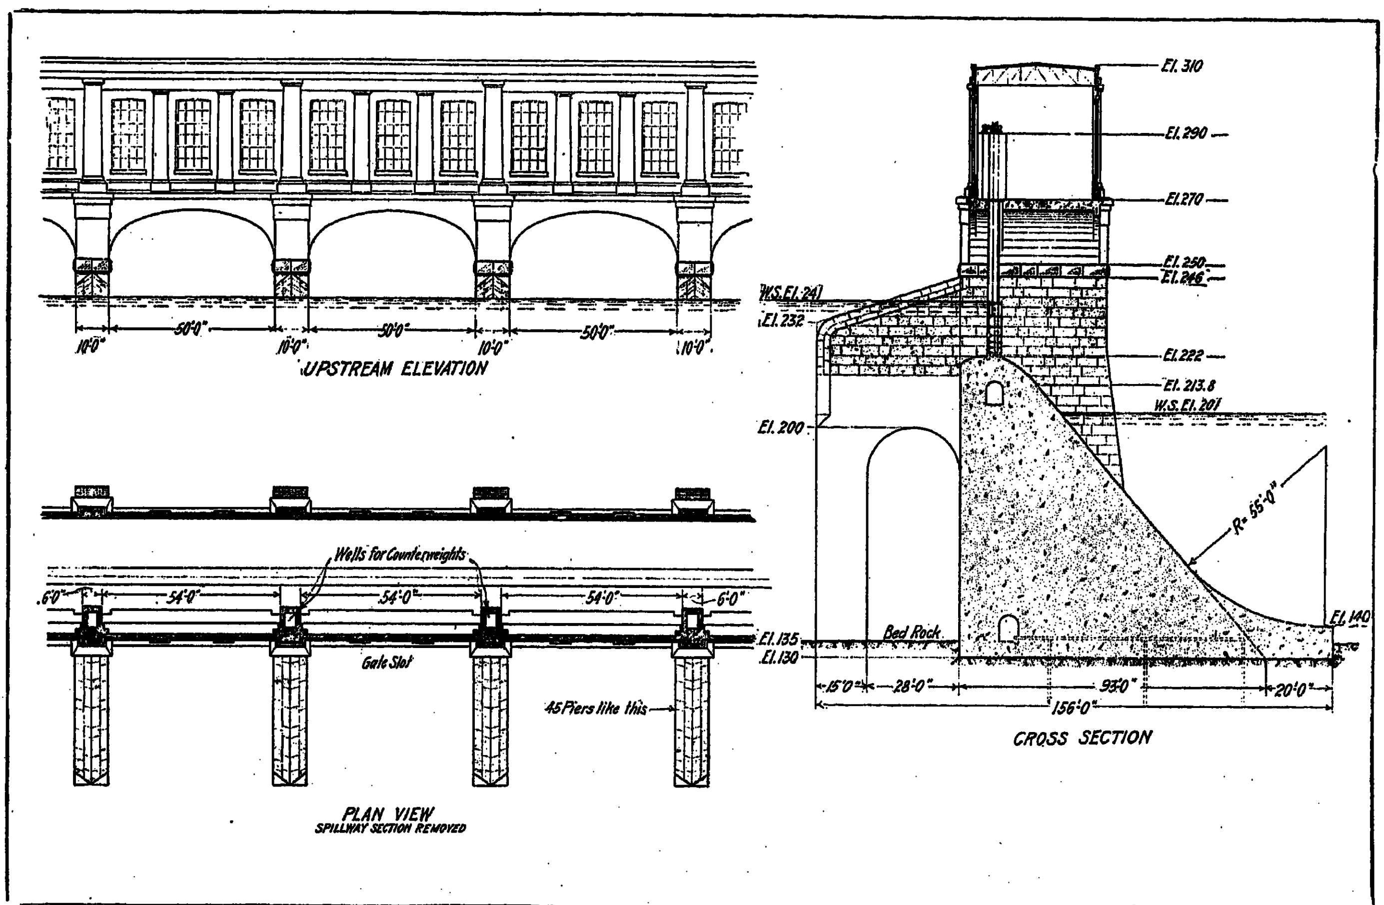

FIG. 19—CROSS-SECTION THROUGH THE MAIN DAM SHOWING ICE BREAKERS 10 FEET THICK SPACED 60 FEET ON CENTERS

Note that the large cakes of field ice approaching these ice breakers will be forced to ride up the sloping noses of the ice breakers in the usual way and thus be broken into fragments for passage through the open channels 18 feet deep immediately below the breakers, and then safely over the spillway to the pool below, from which pool the ice will be cleared by repetitions of the same process until all structures are safe. The plans here recommended will enable such a control of the St. Lawrence ice through the use of stored water from Lake Ontario as will also guarantee the City of Montreal complete immunity from the frequent ice troubles that have occurred in the past.

The St. Lawrence Project

BY H. I. HARRIMAN

of Chase & Harriman, Inc., Boston, Mass.

THE great channels of trade in North America run east and west. The great river systems of the continent run north and south. There is, however, one striking exception to this general rule, where the course of the Great Lakes and the St. Lawrence breaks through the Appalachian Range, and forms a continuous waterway, 2000 miles in length, from the center of the continent to the Atlantic Ocean. Much of this water course is now open to navigation and the American Great Lakes have within the last twenty years witnessed the most remarkable maritime developments of any section in the world. The Lakes extend approximately 1000 miles from Duluth or Chicago to Buffalo through the very heart of America; and within the last two decades there has grown up on these Lakes a traffic whose tonnage exceeds that of the Mediterranean and the Black Sea combined; indeed the movement of vessels through the locks between Lake Superior and Lake Huron is twice the combined movement of vessels through the Suez and Panama Canals, and more tonnage passes Detroit in nine months than clears from New York or Liverpool in a year. Along or near these Great Lakes lives approximately forty per cent of the population of the United States. Not only are the shores of the Lakes thickly populated, but the territory contiguous to them is rich in agriculture and in mineral products. Wheat, grain, livestock, iron, coal and copper are among the great inheritance of this rich fertile region of our country. This region has also become a great manufacturing center. Flour, foodstuffs, packing products, automobiles, rails and other heavy steel products, and many other articles of commerce are produced in this region; and these articles, as well as the products of the soil and the mines, flow eastward over the waters of the Great Lakes until the port of Buffalo is reached, where they must be transferred to the rails, and move the last 500 miles of their journey to the seaboard by car rather than by boat.

Between the eastern end of Lake Erie and sea level in the St. Lawrence River, a distance of 400 miles, there are two natural obstacles which prevent navigation: first, the falls of the Niagara River; and second, the rapids of the St. Lawrence. There have for many years been shallow canals and locks around both of these obstacles, but they have accommodated vessels of such small size as to be of practically no value to commerce. In view of all these facts, it is not surprising that the people of the Middle West living near the Lakes are asking that these obstacles to commerce be removed, and that the ships of the Great Lakes be permitted to pass freely around Niagara and down the St. Lawrence to the ocean. Already the Canadian Government has undertaken the construction of an enlarged Welland Canal around Niagara Falls at the cost of about $80,000,000. This canal will, when completed, accommodate the largest lake vessel, having a capacity of approximately 15,000 dead-weight tons, or 500,000 bushels of grain. The locks of the canal will be 800 feet by 80 feet by 30 feet. The canal will initially be dredged to a depth of 25 feet, but can at any time be deepened to the full 30 feet permitted by the locks. Work on the enlarged Welland Canal has made considerable progress, and the canal should be ready for use during the year 1925.

The Welland Canal will, however, be of little use until the St. Lawrence River is made navigable to the sea. Accordingly it is proposed to drown out the upper rapids of the St. Lawrence by means of a large dam with locks, erected near Cornwall, and to parallel the two lower rapids with two canals and their locks, the canals aggregating about 33 miles in length. By means of these structures a 25-foot navigable waterway will be created from Lake Ontario to the sea. The locks of this project are to have a depth of 30 feet over the sills so that by additional dredging in the canals a continuous depth of 30 feet can be established. When this project is carried through, the largest lake vessels, some of which carry as much as 14,000 tons dead weight, can proceed to tidewater at either Montreal, Quebec or Halifax, where transfers of freight can be made to ocean vessels. It will also be possible for any ocean vessels drawing not more than 25 feet, and ultimately 30 feet, to enter the Great Lakes. More than 200,000,000 tons of freight now move each year east and west between the territory contiguous to the Great Lakes and the Atlantic seaboard. Much of this traffic always will be carried by the railroads of the country, but when the St. Lawrence Project is completed a material portion of this hugh volume of traffic will undoubtedly seek the water channel. This is conclusively proved by the tremendous growth of traffic upon the Great Lakes, which now exceeds 100,000,000 tons annually.

The opponents of the St. Lawrence Project have laid much stress upon the fact that the present channels and ports of the Great Lakes will accommodate only vessels with a draft of twenty feet or less; and that for that reason large ocean vessels cannot ply the Great Lakes until huge additional expenditures have been made upon their channels and harbors. The argument seems immaterial. As previously stated, all types of lake vessels can proceed to tidewater and there discharge their cargoes into ocean-going vessels, and there will be but one transfer and no rail haul, instead of two transfers and a rail haul as at present. If, however, there is a demand for through traffic between lake ports and foreign countries, it is entirely feasible

Address delivered at the Spring Convention of the A. I. E. E., Chicago, Ill., April 21, 1922.

to construct ocean-going vessels of 8000-10,000—or even 12,000 tons burden of present lake draft. Such vessels of 10,000 tons burden are now in use carrying ore between Cuban ports and the Chesapeake Bay; and if the St. Lawrence Project is carried to completion, there is no question that our maritime engineers, who have so successfully designed vessels for the lake trade can also design a vessel of any desired size to ply between lake ports and ocean ports as they now exist.

The opponents of the Project have also based their opposition upon the alleged dangers of narrow and tortuous channels, of fogs and ice, and of seven-month limitation upon the use of the waterway. The St. Lawrence River will be made navigable by the construction of a large dam at the lower end of the International Section, and by two canals around the two sections of rapids that lie entirely within Canada. In the entire length of the St. Lawrence there will be but nine locks and thirty-three miles of canal navigation. For the balance of the distance navigation will be through a river as wide as the Hudson at New York City; and the entire delay incident to canal navigation in the St. Lawrence and in the Welland Canal will be less than the time required by an ordinary freighter to travel 200 miles. Fogs exist in the lower St. Lawrence; but the hydro-graphic charts of the Federal Government indicate that the fog belt between Montreal and Liverpool is of less extent than between New York and the same port. Fogs and ice have not prevented Montreal from becoming the second port of export in North America; nor has the closure during the winter season stopped navigation upon the Great Lakes or prevented the construction of the Erie Canal.

For these reasons I believe that with the opening of the St. Lawrence to navigation the Middle West will have a usable water route to tidewater over which freight can be sent at much less expense than over all-rail, or water-rail, routes now in existence. I further believe that the existence of such a water route will affect not only the rates of the grain and other freight which actually use it, but the whole rail rate structure between the Middle West and the Atlantic seaboard. This has certainly been the effect of the Panama Canal upon rail rates between Atlantic and Pacific ports.

The extent of the saving arising from water transportation cannot be definitely prophesied, but reasonably accurate conclusions can be drawn from existing rates. At present a bushel of wheat is carried from either Chicago or Duluth, 1000 miles to Buffalo, for 2 cents or less; and on the same mileage basis, with due allowance for delays in canals and locks 3 or 3½ cents would be a fair rate to Montreal. The lowest rate at which grain can now be carried from the West to tidewater is 2 cents to Buffalo, and 12 cents from Buffalo to New York or Boston—a total of 14 cents. This shows a saving to tidewater of at least 10 cents per bushel *via* the St. Lawrence route; and as New York and Montreal are equally distant from Liverpool, it would mean an equal saving on the through rate. What holds true of grain will also hold true of many other western products destined for European ports.

I also believe the St. Lawrence route will favorably affect the transportation costs between the Middle West and the Atlantic Coast ports. The rail rate for the entire country is now approximately 12.1 mills per ton-mile. If coal is excluded this average rate rises to 15 mills. Water rates on the Great Lakes average less than 1 mill per ton-mile; and on the ocean vary according to the class of freight from 1 to 3 mills. Probably 2 mills per ton-mile is a fair water rate to compare with an average rail rate of 15 mills.

From Chicago to Boston the rail distance is 1034 miles as against 2682 by water. From Duluth the relative distances are 1513 as against 2775; and taking into account relative rail and water rates and relative distances, it would seem that a ton of freight is now hauled by rail from Chicago to Boston for $15.51, as against an estimated charge of $5.36 by the water route. The corresponding rail rate for Duluth is $22.70 as against an estimated cost of $5.55 by water.

Figures based on averages may not be exact, but they do indicate tendencies; and they certainly give assurances that freight can be carried from the Middle West to Atlantic ports by water much cheaper than by rail.

It is a well recognized economic principle that the price of any commodity in universal use is determined by the price at which the surplus of that product must be sold. The surplus grain of the world is sold in Liverpool. To this market is shipped the surplus grain from the United States, Canada, Argentine, Russia, and Australia; and there in competition the world price of grain is established, this price governing not only the grain sold in the Liverpool market but the grain sold in the producing countries. The price in the producing country is therefore the world price set in the Liverpool market less the cost of transportation between the farm and the English Channel; and the American farmer receives each year for his grain the Liverpool price less the freight to Liverpool. If therefore, it is possible to reduce the freight charge by 10 cents per bushel, the farmer will receive 10 cents per bushel more for his entire crop. This would mean over $350,000,000 per year to the farmers of the country. Every other grain producing region of the world which has a surplus lies within 250 miles of navigation. Our grain region lies from 1000 to 1200 miles from the coast; and this great handicap upon our western farmers is the great reason for their insistence to (use the words of the President) that "the salted and unsalted seas be connected by a suitable channel."

By act of the American and Canadian Governments, a Joint Commission of the two nations has been in-

vestigating the feasibility and cost of the project. This Commission has recently submitted its report to the two Governments, and its findings are that the project is feasible, desirable, and reasonable in cost. The estimates of cost were made by Government engineers of the two nations after an examination extending over a year's period. These engineers estimate the cost of the entire project at $252,000,000, this estimate including the cost of producing 1,464,000 horse power of continuous energy. The figures were based upon 1920 costs—as an example, concrete is estimated at $12.00 per yard. It is further the express belief of the engineers that the figures of cost are conservative and that due allowance has been made for the inevitable contingencies of a project of this size.

Mr. Hugh Cooper, an eminent hydraulic engineer, who has made extensive studies of the St. Lawrence River, believes that the plan proposed by the Government engineers is impracticable, that their estimates of cost are inadequate, and that their scheme is wasteful of the potential energy of the stream. Cooper proposes a different plan which, at a cost of about $300,000,000 for the International section, will make that section navigable and develop about 2,400,000 horse power. To this $300,000,000 must be added about $100,000,000 for the canals around the lower rapids, in order to make the entire river navigable. The total cost of his project is therefore approximately $400,000,000 as against $252,000,000 for the plan of the Government engineers.

The criticisms of Mr. Cooper should be given most careful consideration in the preparation of the final plans. In my opinion, however, the vital fact is that both the Government engineers and Mr. Cooper agree that it is entirely feasible to improve and make navigable the St. Lawrence River, and to develop as an adjunct thereto a huge block of reliable electric energy; and while Cooper's estimates are higher than the estimates of the Government engineers, yet the amount of power which he will develop is far greater and there is really very little difference in the cost of a horse power as developed by one or the other plan.

The value of the power which will be produced on the International section will largely offset the annual cost of the project. Based upon a cost of $252,000,000 the interest charges, sinking fund requirements, and operating expenses of the project, if carried through by the Government, should not exceed $17,000,000 per annum. If the entire annual cost of the project is charged against the power development (and I do not advocate this) it means an annual switchboard cost of from $11.00 to $12.00 per horse power. This is equivalent to a kilowatt hour cost of from 2 to 4 mills depending upon the load factor at which the energy is taken. To this switchboard charge must be added the transmission costs from the St. Lawrence River to the great markets of New England and New York; but after making such allowance it is certain that, according to either plan, energy can be laid down at great central substations in New England and New York at well under 10 mills per kilowatt-hour.

I do not feel that the entire cost of the project should be charged against power. The figures cited are however based upon the entire charge of the project being carried by the power developed; but it may well be argued that navigation should pay a portion of the cost, thus enabling power to be sold at lower rates than above indicated. I, however, wish to point out that the market is ample to absorb all of the power which can be generated; and that the energy will be exceedingly cheap even if power carries all of the charges. Within a reasonable time after the St. Lawrence is open to navigation, it can be made a self-supporting project, and would be well warranted merely as a plan for the development of energy.

The Western proponents of the Great Lakes project have assumed that the project would be carried through in its entirety by the Governments of the two nations, and I have thus far discussed the proposition from that standpoint. A statement, has however, recently been made by gentlemen connected with large financial interests that a group of American financiers are prepared to construct two dams along the International section which would develop nearly 2,000,000 h. p., and whose construction would also drown out the rapids of the international section of the river and by the construction of locks in the two dams (to be paid for by the two Governments) make the river navigable from Lake Ontario to Lake St. Francis.

If such an arrangement can be worked out, it should be given most careful consideration, as the task left to the two governments would be merely the construction of the lower canals with their locks. Under such a plan the government expenditures would probably be less than $100,000,000. Furthermore, it would remove the governments from any connection with the development of hydroelectric energy and leave that business to private enterprise,—a most desirable outcome, if feasible.

My own feeling is that the two great features of the project—continuous navigation from the Great Lakes to the sea, and cheap hydroelectric power—must both be carried out. No plan must be adopted which gives one without the other, or which delays one at the expense of the other. With these fundamental facts in view the more that can be done by private enterprise and the less by the two Governments, the better it is.

Some opponents of the project claim that it will work great injury to the railroads of the country, and tend to increase existing freight rates. Such opponents fail to take into account the tremendous growth of the traffic of the nation. In 1890 the railroad tonnage of the country amounted to 79,000,000,000 ton-miles; in 1900 it had risen to 141,000,000,000 ton-miles; by

1905 it had increased to 187,000,000,000; and in 1921 exceeded 448,000,000,000 ton-miles. This shows a steady increase of approximately 100% in each decade; and would indicate a tonnage of 800,000,000,000 ton-miles by the time the St. Lawrence project becomes an actuality. I remember the frightful congestion of traffic in 1918, and am appalled at considering the expenditures which must be made to handle the inevitable traffic of 1930. At present the population tributary to the Great Lakes is 40,000,000. Twenty-five years from now it may well be 75,000,000; and the requirements of the growing traffic of the country, and of its growing population will demand the use of every possible avenue of transportation. I therefore feel that the development of water transportation from the center of the continent to seaboard will be of immense advantage to the railroads, greatly reducing the investments they must make, and enabling their existing rails to be used for local and high-class tonnage. The following quotations from a recent address of Mr. Elisha Lee, Vice-President of the Pennsylvania Railroad, are of great interest. He says:

> Traffic on our American railroads measured in ton-miles doubles about once in a decade. This rate of increase has been maintained for at least two generations with surprising regularity, despite the varying cycles of booms, panics and depressions through which the country has passed meanwhile.
>
> The next time our country has a real revival of business we shall in all probability be confronted with the most severe congestion of railroad traffic, and the greatest inadequacy of railroad facilities, ever experienced in our history. When that happens rates will be lost sight of. Every one will be clamoring for service. Nothing could more quickly check a wave of prosperity than the inability of our railroad facilities to handle the traffic which good times will create.
>
> I am firmly convinced that we face such a condition with almost absolute certainty in the not remote future.

One more objection remains to be considered, namely; the sentimental objection of the investment of American money in Canadian territory. In this connection, however, it should be remembered that by treaty the Great Lakes and the St. Lawrence for their entire length are open to the equal use of the nationals of both countries. Since the war of 1812 the lakes and the river have been recognized as the joint artery of the two governments. Our use of the St. Lawrence because of our greater population, and industry, will greatly exceed the use of Canada; and there is certainly no sound reason why we should not bear our proportion of the expense irrespective of its location. It should be noted further that each nation is to pay the entire expense of its own power developments; and that expenses are shared only as they refer to navigation. Canada owns the Grand Trunk Railroad, and thus has an investment in the United States of over $200,000,000 and if Canada has not hestitated to invest in railroads partially within the United States, certainly we should not hesitate to invest in a joint waterway more beneficial to us than to our neighbor. If the United States and Canada jointly develop this great route of trade, it will tend to cement the ties of industrial and political friendship which have existed between the two countries for over a century.

Thus far I have considered the St. Lawrence Project from its effect upon the nation as a whole; and my conclusions are that it will greatly benefit the commerce and industry of the country.

Let us turn now to the consideration of the immediate effect of the project upon our own state and upon the Port of Boston. Commercially, it will give us a direct water route between the Middle West and our own ports. It will also bring lake traffic to the terminals of our New England railroads at Ogdensburg and Montreal, and thus reduce the distance to lake navigation from 500 miles at Buffalo to 250 miles at the St. Lawrence. Our traffic will also be free from the crowded gateways at Albany and Buffalo; and our own railroads through their own or affiliated boat lines will reach all of the great ports of the West. The existence of such a route will also help us to maintain our present differential rates which have been so great an asset to New England's industries. Finally, it will give us a definite and compelling reason for the abolition of the rail differential which now exists in favor of Philadelphia and Baltimore.

The project will also give to New England a supply of cheap energy nearly sufficient to operate its railroads, its utilities, and its industries. Previously in this report we have discussed the cost of power generated on the St. Lawrence. Suffice it to repeat at this time that power can be generated on the St. Lawrence and transmitted throughout New England at a cost less than the cost of power made by coal at the mouth of the mine in Pennsylvania. Not least among the advantages of the hydroelectric power of the St. Lawrence is the fact that it will tend to grow cheaper with increased use, whereas power generated by coal is bound to increase in cost with the growing scarcity of fuel. Finally, our power supply will be free from the embargo and the delay at the crowded railroad gateway. The industry of New England needs for its continued maintenance and prosperity efficient and cheap transportation and low-priced power. Both of these will be supplied when the St. Lawrence is open to navigation and its power made available for use.

New England's chief argument against the opening of the St. Lawrence has been its fear that the foreign commerce of the Port of Boston would be seriously affected. This objection is worthy of every consideration. No positive prediction can be made as to the beneficial or harmful effect on Boston's foreign commerce. The arguments which have been presented show great possibilities for good as well as harm. Boston's foreign commerce has for the last twenty years steadily declined, until it has reached the lowest point in its history. This has been due largely to the operation of the rail differentials in favor of South Atlantic Ports, which have diverted from Boston the

grain and other heavy commodities required in a properly balanced cargo. Last year Boston's exports of grain were only about 4,000,000 bushels out of a total of 300,000,000 for the entire country and Canada. If the St. Lawrence route is opened, much grain will be brought to river ports in lake vessels and stored in elevators for export purposes. Much of this grain will go abroad directly by water from Montreal; but it is also true that much of the stored grain will come to Boston and Portland, particularly during the five months when the St. Lawrence is closed, and thus fur-furnish Boston the bulk cargo which her foreign commerce requires. It must also be of great advantage to New England ports to have the tonnage of the Great Lakes brought within 250 miles of its ports and in direct touch with its own rail heads on the St. Lawrence; and New England's railroads whose interests are identical with the interests of the Port of Boston, will have every incentive to make rates which will bring the lake commerce to Boston. Mr. A. H. Ritter, of the Department of Commerce, has very clearly brought out the fact that Boston has a large inbound commerce, and is particularly in need of export products, in order that ships may have both inward and outward cargoes. He also points out that Montreal has very little inbound commerce, and that a vessel could better afford to come loaded to Boston and pay the rail haul from Ogdensburg or Montreal to Boston for export cargoes, rather than to go to Montreal empty and effect the saving of the rail haul.

It should also be remembered that the value of any port is measured by its service to domestic as well as foreign commerce, and no one can doubt that a large amount of domestic commerce will flow by water from the Port of Boston to the ports of the Great Lakes. While, therefore, there is a possibility that some of the commerce of the West now flowing through New York and Boston will flow directly to Europe via the St. Lawrence, yet, so far as Boston is concerned, there is every probability that through this route she will gain the bulk cargo, at least during the winter season, which her foreign commerce now lacks.

Various other local objections have been raised. For instance, Montreal fears that freight will pass by it and that it will become a way-station on the St. Lawrence. Portland is apprehensive lest it lose some of the grain which the Grand Trunk now ships through that harbor when the St. Lawrence is closed. Buffalo fears that it will lose the transfer charges now paid at that port; and New York State fears that the Erie Canal will receive less traffic.

All of these local objections must be given due consideration. I think, however, it can be assumed that no local consideration should stand in the way of a great economic development which will benefit much of the country; and Montreal, Portland, Buffalo, or New York cannot permanently expect to receive a toll for their individual benefit that increases the cost of moving the exports or imports of the world to and from the West, or that denies to New England a much needed supply of cheap power. The weavers of Lancashire objected to the introduction of the power loom because they feared it would deprive them of their livelihood, but the power loom made Manchester. So these local losses will be more than made up by resulting benefits which cannot now be foreseen.

In my opinion, New England and New York have more to gain from this project than even the States of the West which are now so actively supporting it. When men like President Harding and Secretary Hoover advocate this project as one of the greatest constructive engineering projects of this generation, and say it is a development equal in its importance to the Suez or Panama Canals, all must admit that it is of great national, as well as local significance.

The people living in the region of the Great Lakes are in the same position as the people residing along the shores of the Mediterranean would be if the Straits of Gibraltar were closed, or the nations bordering upon the Black Sea if the Dardanelles were obstructed by impassable rapids.

At present the great demand for the improvement of the St. Lawrence comes from the merchant, the manufacturer, and the farmer of the Middle West and the Northwest, and from Canada, who demand that the traffic of the Great Lakes have direct access to the sea; but when the citizens of New England and New York appreciate what the project really means to their industries and to their railroads, they will be equally insistent that the St. Lawrence be opened to world commerce and its power made available for the use of mankind.

I cannot better close than by quoting the words of President Harding in his address to the National Agricultural conference held in Washington on January 23d. He said:

> I have spoken of the advantage which Europe enjoys because of its easy access to the sea, the cheapest and surest transportation facility. In our own country is presented one of the world's most attractive opportunities for extension of the seaways many hundred miles inland. The heart of the continent, with its vast resources in both agriculture and industry, would be brought in communication with all the ocean routes by the execution of the St. Lawrence waterway project. To enable ocean-going vessels to have access to all the ports of the Great Lakes would have a most stimulating effect upon the industrial life of the continent's interior. The feasibility of the project is unquestioned, and its cost, compared with some other great engineering works would be small. Disorganized and prostrate, the nations of central Europe are even now setting their hands to the development of a great continental waterway, which, connecting the Rhine and Danube, will bring water transportation from the Black to the North Sea, from Mediterranean to Baltic. If nationalist prejudices and economic difficulties can be overcome by Europe, they certainly should not be formidable obstacles to an achievement, less expensive, and giving promise of yet greater advantages to the peoples of North America. Not only would the cost of transportation be greatly reduced, but a vast population would be brought overnight into immediate touch with the markets of the entire world.

Another View of the St. Lawrence Project

BY S. WALLACE DEMPSEY

House of Representatives, Washington, D. C. Chairman of the Committee on Rivers and Harbors

THE question as to whether the United States shall help Canada defray the expense of improving the St. Lawrence river, as Mr. Cooper said, is a great question. It is one that involves an enormous amount of money and it would take, the engineers estimate, at least ten years to do the work. So we should know well before we begin what the problem is, what it promises, how it compares with other things. It is a great transportation problem. Primarily at the base of it is the question of transportation. Water power is purely incidental.

I am to talk to you as to how this question presents itself from the standpoint of the United States. Well, we are just at the end of a great war. For the first time in the history of the country we are groaning under the burden of an enormous debt. Every question of Government activity has to be met from that angle and I am going to illustrate it to you. The city of Chicago has furnished a very able man as the first director of the budget, General Dawes,—a man of action, a man of brains. When he provided in the first budget that was ever presented to a Congress of the United States for the expenditure for all our rivers and harbors, how much do you think he estimated? We have been talking about one half a billion or 500,000,000 dollars as the cost of the development in the international section of the St. Lawrence. And on the 50 per cent basis, one half of that would be 250,000,000 dollars. But it is not the 50 per cent basis at all, that is proposed by the Joint Commission organized by Canada and the United States to study and report on the St. Lawrence route and what we are considering today is what the Joint Commission recommends. They have been asked to investigate and to report upon this subject and we are proposing to act on their report. They do not propose that the United States shall bear one half of the expense of this great undertaking. They say that the disproportion in wealth, in population, in commerce, between the United States and Canada shall disappear, that we shall bear—the two countries shall bear,—that expense in proportion to population, wealth and commerce, and that means, as you all know, that the United States shall bear nine-tenths of the cost. And we don't stop there. A great canal has already been dug, the Welland Canal. It is practically completed. Its expense has been borne by the Dominion of Canada and this Joint Commission proposes that the United States shall share in the same proportion the cost of that canal.

We have done the work of improving the Great Lakes. We have dug the canals, we have improved the harbors, we have done all the work that leads to their enormous commerce, the cheapest commerce in the world that floats down from Duluth all the way to Buffalo. And if we should pay nine-tenths of the cost of this canal, which Canada has already constructed, why shouldn't Canada come over and bear its proportion of the cost of this work which we have done for many, many years and which we are still doing?

When as I say, General Dawes began to consider what he would allow to the United States for all of its rivers and harbors in this great country of ours, with about five thousand miles of sea and gulf coast, with 25,000 miles of navigable rivers, with 25,000 more that can be made navigable, how much money, as against nine-tenths of somewhere from 500,000,000 to a billion and a half, which is proposed for this one route, how much do you suppose the General expected to allow us for all of this commerce within our country? Thirteen millions of dollars. And that is all he thought that the present conditions of this country could allow, with its burden of taxation, with the people paying high prices, as Mr. Cooper says, for labor and for supplies, and for materials.

The Committee on Rivers and Harbors convinced him that he was wrong, convinced General Lord, the Finance Officer of the War Department, convinced Secretary Weeks that he was wrong, and as a result they consented to 27,000,000 dollars. At that time we expected 15,000,000 dollars could be used from unexpended balances to the credit of River and Harbor projects, and it turned out that there weren't unexpended balances available. So we went on the floor of the House and we had to make a fight and a strenuous fight, and a fight for which we had to prepare for four or five weeks, in order to enable us to get an additional 15,000,000 dollars for our rivers and harbors.

What was the condition of our rivers and harbors? Why did we need this money? We needed it for two reasons. First, during the war not a dollar's worth of work was done upon any river or harbor in the United States, for the Secretary of War must have certified that it was necessary to win the war. Since it could not come within that definition the harbors were allowed to silt and fill up. And let me give you an illustration. Down in Mobile we adopted a project for deepening the harbor thirty feet, many years ago, and today the harbor in Mobile has less draft than it had when we adopted the project and what is true of Mobile is true generally of the rivers and harbors in the United States, they have been going backward instead of forward ever since the war broke out.

In addition to that this country is growing very rapidly and we need to use all of our transportation facilities, and keep furnishing and supplying new ones from time to time to meet the constantly increasing and multiplying demands of commerce. And on that

Address delivered at the Spring Convention of the A. I. E. E., Chicago, Ill., April 21, 1922.

account it is necessary that we should have our rivers and harbors used to their maximum.

One other thing. Owing to the way that the railroads were managed during Government control, owing to the fact that their operation became enormously more expensive, owing to the fact that freight rates in consequence have soared to an unheard of level, the only relief in sight was by cheap transportation by water, and how could we have it unless we improved our waterways? And then we had living examples of the fact that it was important to improve our waterways. All we had to do was to look to the south of us and we found on the Mississippi River that under Government management, which is always wasteful, always inefficient, we found that in spite of that Government boats are being operated there under Government control, and with all of the wastefulness, with all of the extravagance, with all of the inefficiency of Government operation those boats are paying, taking into account every kind of an overhead charge which it is possible to put into the account against them.

How has it come about that this traffic upon the Mississippi, for the first time in the history of the stream, is really profitable? In a very natural way. In the olden days they used to fit out a barge on the Ohio River and they would send it down the Ohio and down the Mississippi and when it reached New Orleans they would break it up and sell it for firewood. Why? Because they couldn't get a return cargo and it cost more to take it back up the river unloaded than it would cost to build a new raft up on the Ohio. And for the first time in the history of the Mississippi they have found that they can get return cargoes to the full capacity of all the boats, and that is what has made the navigation of the Mississippi profitable, in spite of the drawbacks to which I have referred.

That is only one example of the use to which we can put our waterways and of the necessity of using them. So here we are, from the Governmental standpoint in this position, of needing great sums of money to improve our own waterways in a time when we owe a huge debt and must economize, and we want to examine the whole thing carefully and fairly. We are all Americans, we all have the interests of the whole country at heart. If it is the best thing to build this waterway we want to build it, but we don't want to decide it as a matter of sentiment, we don't care to decide it as a matter of feeling, we want to examine it soberly as we would examine any other business question in the light of the facts, and see whether it will bear such an examination.

We find that it is well nigh impossible to get what our own waterways need as a sheer and dire necessity, we find as we look back over the history of the past twenty years that we have only had about 30,000,000 dollars a year for all our waterways. We find that last year we spent 40,000,000 dollars. We find that it is going to be necessary to spend 100,000,000 of dollars a year on the waterways in the United States to develop and maintain them. And yet as I say, those in charge start off by offering us 13,000,000 dollars to meet a necessity that requires 100,000,000 dollars.

In the face of facts like these, should we not examine a proposal to spend hundreds of millions of dollars on one waterway traversing a foreign country? Isn't that fair, that we should examine it closely, that we should scan it, that we should be entirely satisfied before we reach a conclusion?

Let us take the report of the Joint Engineers, first of all, and see, because that is what we have before us, what they propose. They say that we are to have a channel of 25 feet through the St. Lawrence, and then say we are to be satisfied with the channels in the Great Lakes, except that in the pivotal harbors and through some of the channels we may get an increased depth from 20 to 21, 22 or 25 feet, which are the controlling depths today. What is the situation as to that depth? Is that depth sufficient for the purpose for which it is intended? Is it going to enable ocean going vessels to traverse the St. Lawrence route,—ocean going vessels of a size that can compete with the lake freighters that now carry the traffic of the lakes? We have on the Great Lakes today freighters carrying 14,000 tons, and everyone knows that is the cheapest transportaion anywhere in the world. These great freighters are practically square boxes which require scarcely any space for coal, they are loaded and unloaded in an incredibly short space of time and owing to the fact that they don't need the reserve space, that loading and unloading is so very cheap, that the cost of construction is very low, transportation on the Lakes is, for its cheapness the marvel of the world.

I don't know myself the comparative average costs of transportation on the Great Lakes and of that on the ocean. I recently had the pleasure of having a joint debate with Senator Ransdell of Louisiana, an ardent advocate of the St. Lawrence route, at Boston, when Mr. Harriman, who is to follow me, was present and in that debate Senator Ransdell made the statement that the average cost of transportation per ton per mile on the ocean was three mills, and that the average cost on the Great Lakes was one mill. Now I know nothing about the accuracy of his figures, but I am reliably advised that the cost of transportation on the ocean is much greater than the cost on the Great Lakes. So starting with that as a basis, I ask how you can, for the purpose of economy, substitute ocean navigation, which is far more expensive than navigation on the Great Lakes, for shipment by lake freighters and yet cheapen the cost of transportation to the wheat grower of the northwest? You start with that as your primary proposition and then you come to examine the details, and see whether it is simply the average cost of transportation on the Great Lakes and of transportation on the ocean, that you have to meet, or whether there are other factors that enter into the problem and make it

more clear still that you cannot compete by an ocean going boat with the cost of transportation which is established today by the lake freighter. What kind of ocean going boats, what capacity of ocean going boats will be able to traverse the Great Lakes? That is your first problem. Here you have a depth, a controlling depth of 20 to 22 feet, because your boat must be able to traverse the very shallowest section. The steamship companies say that the largest sized boat, that could traverse the Great Lakes and its channels and harbors, would be one of 4000 tons capacity, and they would have to compete on the Great Lakes with these freighters carrying 14,000 tons. What would the result be? You wouldn't have the ordinary competition between the cost on the ocean and the cost on the Lakes, but you would have in addition to that, not a competition between two boats, one an ocean boat carrying 14,000 tons and another a lake freighter of the same carrying capacity, but you would have this small, insignificant ocean boat, which isn't large enough to be economical on the ocean competing with a 14,000 ton lake freighter, 4000 tons is all that could be carried in an ocean ship upon the St. Lawrence route. Can there be any doubt that the 14,000 ton Lake freighter would carry freight very much more cheaply than the 4000 ton ocean ship?

Before I leave that question of depth, let us go to another demonstration of the fact that the proposed depth would be insufficient. The Joint Commission in its report says that the controlling depth from Montreal to the sea, a distance of a thousand miles, is 30 feet, but they say that that is being improved to 35 feet. What does that mean? It means that Canada and Great Britain have used that channel for ocean going vessels for a very long time and as the result of all of that experience they have found that 30 feet even isn't a sufficient depth, and that to navigate the channel economically, to get the best results, the lowest freight rates, and to make it profitable to use the channel, you must have a depth of 35 feet.

So here is the channel from Montreal to the sea, one thousand miles long and it is proposed to supplement that by a channel, from Montreal west, of twenty to twenty-two feet, and join together that mismatched, dissimilar pair and call it a joint and complete route. Of course it is utterly impossible.

What next do you find? That there isn't simply the disproportion of costs between the lake freighters and the ordinary ocean going boat, but that there is a great difference because they are built on an entirely different principle. The one is built much higher than the other, the ocean vessel having to be built for the buffetings of that enormous expanse of water. But you don't have to build simply the ordinary ocean going boat for the St. Lawrence route. The Encyclopedia Brittanica in its latest edition says that for the navigation of the St. Lawrence route you must have an especially strongly constructed vessel because of the fact that icebergs are present in that channel at all times of the year.

That adds to the overhead, and to the cost of construction; the interest charges, as Mr. Cooper pointed out, go on, and as a result, the cost of carrying the wheat, if you are going to carry it in that ocean-going vessel, is increased by the interest on that added cost of construction.

Then the Joint Commission says that it is not simply a question of fogs, tides, nor icebergs, but the combination of all of these difficulties and dangers of that route, there resulted in 1909 the adoption of what was known as the British North American Clause of Marine insurance requiring a very high marine risk rate all through the St. Lawrence. The Joint Commission in this report recommending this route says that that is a handicap to the usefulness of the route.

Those are a few of the objections to this route. Mr. Redfield, Secretary of Commerce, investigated this matter in 1918 and made a report in which he said that there never would come a time when ocean-going vessels would carry freight in the restricted channels of a canal or a river or upon the Lakes, that the over-head makes it absolutely impossible, the cost of construction, the cost of maintenance, the cost of operation was so very much greater for all boats of that description.

A report was made by the Army Engineers at about the same time, and they reached the same conclusion. I don't understand that any Board of Army Engineers has united in this report of the Joint Commission. My understanding is that a single Colonel from the United States Army was designated on our part, and an Engineer on the British side was designated, and those two engineers joined in the making of this report.

Let us take this St. Lawrence route and examine it regarding waterpower. It runs along the American border for a very short distance. In that distance there occurs one of the opportunities to create water power. Every one in the United States is in favor of the development of the water power on the St. Lawrence, on the Niagara, at every point in the United States where it can be developed. It is the one thing since I have been in Congress that has been my especial care, for which I have fought incessantly, day in and day out, ever since I have been a member of that body, because in the district, which I have the honor to represent, there is located the greatest water power in the world, the power of Niagara. We have developed a small part only of the great power there and I have seen a little village of 3000 people grow to a city of 60,000 people, (with $200,000,000 of assessed valuation), which is the greatest electrochemical center in the world, I saw there the development of more of the things that went to the successful prosecution of the war than were made at any other point in this great and rich nation of ours, with all of its broad territory. So, of course, I believe in the development of power, everywhere throughout our country. But the develop-

ment of power anywhere, if the power is worth developing, doesn't have to be done at Government expense. Go down and examine the applications for the development of water power in the Federal Power Commission at Washington. Talk with the Secretary, Mr. Merril, find if there is any water power that is worth having for which there isn't an application pending. Find if there aren't competitors in each case where the power is worth anything. Find if men aren't eager, not ready, but eager and ready to advance the money at a moment's notice, the instant they can get the license. That is the situation as to the development of power.

Then if anyone says to you, "Why, you can do better by Government development than you can by private development," say to him, that he can look back to the period when the Government controlled the railroads and it had them for only 26 months under operation and say to him that during that period the Government lost the stupendous sum of one billion dollars, one twenty-sixth of its total national debt today incurred by reason of the war. And say to him that you had the poorest service during Government operation you ever had in the history of your country and if he wants a practical illustration, tell him that you couldn't trace a freight car from the time it left a yard until it reached its destination, if it ever reached it. And then tell him, if he wants a particular instance of how bad it was, to go down into New England and find their roads practically ruined and if he will examine the records he will find that during the first 18 months of Government control they earned only 15 per cent of the standard return,—of the average of their earnings for the three years preceding Government control,—and, then if he says to you, "Why, railroads are not water power, and we are talking about water power," tell him to go down to Niagara and visit both sides of the river there and then go on to Quebec and tell him he will find that on the Niagara, on the American side we furnish power 40 per cent cheaper to the consumer than they do over on the Canadian side where it is government controlled, and then tell him to step down to Quebec where it is developed by private enterprise and he will find that it is produced there 32 per cent cheaper under private enterprise than it is by the Government.
